A. Prophylactic therapy with intravenous zoledronic acid every 3 years for the next 10 years to prevent progression of the disease.
B. Prophylactic therapy with oral alendronate 70 mg once a week on a long-term basis to prevent progression of the disease.
C. Close observation with repeat radiographs on an annual basis followed by zoledronic acid treatment, 5 mg IV, if the radiographs shows signs of progression.
D. Surgical removal of the upper part of the tibia with total knee replacement.
E. Observation at periodic intervals with initiation of bisphosphonate treatment should symptoms that are suggestive of Paget disease develop.

Answer: E There is currently no evidence that prophylactic therapy with any bisphosphonate can alter the natural history of the disease. Similarly, there is no evidence that prophylactic surgery would be helpful in this situation. The most appropriate option would be to keep the patient under review to look for the development of symptoms that might be attributable to the Paget disease and give treatment if these occur.

OSTEONECROSIS, OSTEOSCLEROSIS/HYPEROSTOSIS, AND OTHER DISORDERS OF BONE

MICHAEL P. WHYTE

OSTEONECROSIS

DEFINITION

Osteonecrosis (aseptic, avascular, or ischemic necrosis of bone) refers to skeletal infarction. Bone infarcts may be asymptomatic, cause self-limited discomfort, or engender painful collapse of subarticular bone that leads to joint destruction.

PATHOBIOLOGY AND PATHOGENESIS

Many conditions are associated with osteonecrosis (Table 248-1). In adults, the most common causes are ethanol abuse and long-term glucocorticoid therapy, both of which have dose-dependent effects.

Skeletal infarction may result from blood vessel destruction (e.g., joint dislocation, fracture), obstruction (e.g., thromboemboli, sickle cell disease, fat emboli, caisson disease), or, hypothetically, compression from local expansion of fatty tissue (e.g., ethanol abuse, glucocorticoid treatment, diabetes mellitus). However, symptoms may not occur unless, weeks later, resorption of dead bone during skeletal repair leads to pathologic fracture. Certain skeletal sites (often subarticular) are predisposed to osteonecrosis,

TABLE 248-1 CAUSES OF ISCHEMIC NECROSIS OF CARTILAGE AND BONE

Endocrine/metabolic
Ethanol abuse
Glucocorticoid therapy
Cushing disease
Diabetes mellitus
Hyperuricemia
Osteomalacia

Trauma (e.g., dislocation, fracture)
Human immunodeficiency virus (HIV) infection
Dysbaric conditions (e.g., caisson disease)
Collagen vascular disorders
Irradiation
Pancreatitis
Organ transplantation
Hemodialysis
Burns
Intravascular coagulation
Idiopathic, familial
Pregnancy

but the locations differ for traumatic and nontraumatic processes and for children and adults. *Osteochondrosis* refers to necrosis of ossification centers; more than 50 eponymic types have been recorded. The susceptibility of children to osteochondrosis and its pathogenesis are poorly understood. At all ages, however, the femoral head is especially prone to infarction. Nontraumatic osteonecrosis commonly affects the humeral head, femoral condyles, distal end of the tibia, and talus. Although the pathogenesis is uncertain, administration of potent bone antiresorptive agents, especially to patients with malignant disease, has been associated with osteonecrosis of the jaw (Fig. 248-1).[1]

CLINICAL MANIFESTATIONS

Pain occurs acutely if there is skeletal collapse. Chronic arthralgia results from desquamated necrotic tissue and articular destruction.

DIAGNOSIS

Magnetic resonance imaging that demonstrates bone marrow edema is especially sensitive for detection of early osteonecrosis. Bone scintigraphy discloses skeletal reconstitution with or without fracture. Relatively late in the pathologic process, radiographs first show patchy areas of osteopenia and osteosclerosis that reflect skeletal repair. A linear subchondral radiolucency (crescent sign) indicates bone collapse.

TREATMENT Rx

Non–weight bearing is advisable for the affected limb. Decompression by trephine insertion is used at some sites. Arthrotomy to remove debris, transpositional osteotomy, arthroplasty, or joint replacement may be necessary.

OSTEOSCLEROSIS/HYPEROSTOSIS

Many conditions are associated with radiographic evidence of increased bone density. Skeletal dysplasias, metabolic disturbances, and various other disorders can cause generalized or focal increases in bone mass (Table 248-2). Aberrations in skeletal growth, modeling (shaping), or remodeling (turnover) may be at fault. *Osteosclerosis* refers to thickening of trabecular (spongy, cancellous) bone. *Hyperostosis* describes widening of cortical (compact) bone. Increases in trabecular bone, cortical bone, or both may augment skeletal density.

Osteosclerosis

Neoplastic, hematologic, and metabolic disorders may preferentially cause sclerosis in trabecular bone because it houses marrow and remodels more rapidly than cortical bone.

FIGURE 248-1. Exposed dead bone characterizes osteonecrosis of the jaw.

From Whyte MP. Skeletal disorders characterized by osteosclerosis or hyperostosis. In: Avioli LV, Krane SM, eds. *Metabolic Bone Disease.* 3rd ed. San Diego: Academic Press; 1998.

FIBROGENESIS IMPERFECTA OSSIUM

DEFINITION

This rare, sporadic condition features generalized osteopenia, but coarsening of the remaining trabeculae places it among disorders that manifest osteosclerosis.

PATHOBIOLOGY

The cause is unknown. Subperiosteal bone formation and collagen synthesis in nonosseous tissues seem to be normal.

CLINICAL MANIFESTATIONS

Intractable skeletal pain typically begins gradually during middle age or later and then rapidly increases with a debilitating course and eventual immobility. Spontaneous fractures are a prominent complication. Physical examination reveals marked bone tenderness.

DIAGNOSIS

On radiography, only the skull is spared. Initially, osteopenia and a slightly abnormal appearance of trabecular bone are noted. Subsequently, the changes suggest osteomalacia. Corticomedullary junctions become indistinct as compact bone is replaced by an abnormal cancellous pattern. Generalized osteopenia causes the remaining spongy bone to appear coarse and dense, in a fishnet pattern of mixed lytic and sclerotic areas. Alkaline phosphatase activity in serum is increased.

The skeletal lesion is a localized form of osteomalacia that varies considerably in severity from area to area.

Hyperostosis

PROGRESSIVE DIAPHYSEAL DYSPLASIA (CAMURATI-ENGELMANN DISEASE)

PATHOBIOLOGY

Progressive diaphyseal dysplasia (Camurati-Engelmann disease) affects all races and is inherited as an autosomal dominant trait with variable expressivity. New bone formation gradually envelops both the periosteal and endosteal surfaces of long bone diaphyses. In patients with severe disease, osteosclerosis also occurs in the axial skeleton.

Mutations alter the gene that encodes transforming growth factor-β1. Osteoblast differentiation may be deranged.

CLINICAL MANIFESTATIONS

During childhood, limping or a broad-based, waddling gait is noted. Muscular dystrophy can be diagnosed erroneously. Severely affected individuals may have a characteristic body habitus featuring an enlarged head with a prominent forehead, proptosis, and thin limbs with little subcutaneous fat or muscle mass and tender, thickened bones. Cranial nerve palsies and raised intracranial pressure can occur. Some patients have hepatosplenomegaly and Raynaud phenomenon. Symptoms may remit after puberty.

DIAGNOSIS

Irregular hyperostosis of the diaphyses of the major long bones slowly develops as a result of periosteal and endosteal new bone formation. The femur and tibia are most commonly affected. Metaphyses may be involved. The age at onset, rate of progression, and severity are variable. Clinical, radiographic, and bone scan findings are generally concordant. Serum alkaline phosphatase activity, biochemical markers of skeletal turnover, and erythrocyte sedimentation rate may be elevated. Histopathologic study reveals newly formed woven bone that matures and becomes incorporated into cortical bone. Electron microscopy of muscle may show myopathic changes and vascular abnormalities.

TREATMENT Rx

Glucocorticoid therapy (typically a low dose of prednisone on alternate days) can relieve bone pain and may normalize skeletal histology. Bisphosphonates are sometimes useful.

ENDOSTEAL HYPEROSTOSIS

PATHOBIOLOGY

Sclerosteosis and van Buchem disease, autosomal recessive disorders, are the most severe types of endosteal hyperostosis. Sclerosteosis is caused by deactivating mutations in a gene called *SOST*. Van Buchem disease involves a deletion downstream of *SOST*. Enhanced osteoblast activity from sclerostin deficiency, with failure of osteoclasts to compensate for the increased bone formation, leads to the skeletal changes.

CLINICAL MANIFESTATIONS

Sclerosteosis (cortical hyperostosis with syndactyly) occurs primarily in individuals of Dutch ancestry. The gender distribution appears to be equal. Patients are tall and heavy beginning in childhood; have a prominent, square mandible; and are deaf and experience facial nerve palsy from cranial nerve entrapment. Raised intracranial pressure and headache may reflect a small cranial cavity that can shorten life expectancy. Van Buchem disease causes progressive asymmetrical enlargement of the jaw during puberty. Patients may be symptom free, or, beginning as early as infancy, they may have recurrent facial nerve palsy, deafness, and optic atrophy from narrowing of cranial foramina. Long bones may hurt with applied pressure but are strong.

DIAGNOSIS

In sclerosteosis, the skeleton is radiographically normal in early childhood except for syndactyly, which is common and most often involves the index and third fingers. Progressive bone thickening widens the skull and causes prognathism. Osteosclerosis involves the skull base, facial bones, vertebrae, pelvis, and ribs. Endosteal thickening homogeneously widens diaphyseal cortices and narrows medullary canals. Computed tomography has shown fusion of ossicles and narrowing of the internal auditory canals and cochlear aqueducts. Serum alkaline phosphatase activity can be increased from enhanced bone formation.

TREATMENT Rx

Surgical decompression of narrowed foramina may alleviate cranial nerve palsies.

PACHYDERMOPERIOSTOSIS

PATHOBIOLOGY

Pachydermoperiostosis (hypertrophic osteoarthropathy, primary or idiopathic) is an autosomal dominant disorder that features clubbing of the digits, hyperhidrosis with thickening of the skin (especially of the face), and periosteal new bone formation, most prominently in the distal ends of the limbs. Not all patients manifest all three principal features.[2] A loss-of-function mutation is found in the gene that encodes 15-hydroxyprostaglandin dehydrogenase. Autosomal recessive inheritance also seems to occur.

CLINICAL MANIFESTATIONS

Men seem to be more severely affected than women, and blacks are affected more commonly than whites. Symptoms typically begin during adolescence, intensify during the next decade, but then become quiescent. Arthralgia and fatigue are common. Stiffness and limited mobility occur in both the appendicular and the axial skeleton. Clubbing, with slowly progressive enlargement of the hands and feet, results in a pawlike appearance. Cutaneous changes include thickening, furrowing, pitting, and oiliness, especially of the scalp and face.

DIAGNOSIS

Periostitis thickens the distal portions of the tibia, fibula, radius, and ulna. Clubbing is obvious, and acro-osteolysis can occur. Periosteal proliferation is exuberant, with an irregular texture, and it often involves the epiphyses, whereas secondary hypertrophic osteoarthropathy (pulmonary or otherwise) typically causes a smooth and undulating periosteal reaction. Ankylosis of the joints, especially in the hands and feet, may trouble older patients. Bone scanning reveals symmetrical, diffuse, regular uptake along the cortical margins of long bones, especially in the legs—the double stripe sign.

TREATMENT Rx

Patients with painful synovial effusions may respond to nonsteroidal anti-inflammatory drugs. Contractures or neurovascular compression by osteosclerotic lesions may require surgical intervention.

OSTEOSCLEROSIS WITH HYPEROSTOSIS

Osteopetrosis

DEFINITION

Osteopetrosis (marble bone disease) is a group of rare disorders characterized by an increase in bone mass due to dysfunction in or lack of osteoclasts during growth. There are two major clinical categories: the autosomal recessive or "malignant" type, which often results in death by early childhood if untreated; and the autosomal dominant or "benign" type, which causes lesser complications. Autosomal recessive types can also feature intermediate severity, neuronal storage disease, or renal tubular acidosis with cerebral calcification due to carbonic anhydrase II deficiency. Bisphosphonate-induced osteopetrosis has been reported.

PATHOGENESIS

The defective gene causing autosomal dominant osteopetrosis encodes a chloride channel important for osteoclast activity. Bi-allelic mutations in this gene, or ones that encode components of a vacuolar proton pump, result in malignant osteopetrosis. Carbonic anhydrase II deficiency is caused by deactivating mutations in the gene that encodes this isoenzyme. Especially rare autosomal recessive cases involve deficient osteoclastogenesis from loss-of-function mutations within the genes for either receptor activator of nuclear factor κB (RANK) or its ligand (RANKL).

Histopathologic studies show that all true forms of osteopetrosis feature profound deficiency of osteoclast action. Bone embedded primary spongiosa (calcified cartilage deposited during endochondral bone formation) persists away from growth plates and constitutes the pathognomonic finding. Defective endosteal bone resorption impairs the formation of marrow space. Quiescent skeletal remodeling leads to bone fragility from the diminished interconnection of osteons and the delayed conversion of immature (woven) bone to mature (compact) bone. Neuronal storage disease (ceroid-lipofuscin) may reflect a lysosomal defect. Deficient superoxide production (necessary for bone resorption) has been considered a pathogenetic factor.

CLINICAL MANIFESTATIONS

Malignant osteopetrosis can be manifested during infancy as nasal "stuffiness" from underdeveloped mastoid and paranasal sinuses. Small cranial foramina may cause optic, oculomotor, or facial nerve palsy. Failure to thrive, delayed dentition, and fractures are common. Hypersplenism and recurrent infection, bruising, and bleeding reflect myelophthisis. Short stature, large head, frontal bossing, nystagmus, hepatosplenomegaly, and genu valgum are characteristic physical features. Untreated children usually die during the first decade of life of hemorrhage, pneumonia, severe anemia, or sepsis. Benign osteopetrosis can cause fracture, facial palsy, deafness, mandibular osteomyelitis, bone marrow failure, impaired vision, psychomotor delay, carpal tunnel syndrome, or osteoarthritis. Carbonic anhydrase II deficiency can cause failure to thrive, fracture, developmental delay, mental subnormality, and short stature. Cerebral calcification develops during childhood, but defective skeletal modeling and osteosclerosis may resolve. Both proximal and distal renal tubular acidosis have been described.

DIAGNOSIS

A generalized increase in bone density is the radiographic hallmark of osteopetrosis. In severe disease, modeling defects in long bones produce an "Erlenmeyer flask" deformity (Fig. 248-2). Alternating dense and lucent bands commonly occur in the metaphyses and pelvis. The cranium is usually thickened and dense, especially at the base, and the paranasal and mastoid sinuses are underpneumatized. Vertebrae may show, on a lateral view, a "bone-in-bone" (endobone) configuration or end-plate sclerosis causing a "rugger jersey" appearance. Skeletal scintigraphy can disclose fractures and osteomyelitis. Magnetic resonance imaging helps monitor the response to bone marrow transplantation.

Serum levels of acid phosphatase and creatine kinase (brain isoenzyme) are often increased. In malignant osteopetrosis, hypocalcemia with secondary hyperparathyroidism and elevated serum concentrations of calcitriol can accompany radiographic changes that resemble rickets. In benign osteopetrosis, biochemical indices of mineral homeostasis are typically unremarkable, although serum parathyroid hormone levels may be elevated.

FIGURE 248-2. Osteopetrosis. Anteroposterior radiograph of the distal end of the femur shows a widened metadiaphyseal region, with characteristic alternating dense and lucent bands. (From Whyte MP, Murphy WA. Osteopetrosis and other sclerosing bone disorders. In: Avioli LV, Krane SM, eds. *Metabolic Bone Disease.* 2nd ed. Philadelphia: WB Saunders; 1990.)

TREATMENT

Rx

Because the origin, molecular pathogenesis, prognosis, and treatment of the more than 10 types of osteopetrosis can differ, precise diagnosis is crucial.[3] Now, commercially available mutation analysis can delineate most patients. For the malignant form, prompt use of human leukocyte antigen–identical bone marrow transplantation to supply functional osteoclasts has remarkably benefited some children. Calcium-deficient diets have been tried but may be limited by hypocalcemia and rickets and have uncertain efficacy. Pharmacologic doses of calcitriol (1,25-dihydroxyvitamin D_3) administered orally, together with dietary calcium restriction (to prevent hypercalciuria and hypercalcemia) or human interferon-γ, believed to enhance superoxide production, have reportedly stimulated osteoclast activity. Prednisone alone or with a low-calcium, high-phosphate diet can sometimes be effective. Glucocorticoid therapy stabilizes pancytopenia and hepatosplenomegaly. Hyperbaric oxygenation helps treat osteomyelitis. Surgical decompression of optic and facial nerves can be beneficial.

Pyknodysostosis

EPIDEMIOLOGY

Pyknodysostosis is believed to have affected French impressionist painter Henri de Toulouse-Lautrec (1864-1901). Most descriptions have come from Europe and the United States, but the disorder seems to be especially common in Japan.

PATHOBIOLOGY

This autosomal recessive condition is caused by loss-of-function mutations in *CTSK*, the gene that encodes cathepsin K.[4] Consequently, bone collagen degradation and skeletal turnover are diminished. In chondrocytes and osteoblasts, abnormal inclusions have been described.

CLINICAL MANIFESTATIONS

Characteristic features of pyknodysostosis seen during infancy or early childhood are relatively large cranium, fronto-occipital prominence, proptosis, bluish sclerae, beaked and pointed nose, small facies and chin, obtuse mandibular angle, high-arched palate, dental malocclusion with retention of primary teeth, and disproportionate short stature. Cranial sutures remain open. Fingers are short and clubbed from acro-osteolysis or aplasia of the terminal phalanges, and the hands are small and square. Repeated fractures cause knock-knee deformity. Mental retardation is noted in approximately 10% of patients. Adult height ranges from 4 feet 3 inches to 4 feet 11 inches. Life expectancy can be shortened by recurrent respiratory infections and

right-sided heart failure from chronic upper airway obstruction secondary to micrognathia.

DIAGNOSIS

Osteosclerosis is uniform, first becoming apparent in childhood and increasing with age. Skeletal modeling defects do not occur, although long bones appear to have thick cortices because of narrow medullary canals. Clavicles are gracile and hypoplastic at their lateral segments. The calvarum and base of the skull are sclerotic, orbital ridges are dense, and wormian bones are present.

TREATMENT Rx

No effective medical therapy has been documented. Fractures of the long bones usually mend satisfactorily. Internal fixation of long bones is formidable because of their narrow medullary space and bone hardness. Tooth extraction is difficult. Osteomyelitis of the mandible may require antibiotic, surgical, or hyperbaric therapy.

Hepatitis C–Associated Osteosclerosis

Rarely, achy and tender limbs develop periodically in individuals who are infected with hepatitis C virus. Radiographic studies reveal a marked generalized increase in bone mass from osteosclerosis and hyperostosis. Disturbances in the insulin-like growth factor system may explain the enhanced bone formation. Calcitonin or bisphosphonate therapy to slow bone turnover or antiviral treatment has benefited some patients.

FOCAL OSTEOSCLEROSIS/HYPEROSTOSIS

Osteopoikilosis

Osteopoikilosis ("spotted bones") is generally a radiographic curiosity due to a deactivating mutation of the *LEMD3* gene transmitted as a highly penetrant autosomal dominant trait. The bone lesions are usually asymptomatic. However, incorrect diagnosis may lead to confusion with serious conditions, including metastatic disease.[5] Some patients have connective tissue nevi called *dermatofibrosis lenticularis disseminata* (or Buschke-Ollendorff syndrome). On radiologic examination, numerous small, round or oval foci of bone sclerosis appear in cancellous bone in the tarsal, carpal, pelvic, and metaepiphyseal regions of tubular bones.

Osteopathia Striata

This finding is usually an autosomal dominant curiosity of asymptomatic linear striations in the metaphyseal regions of long bones and in the ilium. However, two clinically important X-linked dominant disorders with osteopathia striata affect predominantly females: osteopathia striata with cranial sclerosis due to mutation of the *WTX* gene[6]; and osteopathia striata with widespread linear areas of dermal hypoplasia and various bone defects in the limbs due to mutation of the *PORCN* gene (Goltz's syndrome).

Melorheostosis

DEFINITION

Melorheostosis is a sporadic disorder that features bone changes with the appearance of wax that has dripped down a candle. No mendelian basis has been established. The anatomic distribution suggests a postzygotic segmentary defect.

CLINICAL MANIFESTATIONS

Monomelic involvement is usually noted; bilateral disease is generally asymmetrical. Cutaneous changes over affected bones are common (e.g., linear scleroderma-like areas and hypertrichosis) and often appear before the hyperostosis. Symptoms typically begin during childhood, with pain and stiffness as the major complaints. Joints may become contracted and deformed from ectopic bone. Leg length inequality results from soft tissue contractures and premature fusion of epiphyses. Skeletal changes seem to progress most rapidly throughout childhood. During adult life, melorheostosis may or may not gradually spread, but pain is especially common.

DIAGNOSIS

As seen radiographically, irregular, dense, eccentric periosteal and endosteal hyperostosis affects a single bone or several adjacent bones. The lower limbs are most commonly involved. Endosteal thickening predominates during infancy and childhood, and periosteal new bone formation is prominent during adulthood. Ectopic bone formation may occur, particularly near joints.

TREATMENT Rx

Surgical correction of contractures is difficult. Recurrent deformity is common.

Mixed Sclerosing Bone Dystrophy

This typically sporadic disorder features combinations of osteopoikilosis, osteopathia striata, melorheostosis, cranial sclerosis, and other skeletal aberrations in one individual. Complications derive from the specific types of osteosclerosis or hyperostosis, such as nerve palsy with cranial sclerosis and bone pain with melorheostosis.

OTHER DISORDERS OF BONE

Fibrous Dysplasia

This sporadic developmental disorder features one or more expansile fibrous lesions within bone. Polyostotic disease is typically seen before the age of 10 years; monostotic disease begins in adolescence or early adulthood. *McCune-Albright syndrome* refers to polyostotic fibrous dysplasia, cafe au lait spots (Fig. 248-3), and endocrine hyperfunction.[7]

PATHOBIOLOGY

Fibrous dysplasia and McCune-Albright syndrome are caused by postzygotic mosaicism for an activating mutation in the gene that encodes the α subunit of the receptor subunit/adenylate cyclase–coupling G protein, *GNAS*. Imperfect bone forms because mesenchymal cells do not fully differentiate to osteoblasts.

CLINICAL MANIFESTATIONS

Monostotic fibrous dysplasia is more common than polyostotic disease. The skull and long bones are affected most often. The skeletal lesions can deform bones, cause fractures, and occasionally entrap nerves. Sarcomatous degeneration is rare (<1%) but typically occurs within the facial bones or femur and is more frequent with polyostotic disease. Pregnancy may reactivate quiescent lesions. McCune-Albright syndrome usually causes pseudo–precocious puberty in girls. Less commonly, one sees pseudo–precocious puberty in boys. There can also be thyrotoxicosis, Cushing's disease,

FIGURE 248-3. McCune-Albright syndrome. Typical rough-border ("coast of Maine"), pigmented cafe au lait spots. (From Whyte MP. Metabolic and dysplastic disorders. In: Coe FL, Favus MJ, eds. *Disorders of Bone and Mineral Metabolism*. New York: Raven Press; 1992.)

FIGURE 248-4. Fibrous dysplasia. A characteristic expansile lesion with a ground-glass appearance has caused thinning of the cortex in the mid-diaphysis of the fibula. (From Whyte MP. Fibrous dysplasia. In: Favus MJ, ed. *Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism.* 3rd ed. Philadelphia: Lippincott-Raven; 1996.)

acromegaly, hyperprolactinemia, or hyperparathyroidism. In some patients, acquired renal phosphate wasting causes hypophosphatemic rickets or osteomalacia.

DIAGNOSIS

The skeletal lesions have a characteristic radiographic appearance. In the long bones, they are found in either the metaphysis or diaphysis, typically are well defined with thin cortices, and have a ground-glass appearance (Fig. 248-4). With aging, the defects can become lobulated, with trabeculated areas of radiolucency.

TREATMENT

Rx

In patients with mild disease, bone lesions may not expand. In severe cases, individual defects can progress, and new ones may appear, during childhood. Spontaneous healing does not occur, but pathologic fractures generally mend well. Stress fractures, however, can be difficult to detect and to treat. When the skull is involved, nerve compression may require surgical intervention. In McCune-Albright syndrome, search for and pharmacologic control of associated endocrinopathies are often important. Bone antiresorptive treatment has helped some patients.

Hereditary Multiple Exostoses

This relatively common, highly penetrant, autosomal dominant disorder features irregular bone excrescences that protrude from expanded metaphyses. Mutations have been identified in the *EXT1* and *EXT2* genes. Osteocartilaginous exostoses arise from growth plates and increase in size until linear growth ceases. Lesions may or may not become detached from the parent bone. Their structure is relatively unremarkable, with an outer cortex and an inner spongiosa. Disability results primarily from limb length discrepancies when linear bone growth suffers at the expense of transverse expansion. Compression of nerves, the spinal cord, or the vascular system occurs occasionally. Sarcomatous degeneration (0.5 to 2% of patients) should be suspected when an exostosis enlarges rapidly, especially in an adult.

Enchondromatosis (Dyschondroplasia, Ollier Disease)

This sporadic disorder features cartilaginous masses within the trabecular bone that arise from growth plates. The condition begins in childhood with localized swelling and interferes with linear bone growth. At puberty, expansion of cartilage masses ceases, and these lesions can be replaced by mature bone. Enchondromas appear radiographically as lucent defects in flat bones or in metaphyses of tubular bones, often with central calcific stippling. When enchondromatosis occurs together with multiple hemangiomas (Maffucci syndrome), the enchondromas or hemangiomas undergo malignant transformation in 15% of cases. Ollier disease and Maffucci syndrome are caused by somatic mosaic mutations in the *IDH1* and *IDH2* genes.

Achondroplasia

Chondrodystrophies are disorders of cartilage growth that result in disproportionate short stature. Achondroplasia is the most common. A defect occurs in the gene that encodes fibroblast growth factor receptor type 3; 80% of cases are the result of new autosomal dominant mutations, which are more prevalent with increasing paternal age. Short tubular bones form because of abnormal endochondral ossification in the limbs. In the chondrocranium, membranous ossification is undisturbed; hence the skull vault is normal. However, the cranial base and foramen magnum are small. The head is large, with frontal bossing and midface hypoplasia. Lumbar lordosis is greatly exaggerated, and the spinal canal narrows from the upper to lower segments of the vertebral column. This disturbance is revealed radiographically by a decreasing interpediculate distance. The trunk length is relatively normal, but the limbs show rhizomelic shortening, and the hands have a trident configuration. The long bones appear massive because of their disproportionately normal width. Growth plates are not grossly disorganized, and chondrocytes appear normal. Complications can include hydrocephalus and compression of the brain stem, spinal cord, or nerve roots. Minimal impingement by a disc or osteophyte on the small spinal canal can cause neurologic disturbances.[8] Despite these problems, achondroplasia is compatible with good health and a normal lifespan.

249 APPROACH TO THE PATIENT WITH ALLERGIC OR IMMUNOLOGIC DISEASE

STEPHEN I. WASSERMAN

Allergic diseases and disorders of the immune system affect multiple organ systems and may arise in a variety of manners. The reader is directed to Section VII for a detailed discussion of the immune system and specific autoimmune and acquired immune disorders. This chapter addresses allergic disorders, the most common manifestation of immune system dysfunction, and primary immune deficiencies, which are uncommon manifestations of immune dysfunction. For clarity, these two issues are treated separately.

ALLERGIC DISEASE

DEFINITION

Allergic disorders are common, and their prevalence is increasing, particularly in urbanized, Western societies. It is said that allergic diseases are the most common disorders seen by primary care physicians. Moreover, even in nonallergic patients, consideration of allergy frequently enters the differential diagnosis of a problem under consideration. Therefore, an appreciation of how to approach the diagnosis and treatment of allergic patients is of major importance to the practice of internal medicine. Allergic disorders are those caused by the interaction of a sensitized host (one who has made immunoglobulin E [IgE] antibody recognizing a specific antigen) with a specific allergen. Not all patients possessing specific IgE antibody react adversely on interaction with the allergen, and such individuals are sensitized but not allergic. The primary allergic conditions are seasonal allergic rhinoconjunctivitis (hay fever), perennial allergic rhinitis/sinusitis, asthma, anaphylaxis (especially secondary to foods, medications, and hymenopteran stings), urticaria or angioedema, atopic dermatitis (eczema), and food allergy.

EPIDEMIOLOGY

It is currently estimated that more than 50% of the population is atopic (i.e., able to mount an IgE immune response and to exhibit an immediate positive prick-puncture hypersensitivity response to common aeroallergens). Clinically, 10 to 20% of the general population will develop allergic rhinoconjunctivitis, 5 to 7% will have active asthma, and 20% will experience urticaria at some time. The incidence of allergic rhinitis and asthma is increasing worldwide and most rapidly in those areas with prior low incidence of these disorders.

The increase in allergic diseases noted in the past two decades is thought to result from better hygienic conditions, decreases in infant and childhood infections, and increasingly sedentary and indoor lifestyle with its attendant exposures to indoor allergens and risk for obesity. These changes appear to be associated with a less effective activation of the innate immune system, thereby altering the protective maturation of the acquired immune system. The immune bias in utero and in infancy is toward a type 2 helper T-lymphocyte (T_H2)–directed immune response, which is the immune pathway required for the expression of allergic disease. Ineffective generation of regulatory T lymphocytes underlies the genesis and persistence of allergy. It is therefore postulated that without sufficient early childhood immunologic exposure (e.g., with infection) to induce a switch to an effective and protective T_H1 immune response, allergic disease is more likely to emerge during childhood. Substantial epidemiologic evidence has been gathered to support this concept, now termed the hygiene hypothesis. Thus, allergy is more prevalent in individuals of higher socioeconomic status, among those living in urban areas, in less polluted communities (e.g., western Germany), in first-born children compared with later siblings, in multiply immunized individuals, and in those free of mycobacterial disease. Conversely, children living on farms, in rural communities, and in more highly polluted areas as well as children with mycobacterial infection and those who have experienced multiple early childhood infections are less likely to develop allergic disorders. A concentration-effect relationship appears to exist between exposure to endotoxin (as a marker for hygiene) and the incidence of allergic sensitization. Low and very high levels of exposure to endotoxin are associated with abnormal immune maturation and allergic expression, whereas moderate levels of exposure predispose to a nonallergic phenotype.

PATHOBIOLOGY

The persistence or aberrant activation of T_H2 lymphocytes leads to the generation of cytokines (e.g., interleukins-4, -5, -13), which stimulate B-lymphocyte synthesis of IgE antibody and the production of eosinophilic polymorphonuclear leukocytes. The expression of allergic disorders results from the interaction of a specific allergen with allergen-reactive IgE bound to high-affinity receptors on mast cells and basophils. This interaction leads to the activation of these target cells and to their release of preformed, granule-associated mediators (exemplified by histamine); the synthesis of lipid mediators from membrane lipids (sulfidopeptide leukotrienes); and the transcription and secretion of cytokines, including tumor necrosis factor-α and interleukins-4, -5, and -13. These mediators directly induce smooth muscle contraction, vascular dilation, and endothelial leakage; they also cause vascular adhesion molecule expression, and they attract and activate inflammatory leukocytes, particularly $CD4^+$ T lymphocytes, basophils, and eosinophils. These and other IgE-dependent mediators are thought to be responsible for stimulating smooth muscle proliferation and tissue remodeling.

DIAGNOSIS

Allergy is a systemic immune disorder, so its expression can be multifocal. It is essential to remember this fact when examining a patient with suspected allergic problems because a focus on only the major presenting symptom may be insufficient to identify all the pertinent medical issues in a given patient.

History

Allergic disease has a high degree of heritability, with a great degree of concordance in identical twins. The risk of expressing allergic disease is highest if both parents are atopic. The inheritance of specific manifestations of allergy and of the specific allergen to which a patient is sensitized is less simple. Often, the diagnosis of allergic disorders is straightforward and can be made by asking about the nature of the patient's complaints, when and where reactions occur, and what exposures the patient believes are relevant to symptom induction or exacerbation (Table 249-1).

Seasonal and Perennial Rhinitis

Patients with seasonal and perennial rhinitis (Chapter 251) commonly present with complaints of itchy nose and palate; sneezing; watery rhinorrhea; itching, watery, and burning eyes; and nasal obstruction, which, when severe, may cause anosmia. In the evaluation of possible causes of seasonal rhinoconjunctivitis or sinusitis, the time of the year when symptoms occur is pertinent. Symptoms may be associated with the pollination of trees (early spring), grasses (late spring and summer), or weeds (fall). Important geographic differences exist in allergen concentration and exposure; for example, there is little ragweed in the western United States, and the grasses present in New England and Florida are quite different. In some patients with perennial symptoms, the multiple overlapping pollen seasons are responsible for their symptoms. However, indoor exposures at home, school, work, or recreational sites to furred animals, dust mites or insects, and mold should be addressed in the search for additional causes of perennial symptoms. Mold and mites are to be expected in humid environments, and mites are nearly ubiquitous in bedding and in homes with pets, carpeting, and overstuffed furnishings. Additional occupational or recreational exposures may be pertinent in selected situations (e.g., bakers, health care workers, food handlers, horse fanciers, laboratory animal handlers) in which specific inciting allergens may be identified. Because many patients with rhinitis have concomitant asthma, it is important to obtain information about the presence of this disease in patients with rhinitis. The concurrence of asthma and rhinitis has led to the concept of a "single airway" in which insults/responses in one part of the airway (i.e., upper) may be reflected in the other (i.e., lower).

Asthma

Patients with asthma (Chapter 87) may present with cough or wheeze with dyspnea, which is reversible spontaneously or with treatment. In addition to the association with rhinitis, the influence of exercise, exposure to tobacco smoke, effect of respiratory infection (particularly viral), occupational exposures (e.g., ≤30% of atopic animal handlers develop asthma), and medication use (e.g., β-adrenergic blocking drugs) are pertinent. Because most patients with asthma have concurrent rhinitis, it is essential that the physician evaluate this issue in all asthmatic patients. Wheezing may accompany other

TABLE 249-1 SYMPTOMS, SIGNS, AND TREATMENT OF ALLERGIC DISEASE

SYMPTOMS AND SIGNS	APPROACH TO TREATMENT
SYMPTOMS	
Cutaneous: itch, rash	H_1-antihistamine
Ocular: gritty sensation, itch	Topical H_1-antihistamine or mast cell stabilizing agent
Upper respiratory: palatal pruritus, clear rhinorrhea, sneeze, nasal obstruction	Topical corticosteroid, oral H_1-antihistamine, leukotriene receptor antagonist, topical nasal H_1-antihistamine
Lower respiratory: wheeze, cough, dyspnea	β_2-Agonist, inhaled corticosteroid, inhaled β_2-agonist, leukotriene receptor antagonist, oral methylxanthine, parenteral corticosteroid, parenteral anti-IgE
Gastrointestinal: nausea, vomiting, cramping pain	Epinephrine (if caused by anaphylaxis), oral corticosteroid, oral cromolyn
SIGNS	
Cutaneous: flushing, urticaria, angioedema, eczema	
Ocular: conjunctival erythema, chemosis	
Upper respiratory: pallor, edema, clear rhinorrhea, polyps	
Lower respiratory: wheeze	

disorders, including pulmonary edema in congestive heart failure and pulmonary embolic disease.

Urticaria and Angioedema

Patients with urticaria (Chapter 252) describe pruritic, erythematous cutaneous lesions with regular or irregular borders occurring anywhere on the body; they may vary in size from small (1 × 1 mm) to extremely large. Skin lesions are often preceded by intense intertriginous pruritus and erythema. Individual urticarial lesions generally persist for a few hours and rarely last for more than 24 hours.[1] However, many disorders can cause a sensation of itching; for more on skin and systemic diseases associated with pruritus (see Chapter 436). Angioedema (Chapter 252) is most frequently appreciated in the face, hands, and other soft tissues and is generally accompanied by symptoms of stretching, tingling, and tightness of the skin rather than by pruritus. Lesions, especially in the face, typically last 24 to 36 hours. Although most cases of urticaria or angioedema are not IgE-allergen mediated (particularly in chronic urticaria), it is important to identify foods and medications used by patients with acute urticaria or angioedema, particularly those substances ingested within 2 to 4 hours of the development of lesions, and to inquire about insect stings. Chronic urticaria is less often IgE mediated; questions about medications, especially nonsteroidal anti-inflammatory drugs, recent infection (especially with Epstein-Barr virus), and the presence of autoantibodies to the IgE receptor must be addressed. Approximately one half to two thirds of patients with such autoantibodies also have antibodies to thyroid antigens. In angioedema, the use of angiotensin-converting enzyme inhibitors must be sought, with special attention to those of African American heritage. Atopic dermatitis is another allergic cutaneous disorder in which patients complain of intense pruritus, especially in flexural surfaces. In adults, foods (IgE mediated) and cutaneous infection with *Staphylococcus aureus* (superantigen mediated) are the most commonly identified precipitating events for atopic dermatitis.

Anaphylaxis

Anaphylaxis (Chapter 253) is the most important allergic emergency and is potentially fatal. It is an acute allergic response associated with cutaneous (urticaria, angioedema, flushing), respiratory (laryngeal edema, asthma), cardiovascular (arrhythmia, hypotension, extravascular fluid loss), gastrointestinal (nausea, vomiting, abdominal pain, diarrhea), and nonspecific symptoms (metallic taste, sense of impending doom) that may occur singly or together. Historical information of note includes all medications, foods, and other encounters occurring within 2 hours of the reaction. Epidemiologic data suggest that foods (especially peanuts, tree nuts, shellfish, milk, and eggs), hymenopteran stings, and medications (antibiotics, muscle relaxants, radiocontrast media) are the most frequently identified causes of this important problem. Patients with elevated basal tryptase levels are at increased risk for anaphylaxis, especially with hymenopteran stings, and all patients suffering anaphylaxis after such an exposure should have baseline tryptase determined; if it is elevated, appropriate follow-up evaluation for occult mast cell disorders should be undertaken.

Food Allergy

Patients presenting with food allergy[2] often complain of oral pruritus and nausea, vomiting, diarrhea, and abdominal pain. Eczema, urticaria, and anaphylaxis, as noted previously, may also be consequences of food allergy. In general, allergic symptoms consequent to foods occur within minutes to 2 hours of ingestion of the causative food; delayed symptoms are unlikely to be mediated by an IgE-allergen interaction. Eosinophilic esophagitis has recently been added to the list of disorders in which food allergy is thought to play a role. Other symptoms attributable to foods are less easily explained by allergic mechanisms and are termed food intolerance.

Physical Examination

The physical examination of a patient with suspected allergic disease should emphasize the organ systems pertinent to the patient's complaints. The skin should be examined for the presence of urticarial or angioedematous lesions and for signs of atopic dermatitis, including flexural papules, excoriations, and lichenification. Keratosis pilaris, particularly on the outer aspect of the upper arm, commonly accompanies atopic dermatitis. Urticaria typically consists of small, pink, irregular lesions that blanch on pressure and then clear, leaving normal skin. In a patient with urticaria, a simple test for dermatographism should be undertaken. Angioedematous lesions are larger, more diffuse, and pale, and they are found most often on the face and in acral areas.

The eyes, ears, nose, and throat should be examined in all patients thought to have allergic disease, particularly those whose symptoms suggest seasonal or perennial allergic rhinoconjunctivitis-sinusitis or asthma. In allergic disease, the conjunctivae are often injected and may be edematous. "Cobblestoning" of the epithelium may be present. The periorbital tissues may be swollen and darkened. Examination of the nares may show pale and edematous nasal mucous membranes and swollen turbinates, and polyps may be seen. Secretions, generally clear, may be seen in the nasal passages or in the posterior pharynx. Such secretions generally contain copious numbers of eosinophils (see later), and their absence is a point against an allergic cause. Fever and discolored secretions, particularly those that are thick and yellow or green, in the presence of neutrophilic polymorphonuclear leukocytes suggest infection. Percussion over the maxillary or frontal sinuses may elicit tenderness in acute sinusitis. In chronic sinusitis, the physical examination may be unrevealing. In acute otitis media, patients may have erythema and bulging or perforation of the tympanic membrane, with fluid in the canal; in chronic cases, the drum may be scarred and retracted. Alteration in airborne conduction may be noted as well.

Patients with acute asthma may display tachypnea and auditory wheezes, and they may be unable to speak in full sentences because of shortness of breath. Use of accessory muscles of respiration and evidence of cyanosis should be sought. Examination of the chest includes inspection for evidence of chronic hyperinflation and auscultation for wheezing (which, if unilateral, may suggest a foreign body or tumor). In mild asthma, the examination findings may be normal, or the only physical finding may be wheezing on forced expiration and a slight prolongation of the expiratory phase.

Patients experiencing acute anaphylaxis usually demonstrate flushing, and concomitant urticaria and angioedema are often present. Assessment of vital signs may disclose hypotension and tachycardia. In some situations, hoarseness or stridor related to laryngeal edema or wheezing secondary to asthma can be identified. Hyperactive bowel sounds may be noted. Progressive hypoxia and cyanosis may ensue. In severe anaphylaxis, cardiovascular collapse secondary to hypoxia and hypotension may result in death.

Laboratory Evaluation

In the evaluation of patients with allergic disorders, the laboratory may be of assistance in both the identification and the quantification of specific organ dysfunction as well as in the assessment of the presence and specificity of IgE antibody.[3]

Assessment of Total and Allergen-Specific Immunoglobulin E

Essentially all (>95%) IgE antibody is bound to specific high-affinity receptors on tissue mast cells and circulating peripheral blood basophils. The small amount of free serum IgE antibody circulates in nanogram quantities and can be identified only with techniques of sufficient sensitivity. A large proportion

TABLE 249-2 ADVANTAGES AND DISADVANTAGES OF DIFFERENT ALLERGY TESTING METHODS

METHOD	PATIENT SELECTION	CLINICAL ADVANTAGES	CLINICAL DISADVANTAGES
Skin testing	Clinical indication suggesting allergic disease	Rapid (15-30 min) turnaround Sensitive and specific; prick-puncture for aeroallergens; prick-puncture followed by intradermal testing for drugs, sera, and venoms	Patient must not be taking H_1-antihistamine agents for 5-7 days Not interpretable in the presence of dermatographism Requires sufficient normal skin to enable testing
In vitro testing	Clinical indication suggesting allergic disease	Antihistamine therapy not contraindicated Dermatographism not a problem Sensitive and specific; equal to prick-puncture skin testing	Requires blood to be drawn Slow turnaround (7-14 days)

of IgE in a given individual may be directed toward a single antigen. Therefore, total IgE levels may be normal in the presence of allergic disease, and the measurement of total serum IgE is rarely of help in making a diagnosis. In a few situations, such as adult atopic dermatitis or allergic bronchopulmonary aspergillosis, measurement of total serum IgE levels may provide insight into disease severity or risk of disease exacerbation.

Of more importance is the identification of allergen-specific IgE in a patient with suspected allergic disease (Table 249-2).[4] Such specific IgE may be identified in vitro or in vivo. A search for allergen-specific IgE is particularly useful in the evaluation of patients with suspected allergic rhinitis, asthma, eczema, food reactions, and anaphylaxis. In vitro assessment is similar to the quantification of total IgE, except the initial capture reagent bound to a solid phase is a specific allergen from pollen, mold, insect, venom, food, or other material. Development of the assay is identical to that used to quantify total IgE, and results are generally reported in a semiquantitative manner. The magnitude of the reaction is weakly correlated with the expression of allergy, although for certain foods, more precise correlative data exist on the risk of allergy and the amount of allergen-specific IgE detected. To assess allergen-specific IgE in vivo, a minute quantity of the allergen in question is introduced into the skin by a prick-puncture technique, and the cutaneous response is assessed 15 to 30 minutes thereafter. A positive response is one in which a wheal and flare at least 2 mm larger than that caused by a saline control occur at the injection site. In vivo tests are rapid and inexpensive; their use requires the absence of dermatographism, that patients not be taking antihistamine medications, and that patients exhibit a positive response to a control with histamine. In some situations (e.g., penicillin allergy or hymenopteran sting), a more diluted allergen is injected intradermally, and the wheal and flare response is assessed similarly. The presence of allergen-specific IgE antibody and a clear temporal correlation between exposure to allergen and genesis of symptoms are required to conclude that a patient is allergic to a specific allergen. In the absence of symptoms, a patient with allergen-specific IgE is termed sensitized but not allergic.

Specific in vivo challenge tests can also be used to identify allergen responsiveness. Such tests in the presence of specific IgE antibody may be useful in research settings, or they may be used clinically to clarify the exact relationship between exposure and symptoms. The tests can be dangerous, however, because they introduce the allergen to which the patient is presumed allergic. In the case of food allergy, such challenges are best done in a double-blind and placebo-controlled manner; they may be useful to distinguish allergy from sensitization or to eliminate a suspect food from consideration. However, food challenge tests are unnecessary in the case of anaphylaxis and a positive test response for IgE antibody to the putative allergen. Because many patients falsely believe that foods are responsible for their symptoms, such double-blind challenges may be useful in directing patients' concerns to more productive areas. Inhalation tests employing specific allergens or chemicals have been helpful in elucidating some cases of occupational allergy or asthma.

Other Laboratory Aids in Allergic Disease

In a patient with acute asthma, chest radiographs generally demonstrate hyperinflation. In some instances, evidence of bronchiectasis may be present, a finding that raises the specter of allergic bronchopulmonary aspergillosis. The presence of a tumor or radiopaque foreign body may be noted on a chest radiograph and should be sought in a patient with unilateral localized wheezing. In the examination of a patient with asthma, assessment of both airflow and volumes can provide a clear picture of the severity of asthma and its response to treatment. Flow-volume loops can also identify the presence of vocal cord dysfunction or tracheomalacia. When patients with airway obstruction are evaluated, their response to an inhaled β_2-adrenergic agonist medication (or a short-acting anticholinergic agent) can be helpful in elucidating the reversible nature of their disorder. A large majority of asthmatic patients exhibiting bronchoconstriction display a bronchodilatory response to the inhalation of such agents. In suspected cases of asthma in which pulmonary function is normal, a histamine or methacholine challenge can be performed. These agents take advantage of the nonspecific bronchial hyperresponsiveness that is characteristic of patients with asthma. Failure to develop bronchoconstriction on inhalation of either of these agents strongly argues against the diagnosis of asthma.

Other laboratory tools may be of clinical benefit in the identification and classification of allergic disorders. Audiometry may clarify the degree of hearing loss caused by otitis media in a patient with allergic rhinitis. When sinusitis is suspected, computed tomography of the sinuses provides the most complete image and has the highest degree of sensitivity for the identification of mucosal thickening, opacification of air spaces, and presence of polyps and bone erosions. Computed tomography is particularly useful in the examination of the ethmoid and sphenoid sinuses, which are often affected in chronic allergic disease and are difficult to assess on physical examination or with plain radiographs. Imaging studies are not indicated, however, in most cases of acute sinusitis.

The quantification of blood, sputum, nasal mucus, or tissue eosinophilia and the response to corticosteroid therapy are useful correlates in the identification and management of allergic disease. The quantification of tryptase, a mast cell–specific protease with a serum half-life of 2 hours, can assist in the diagnosis of anaphylaxis if it is performed on serum or plasma obtained within hours of a systemic response with associated hypotension. Quantification of exhaled nitric oxide has been used to assess airways inflammation in asthma and primarily reflects eosinophilic inflammation.

IMMUNOLOGIC DISEASE

EPIDEMIOLOGY

Diseases related to disordered immune function (immunodeficiency) are far less common than allergic disorders.[5] The most frequent is IgA deficiency, which occurs in approximately 1 in 1000 individuals and is often asymptomatic. Next most frequent are disorders of B and T lymphocytes, such as common variable hypogammaglobulinemia, and other disorders, including DiGeorge syndrome and severe combined immunodeficiency (Chapter 250). Much less common are defects in neutrophil function or complement.

DIAGNOSIS

The clinical expression of immunodeficiency disorders is primarily infection, related to impaired host defense. Thus, the diagnosis of suspected immunodeficiency involves the evaluation of recurrent, persistent, severe, unusual, and otherwise unexplained infections. Many but not all immune disorders arise in early childhood, and with improved management, many patients presenting in childhood live into adulthood. It is important for the general internist and internal medicine subspecialist to be cognizant of the presentation of these disorders.

History

The most important historical information includes the following: age at onset of the problem in question; family history of frequent infection or death at an early age from infection; number, site, and type of infections; and presence of other physical abnormalities (Table 249-3). The earlier the onset of infections, the more severe the immune defect is likely to be. T-lymphocyte defects, with or without B-cell deficiencies, usually are manifested in the first 3 to 5 months of life, whereas B-cell function is supported by maternal antibody until after 6 months of age. Many of the immune disorders are X-linked,

TABLE 249-3 KEY POINTS REGARDING IMMUNOLOGIC DISORDERS

ANTIBODY DEFICIENCY DISORDERS
Onset after 6 months of age
Recurrent respiratory infection
Infection with bacteria, especially encapsulated organisms
Absence of isohemagglutinins
Evaluation of B-cell function, not numbers
CELLULAR IMMUNE DEFECTS
Onset before 6 months of age
Recurrent viral, fungal, or parasitic (opportunistic) infection
Defective delayed hypersensitivity skin responses
Malabsorption or diarrhea
COMPLEMENT DEFICIENCIES
Recurrent bacterial infection
Recurrent neisserial infection (deficiency of late components)
Associated rheumatic disorder (especially systemic lupus erythematosus)
FACTORS SUGGESTING NEUTROPHIL DYSFUNCTION
Late separation of umbilical cord
Persistent neutrophilic leukocytosis
Recurrent or persistent gingivitis or periodontitis
Recurrent bacterial infection with granuloma formation

and a careful family history is critical in such situations. Infection-related death of a patient's male sibling or the patient's mother should lead to the search for such an X-linked disorder.

In a patient with a T-cell disorder, viral, fungal, mycobacterial, and other opportunistic infections (*Pneumocystis jiroveci, Toxoplasma gondii*) are most commonly noted, and live virus vaccination may be associated with disseminated and progressive viral disease. Persistent thrush, diarrhea, malabsorption, and failure to thrive occurring in early childhood may suggest the presence of T-cell abnormalities.

In B-cell or antibody deficiency, pyogenic bacterial infections predominate, particularly infections involving encapsulated microorganisms. Such infections usually affect the upper and lower respiratory tract and the skin and are severe, recurrent, and often persistent. Infections with unusual organisms, with unexpected complications, or involving multiple sites (lung, sinus, joint, bone, or meninges, with abscess formation or sepsis) should raise the index of suspicion. In adults, the most common disorder in this class is termed common variable immunodeficiency.

As in any patient with infection, information should be sought about exposure to ill individuals or to irritants such as tobacco smoke, the hygiene of the environment to which the patient has been exposed, and the presence of an anatomic abnormality or allergy that could predispose to infection.

Physical Examination

Physical examination beyond that necessary to assess the extent and severity of a particular infection should focus on immune organs. Assessment of tonsillar tissue and determination of the presence and size of lymph nodes, spleen, and liver are important. Patients with common variable immunodeficiency often present with hepatosplenomegaly and lymph node hyperplasia, whereas in X-linked hypogammaglobulinemia, lymph tissue is absent. Telangiectasia (ataxia-telangiectasia), cardiac defects (DiGeorge syndrome), chronic eczema (Wiskott-Aldrich syndrome), and chronic periodontitis (neutrophil defects) all suggest immunodeficiency syndromes.

Laboratory Evaluation

The proper use of the laboratory is essential to elucidate a suspected immunodeficiency disorder.[6] Screening tests appropriate to the generalist's initial approach include complete blood count, total neutrophil and lymphocyte enumeration, quantitative immunoglobulin levels, and assessment of isohemagglutinins (especially when common variable immunodeficiency is suspected). In some situations, quantification of IgG subclasses may be warranted to identify a specific subclass deficiency. In considering T-lymphocyte defects, it is important to enumerate total T cells and specific T-cell subsets. Delayed hypersensitivity skin testing to recall antigens is also helpful in assessing cellular immunity. When neutrophil defects are suspected, a nitroblue tetrazolium test or measurement of phagocytic potency can be performed. Complement defects are best addressed by obtaining a CH_{50} level. CH_{50} is the amount of the patient's serum required to cause lysis of 50% of test erythrocytes. It is compared with the amount of pooled normal serum required to cause the same degree of lysis. Tests for specific individual components of complement, or of complement regulatory proteins, can also be obtained under special circumstances (e.g., late complement components in patients with recurrent *Neisseria* species infection).

Additional tests of antibody production in response to defined stimuli, including vaccinations, may be helpful when selective antibody deficiency is suspected or when borderline immunoglobulin levels are encountered in the presence of frequent infection. In some situations, assessment of T-cell proliferation to mitogens or antigen may be of benefit. Further testing might include the assessment of natural killer-cell function and the production of cytokines by activated lymphocytes. In general, such additional laboratory tests should be performed in consultation with an expert in immune disorders.

REVIEW QUESTIONS

1. Which of the following young adults is most likely to suffer from hay fever, seasonal rhinoconjunctivitis, atopic eczema, and dermatitis?

A. Raised in a wealthy family with access to excellent preventive health care
B. Born, raised, and living on a farm
C. Grew up as a "sickly child" with multiple ear infections, upper respiratory tract infections, and other infections
D. During childhood, had a mother with active TB that was being treated at home "for a long time with pills"
E. Youngest of five children whose parents did not allow him to have childhood immunizations

Answer: A This question relates to the concept known as the hygiene hypothesis, which postulates that decreased microbial stimulation early in life may lead to delayed maturation of the immune system, which in turn results in an increased risk of allergic diseases later in life. Although the situation with asthma specifically appears to be more complex, other allergic diseases are more prevalent in individuals of high socioeconomic status, in first-born children compared with later siblings (especially in large families), in multiply immunized individuals, and in those free of mycobacterial disease. In contrast, children raised on farms are less likely to develop allergic disorders later in life, possibly because of their early exposure to diverse microbial environments in animal sheds, haylofts, harvesting, and other farm activities. See Epidemiology.

2. Which of the following symptoms is characteristic of an anaphylactic reaction?

A. Angioedema
B. Metallic taste
C. Abdominal pain
D. Sense of impending doom
E. All of the above

Answer: E Anaphylaxis, the most important and a potentially fatal allergic emergency, can be manifested with any single one or a combination of a wide variety of symptoms, including cutaneous (urticarial, angioedema, flushing), respiratory (stridor from laryngeal edema, wheezing), cardiovascular (hypotension, arrhythmia, extravascular fluid loss), gastrointestinal (vomiting, abdominal pain, diarrhea), or nonspecific symptoms (metallic taste in mouth, sense of impending doom). See Anaphylaxis under the History section of Diagnosis.

3. Diagnosis of a specific allergic disorder requires

A. No laboratory testing if the clinical history is characteristic
B. Increased serum level of total IgE
C. Increase in serum allergen-specific IgE
D. Increase in serum allergen-specific IgE coinciding with symptoms
E. Demonstration of dermatographism

Answer: D The presence of allergen-specific IgE antibody and a clear temporal correlation between exposure to allergen and the genesis of symptoms are required to conclude that a patient is allergic to a specific allergen. In the absence of symptoms, a positive test response for allergen-specific IgE alone is termed sensitization but not allergy. Total levels of IgE in serum may be normal in the presence of allergic disease, and therefore its measurement is rarely helpful in making a diagnosis. See Assessment of Total and Allergen-Specific Immunoglobulin IgE under Laboratory Evaluation.

4. A young woman is found unresponsive, lying on a sidewalk. She is brought to the emergency department, where she is resuscitated but found to be in respiratory failure, requiring intubation, and in shock. No previous history is known, and the cause of her shock is not clear. Which of the following tests can diagnose anaphylactic shock in this case?

A. Increased serum IgE level
B. Eosinophilia
C. Increased serum tryptase level
D. Histamine or methacholine challenge
E. None of the above is useful without a clinical history

Answer: C The quantification of tryptase, a mast cell–specific protease with a half-life of 2 hours, can be helpful to diagnose anaphylaxis if it is performed on serum or plasma obtained within hours of a systemic reaction with associated hypotension. Histamine or methacholine challenge is not even feasible under these circumstances. The other blood tests are not sufficiently sensitive or specific.

5. In the evaluation of a patient with frequent infections for a possible immunodeficiency disorder, her history reveals late separation of the umbilical cord at birth, recurrent and persistent gingivitis and periodontitis, and recurrent bacterial infections with granuloma formation. Which of the following categories of immunologic disorders is she most likely to have?

A. Cellular immune defect
B. Neutrophil dysfunction
C. Complement deficiency
D. IgA deficiency
E. Severe variable immunodeficiency

Answer: B These findings along with persistent neutrophilic leukocytosis are characteristic of disorders of neutrophil dysfunction. Infections in individuals with cellular immune defects are more likely to be viral, fungal, or parasitic (opportunistic) in etiology, and they may also have malabsorption and diarrhea. Complement deficiencies are typically associated with recurrent bacterial infections, especially neisserial infections, and rheumatic diseases like systemic lupus erythematosus. IgA deficiency and other antibody deficiency disorders are characterized by recurrent respiratory infections with encapsulated organisms.

PRIMARY IMMUNODEFICIENCY DISEASES

CHARLOTTE CUNNINGHAM-RUNDLES

Since the descriptions of the first genetic immune defects, severe combined immunodeficiency (SCID) and X-linked agammaglobulinemia (XLA), in the 1940s, the number of known primary immune defects (175+) has expanded exponentially.[1] To keep pace, every few years the International Union of Immunological Societies has compiled these defects into eight general categories: T- and B-cell combined defects, B-cell/antibody defects, complement disorders, phagocyte defects, defects with syndromic features, diseases of immune dysregulation, autoinflammatory syndromes, and defects of innate immunity (Table 250-1).[2] Autoinflammatory syndromes are covered in Chapter 261. In this chapter, our current understanding of these other primary immune defects is considered with emphasis on immune defects found in adults. Complement and phagocyte disorders are discussed in more detail in Chapters 50 and 169, respectively.

AN APPROACH TO EVALUATION OF THE IMMUNE SYSTEM

Because of the numbers and types of immune deficiency, recognition of the many clinical phenotypes can be difficult, leading in many cases to a delayed diagnosis. The spectrum of immune defects found in populations varies with the age of the patient and with the combined T- and B-cell immune defects, defects of phagocyte function, defects with syndromic features, defects of immune dysregulation, and innate defects; selected infections are more commonly recognized in childhood, whereas defects of complement and antibody production are more characteristic of adults. However, there are many exceptions to this general observation; in addition, even if an immune defect has been diagnosed in childhood, adequate treatment has allowed these patients to increasingly appear in the offices of internists and adult specialists.

For most patients, the first symptom of an immune defect is a series of relatively common infections, particularly involving the respiratory tract. These may include chronic sinusitis, otitis, and bacterial pneumonia. For adults with immune defects, infections are likely to last longer, are likely to require additional courses of antibiotics, and tend to recur. Infections may lead to additional complications or procedures, such as empyema after bacterial pneumonia or the need for myringotomy tubes in an adult with chronic otitis. For infants and children, chronic infections lead to poor appetite and an obvious failure to grow normally; for adults, some weight loss may occur, but it is less apparent. Because of lack of immunity, shingles (Chapter 375)

is relatively common in patients with T-cell defects or lack of antibody. Other common clinical presentations include acute gastrointestinal infections with characteristic organisms such as *Giardia* (Chapter 351) and chronic intestinal inflammatory diseases with weight loss and malabsorption (Chapter 140). General guidelines to approach the laboratory evaluation of the main immune defects outlined in this chapter, based on clinical presentations,[3] are provided in Table 250-2. Flow charts of the work-up of immune defects in Table 250-1, based on clinical phenotypes, have been published.[4]

TABLE 250-1 CATEGORIES OF PRIMARY IMMUNODEFICIENCY DISEASES

T- and B-cell combined deficiencies
Antibody deficiencies

Phagocyte defects
Well-defined defects with syndromic features
Immune dysregulation syndromes
Autoinflammatory defects
Defects of innate immunity

T- AND B-CELL COMBINED DEFECTS

DEFINITION

Combined immune defects are diseases in which both the T- and B-cell compartments are greatly impaired. With the very early onset and severe nature of these defects, this group contains all forms of SCID and other syndromes in which both T- and B-cell limbs of the immune system are markedly abnormal.

EPIDEMIOLOGY

The incidence of SCID has undergone a downward revision from the estimated 1 : 100,00 a few years ago because of newborn screening, currently performed for about half of all newborns in the United States.[5] The aggregate incidence of these forms, listed in Table 250-3, appears to be about 1 : 54,000. When the larger spectrum of combined immune defects is also included, the incidence is likely to be higher.

PATHOBIOLOGY AND GENETICS

The hallmark of combined defects is that they eliminate or greatly impair T-cell development, in most cases leading to profound lymphopenia. Infants

TABLE 250-2 CLINICAL PRESENTATION AND EVALUATION OF THE IMMUNE SYSTEM

CLINICAL PRESENTATION	DEFECTS	IMMUNE DEFECTS	CONDITIONS	LABORATORY TESTING
Recurrent or chronic bacterial, viral, or fungal infections Opportunistic infections	Cell-mediated immunity	Impaired killing of intracellular organisms Impaired viral immunity Hypogammaglobulinemia	SCID	Absolute lymphocyte count Enumeration of T cells and T-cell subsets Proliferative tests for T-cell function
Bacterial infections Viral infections Autoimmunity Inflammatory diseases Enteropathy Giardiasis	B cells	Hypogammaglobulinemia Impaired bacterial killing Impaired clearance of virus or toxins	Hypogammaglobulinemia Agammaglobulinemia IgA deficiency CVID IgG subclass defects Antibody deficiency	Enumeration of B cells Serum IgG, IgA, and IgM Antibody testing (i.e., tetanus, diphtheria) Vaccine challenge and antibody testing (pneumococcal vaccine)
Bacterial infections Susceptibility to meningococcal disease Autoimmunity Angioedema	Complement	Impaired opsonization Impaired bacterial killing Lack of clearance of immune complexes	Complement C2 deficiency Other complement defects HAE	CH_{50} AH_{50} Measuring individual components C1 inhibitor protein and function
Bacterial infections Poor skin healing Fungal infections Stomatitis Periodontal disease	Phagocytic cells	Impaired neutrophil mobilization Impaired opsonization Impaired bacterial killing	Chronic neutropenia Cyclic neutropenia Autoimmune neutropenia LAD CGD	Absolute neutrophil counts Neutrophil oxidative burst examined by dihydrorhodamine test by flow cytometry Examination of the blood smear Antineutrophil antibodies

CGD = chronic granulomatous disease; CVID = combined variable immunodeficiency; HAE = hereditary angioedema; LAD = leukocyte adhesion deficiency; SCID = severe combined immunodeficiency.

TABLE 250-3 EXAMPLES OF COMBINED IMMUNE DEFECTS

SCID TYPE	GENES	INHERITANCE	LABORATORY FEATURES	DISEASE AND COMPLICATIONS
Defects of V(D)J recombination	*RAG1*, *RAG2* ARTEMIS DNA-PKcs	AR	Very low lymphocyte numbers with loss of T and B cells; hypogammaglobulinemia	Severe infections, failure to thrive; leaky versions may have autoreactive T cells (Omenn syndrome)
Adenosine deaminase deficiency	Adenosine deaminase	AR	Variably low lymphocyte numbers with loss of T and B cells; also decreased NK cells; hypogammaglobulinemia	Severe infections, failure to thrive; often with costochondral junction flaring, neurologic features, hearing impairment, lung and liver manifestations
X-linked SCID	Common γ chain of cytokine receptors	XL	Low lymphocyte numbers with loss of T cells; B cells present; markedly decreased NK cells; hypogammaglobulinemia	Severe infections, failure to thrive; leaky cases may present with low T or NK cells or Omenn syndrome
JAK3 deficiency	*JAK3*	AR	Low lymphocyte numbers with loss of T cells; B cells present; hypogammaglobulinemia	Severe infections, failure to thrive; leaky cases may present with variable T or NK cells
IL-7 deficiency	α chain of the IL-7 receptor	AR	Low lymphocyte numbers with loss of T cells; B cells present; normal NK cells; hypogammaglobulinemia	Severe infections, failure to thrive; leaky cases may present with low T or NK cells or Omenn syndrome
T-cell receptor chain defects	γ-, ε-, and ζ-chain mutations	AR	Low lymphocyte numbers due to loss of T cells; normal B and NK cells; hypogammaglobulinemia	Severe infections, failure to thrive; leaky cases may present with low T or NK cells or Omenn syndrome

AR = autosomal recessive; DNA-PKcs = DNA-dependent protein kinase catalytic subunits; IL-7 = interleukin-7; JAK3 = Janus kinase 3; NK = natural killer; SCID = severe combined immunodeficiency; XL = X-linked.

with defects that affect the formation of T- and B-cell receptors, such as defects of the recombinase activating genes *RAG1* and *RAG2*, which impair VDJ recombination, have few if any T and B cells. Similarly, other defects of DNA recombination or repair genes (ARTEMIS, DNA-PKcs) will have a similar phenotype. When T-cell immunity is absent, B cells may be present, but they will have no function. This is the case for the most common form of SCID, the X-linked form, due to mutations in the cytokine γ chain, the signaling component of six cytokine receptors: interleukin (IL)–2, IL-4, IL-7, IL-9, IL-15, and IL-21. Similarly, defects of the *JAK3* gene, downstream from the cytokine γ chain, or of the IL-7 receptor itself lead to a similar immune profile.

CLINICAL MANIFESTATIONS

With loss of both essential limbs of the adaptive immune system, infants with combined immune defects have severe and recurrent infections due to bacteria, viruses, and fungi. Other common features include diarrhea, dermatitis, and failure to thrive. Clinically, most patients present before the age of 3 months, but there is a significant number of exceptions as infants may present later, although still usually in the first year of life. Without intervention, SCID usually results in severe infections and death by the age of 2 years. In some cases, the immune defect is such that a few T cells can develop, but these are often self-reactive; these cases are often termed leaky SCID. When the presentation of these cases includes rashes and evidence of autoimmunity, infants are said to have Omenn syndrome.

DIAGNOSIS

Newborns normally have an absolute lymphocyte count of 4000/mm^3 or higher. Thus, the first measure in suspected SCID is the complete blood count; most infants have significant lymphopenia. When the clinical manifestations suggest SCID, a flow cytometer panel is used to enumerate T, B, and NK cells; this will also suggest genes that may be responsible. Further genetic testing can be done, but only after stem cell transplant approaches have been launched.[6] A number of states have recently introduced newborn screening for SCID, based on standard blood spot (Guthrie) cards to determine if the DNA signature of new T cells emigrating from the infant thymus can be detected in normal numbers. This method has been shown to be both highly sensitive and specific and is likely to be universally adopted.

TREATMENT AND PROGNOSIS

Rx

Without immune reconstitution, infants with SCID will die, and prompt recognition is essential. Early reconstitution with stem cells from human leukocyte antigen (HLA)–matched bone marrow or mobilized peripheral blood is mandatory. When the diagnosis is made early and no severe infections have occurred, hematopoietic stem cell transplantation (HSCT; Chapter 178) is likely to be curative in 90% of cases. Gene therapy in some cases is gaining a new role and will likely lead to additional options in the future.

ANTIBODY DEFECTS

DEFINITION

The antibody defects are due to loss of B-cell development, loss of production of one or more of the immunoglobulin (Ig) isotypes, or loss of functional antibody production.

EPIDEMIOLOGY

As a group, antibody defects are the most prevalent immune defects and are found in patients of all ages. Selective IgA deficiency is most common in patients of white background, but the incidence varies with the population studied from 1 : 400 to more than 1 : 10,000. IgA deficiency is found in 1 : 400 in Finland but much less commonly in African Americans or Asians (1 : 14,000 or fewer). Common variable immune deficiency (CVID) has an estimated incidence of 1 in 50,000; IgG subclass or selective antibody defects are also common, but the incidence is unknown.

PATHOBIOLOGY AND CLINICAL MANIFESTATIONS

Whereas the genetic causes have been elucidated for many of the combined forms of immune deficiency, the genes are not yet known for many of the more common B-cell defects (Table 250-4). Antibody defects can be considered in three main forms: B cells are absent; B cells are present but one or more immunoglobulin isotypes is not made; and B cells and immunoglobulin levels are normal but the produced immunoglobulins have no function.

Lack of B Cells Leading to Agammaglobulinemia

The first severe antibody defect described was the X-linked form of agammaglobulinemia (XLA). The gene affected, a tyrosine kinase (BTK) located on the X chromosome, is essential for downstream signaling from the B-cell receptor. Without these signals, B cells do not survive, leading to profound hypogammaglobulinemia. The incidence of this disease is approximately 1 in 100,000. The main clinical manifestations appear in the first year of life, but males may come to clinical attention later, in some cases not until the second decade. Whereas X-linked inheritance is a central feature, the family history may or may not be positive because of de novo mutations. Infections are usually bacterial, generally with encapsulated organisms like *Streptococcus pneumoniae, Haemophilus influenzae, Staphylococcus aureus,* and *Pseudomonas* species. A particular propensity for *Mycoplasma* infections in XLA has been long noted; these may occur in joints or the urinary tract and can be difficult to diagnose as appropriate culture techniques are not widely available.

In addition to XLA, there are other genetic forms of agammaglobulinemia. These are gene defects of the B-cell receptor itself, such as the μ heavy chain, the surrogate light chain λ5, Igα, and Igβ. Similarly, mutations in signaling proteins immediately downstream from the B-cell receptor lead to the same outcome, with loss of all B cells. As these genes are not on the X chromosome, these defects, although rare, are found in both sexes.

Good Syndrome

A special case of agammaglobulinemia with loss of B cells in adults is a poorly understood immune defect associated with thymomas (Good syndrome). This appears to be a secondary immune defect, but it is important to include it here as the loss of B cells, with either agammaglobulinemia or hypogammaglobulinemia, leads to many of the same infectious manifestations as with the other profound antibody defects. Quite rare, Good syndrome occurs in adults, most often after the age of 40 years, and includes an increased incidence of opportunistic infections, such as *Pneumocystis jiroveci, Candida* infections with nail or other cutaneous involvement, viral infections, and inflammatory complications such as lichen planus. The connection between thymoma, loss of B-cell function, and the unusual infections remains unclear.

Hypogammaglobulinemia with B cells

Common Variable Immune Deficiency

Patients with CVID have varying degrees of hypogammaglobulinemia ranging from almost total loss of immunoglobulins to more modest reductions of IgG and IgA or IgM. From the clinical point of view, CVID is a noteworthy disorder as it is relatively common (1 : 25,000 to 1 : 50,000), has a later onset than other immune defects (generally between the ages of 20 and 40 years), and has a highly heterogeneous clinical presentation. Delays in diagnosis are common. Before diagnosis, about 80% of subjects with CVID will have had one or more episodes of pneumonia, sometimes leading to empyema. Over time, bronchiectasis may develop. The bacterial species most commonly found include *S. pneumoniae, H. influenzae, S. aureus,* and *Mycoplasma* species. The gastrointestinal tract is not uncommonly involved; this may be infectious (e.g., *Giardia, Campylobacter,* norovirus) or inflammatory, including lymphoid hyperplasia and forms of inflammatory bowel disease leading to malabsorption. However, a biopsy will show loss of plasma cells in the gastrointestinal mucosa. About one quarter of subjects with CVID have autoimmune conditions such as thrombocytopenia, hemolytic anemia, achlorhydria, pernicious anemia, and granulomatous disease suggesting sarcoidosis.[7] Clinically, lymphadenopathy is common, and splenomegaly is noted in 28%. Malignant disease is also increased, usually B-cell lymphomas, but other cancers appear more common as well. In the past decade, some of the gene mutations responsible for a minority of these cases have been discovered and are included in Table 250-4. However, at this time, most subjects with hypogammaglobulinemia do not have a known gene defect.

Hyperimmunoglobulin M Syndromes

The hyperimmunoglobulin M (hyper-IgM) syndromes are defects in which there is a loss of isotype switch; that is, whereas B cells do produce IgM, they do not secrete IgG or IgA. The prototypic form is the X-linked version in which an essential T-cell activation receptor, the CD40 ligand encoded on the X chromosome, is missing or nonfunctional. Mutations in the gene for its receptor partner, the CD40 on B cells, lead to a similar defect. Several

TABLE 250-4 EXAMPLES OF ANTIBODY DEFECTS

TYPE	GENES	INHERITANCE	LABORATORY FEATURES	DISEASE AND COMPLICATIONS
ABSENT B CELLS: SEVERE REDUCTIONS IN IgG, IgA, AND IgM				
X-linked agammaglobulinemia	Bruton tyrosine kinase	XL	IgG, IgA, and IgM are very low or absent	Severe bacterial infections
Autosomal forms of agammaglobulinemia	Defects of the B-cell receptor or its signaling pathways; λ5, Igα, Igβ	AR	IgG, IgA, and IgM are very low or absent	Severe bacterial infections
Good syndrome	Unknown	Unknown	Variable hypogammaglobulinemia	Associated with thymoma; may have opportunistic infections
B CELLS PRESENT BUT LOW SERUM IgG, IgA, AND/OR IgM				
Common variable immune deficiency	Unknown	Unknown	Low IgG, IgA and/or IgM	Bacterial infections and other inflammatory complications
ICOS deficiency	ICOS	AR	Low IgG, IgA and/or IgM	Recurrent infections; autoimmunity
Defects of the B-cell receptor	CD19, CD81, CD20, CD21	AR	Low IgG, IgA and/or IgM	Recurrent infections
Defects of other B-cell receptors	TACI, BAFFr, TWEAK	AD and sporadic	Variably low IgG, IgA and/or IgM; antibody defects	Recurrent infections and autoimmunity; variable clinical expression
B CELLS PRESENT: SEVERE REDUCTION IN SERUM IgG AND IgA BUT NORMAL OR ELEVATED IgM				
X-linked hyper-IgM syndrome	CD40 ligand	XL	IgG and IgA decreased; IgM may be normal or increased; B-cell numbers may be normal or increased	Bacterial and opportunistic infections, neutropenia, autoimmune disease
CD40 deficiency	CD40	AR	Low IgG and IgA; normal or increased IgM	Bacterial and opportunistic infections, neutropenia, autoimmune disease
Defects of DNA recombination	AID and UNG	AR	IgG and IgA decreased; IgM increased	Bacterial infections; enlarged lymph nodes and germinal centers
B CELLS PRESENT: ISOTYPE DEFICIENCIES				
Selective IgA deficiency	Unknown	Unknown	IgA absent	Usually asymptomatic; allergies and autoimmunity may be more common
IgA with IgG subclass deficiency	Unknown	Unknown	Reduced IgA with decrease in one or more IgG subclass	Infections in some with loss of antibody
IgG subclass deficiency	Unknown	Unknown	Reduction in one or more IgG subclass	Asymptomatic in many; infections in some with loss of antibody
B CELLS PRESENT: NORMAL IgG, IgA, AND IgM				
Antibody deficiency	Unknown	Unknown	Normal serum immunoglobulins but no vaccine responses to protein and carbohydrate antigens or vaccines	May lead to recurrent infections

AD = autosomal dominant; AR = autosomal recessive; ICOS = inducible T-cell costimulator; XL = X-linked.

other genetic defects lead to a similar immunologic phenotype, including defects of the gene for enzyme activation-induced cytidine deaminase (*AICDA*) and uracil-DNA glycosylase, both important for DNA recombination. The complications of the hyper-IgM syndromes include bacterial infections, autoimmunity, and enteropathy similar to CVID but also *P. jiroveci* pneumonia, neutropenia, and unusual cancers. A predilection to infections with *Cryptosporidium* has been noted in hyper-IgM syndromes, which unfortunately can lead to irreversible liver disease.

IgA Deficiency

Selective IgA deficiency (IgA <7 mg/dL with other isotypes normal) is the most common of the primary immunodeficiency disorders, but most subjects are asymptomatic. Lack of infections in most subjects is generally ascribed to the overlapping and compensatory role of other immune functions, but this is not clearly understood. However, allergies, autoimmunity, increased serum IgE, asthma, rheumatoid arthritis, gluten intolerance, and inflammatory bowel disease are found more commonly in selective IgA-deficient subjects than in other populations.[8] Presumably owing to the loss of secretory IgA, *Giardia* infections may occur (Chapter 351). The treatments used in subjects with IgA deficiency are based on the clinical conditions found. Some subjects with IgA deficiency are IgG2 and IgG4 deficient, with loss of antibacterial antibody leading to severe infections and, in some cases, chronic lung disease.

IgG Subclass Defects

Another variable immune deficiency is represented by the IgG subclass defects. The incidence of these is difficult to determine, partly because laboratory normal ranges vary. The clinical consequences depend on how much antibody function is lost. Whereas there are structural differences in IgG isotypes, their functional roles have considerable overlap; thus, the importance of isotype defects can be controversial, especially if loss of antibody is not demonstrable. In adults, IgG3 deficiency appears to be the most common but is likely to have no significance. However, low IgG2 or IgG4, most often found in subjects with selective IgA deficiency, may lead to a profound deficiency of antibody production, especially to carbohydrate antigens such as contained in the pneumococcal vaccine.

Antibody Deficiency with Normal Immunoglobulins

More complex and heterogeneous is the loosely described defect termed antibody deficiency with normal serum immunoglobulins. The incidence is unknown; all ages are affected, but in general, children younger than 5 years are not included to allow transient forms of physiologic immune deficiency to resolve. Although B cells are present and there are normal levels of IgG, IgA, and IgM, these subjects do not form protective levels of serum antibodies after having an infection exposure or vaccination with protein or carbohydrate vaccines. In the most severe cases, even strong immunogens such as herpes zoster or tetanus vaccines are ineffective; in milder cases, the pneumococcal vaccine does not result in titers of antibody considered sufficient for protection.

DIAGNOSIS

The diagnosis of antibody defects is based on the laboratory tests of numbers of B cells, the serum immunoglobulin levels (IgG, IgA, and IgM), and an evaluation of a panel of vaccine responses to determine the levels of functional

antibody.[9] If B cells are absent and the levels of immunoglobulins are very low, further antibody testing is not required. For a young male with a family history of males with immune deficiency, the diagnosis of XLA or hyper-IgM can be investigated by flow cytometer (to determine numbers of B cells for XLA) or by genetic tests (hyper-IgM). For older subjects (generally older than 45 years), a thymoma may be sought by chest computed tomography, which may show a mass in the mediastinum. Most subjects with hypogammaglobulinemia will be found to have B cells in peripheral blood and some amount of serum IgG, IgA, or IgM. In these cases, the loss of functional antibody should be tested by commercial laboratories to determine if protective titers of antibody to common vaccine antigens (i.e., tetanus, diphtheria, *H. influenzae*, and pneumococci) can be detected. In some cases, revaccination may be needed to determine if a response occurs (tested again in 4 to 6 weeks). Most authorities use the laboratory-stipulated protective ranges for protein vaccines and for pneumococcal vaccination, usually 1.3 µg/mL for individual serotypes. When high levels of B cells are found in adults, the possibility of a clonal B-cell expansion should be considered (e.g., chronic lymphocytic leukemia). For subjects with IgG subclass defects or normal immunoglobulins levels, the use of a panel of antibody titers is also recommended to have a clear understanding of immune competence or immune defect.

TREATMENT

Rx

The essential treatment of significant IgG antibody defects is intravenous or subcutaneous immune globulin, usually given in doses of 400 to 600 mg/kg body weight per month. The intravenous forms are usually given every 3 or 4 weeks, the subcutaneous forms weekly or biweekly, depending on body weight. Indwelling ports are not required and are discouraged. Most patients also require occasional courses of antibiotics, chosen on the basis of culture results, at intervals dictated by clinical events. Referring to Table 250-4, the defects that require IgG replacement are those in which B cells are absent (XLA, other agammaglobulinemias, the hyper-IgM syndromes, IgG subclass defects with demonstrable loss of antibody function, and some cases of loss of antibody with normal immunoglobulins). Subjects with IgA deficiency do not require immune globulin replacement unless there is clear loss of antibody. For unclear reasons, some of the antibody defects have an increased incidence of autoimmune or inflammatory complications. These require treatments commonly prescribed for immunocompetent subjects but with a view to minimizing courses of immune suppressants. Immune cytopenias may be treated with rituximab with some success; splenectomy is to be avoided. As many subjects with antibody defects have experienced one or more bouts of pneumonia, lung functions may be abnormal and intermittent or prophylactic antibiotics required, but there is no consensus on the medications, dose, or intervals to use.

PROGNOSIS

The prognosis for subjects with antibody defects is variable and depends on the degree of the defect, the response to treatment, whether organ damage has occurred, and whether other complications develop. Subjects with loss of B cells have a pure B-cell defect; when they are diagnosed and treated early with sufficient immune globulin, the prognosis appears excellent. Subjects with selective IgA deficiency can be indistinguishable from age-matched healthy peers. CVID subjects with varying degrees of hypogammaglobulinemia ranging from almost total loss of immunoglobulins to more modest reductions of IgG and IgA or IgM often have additional complications, in some cases because the diagnosis has been delayed and pulmonary or other damage has occurred. Chronic lung disease, lymphoid hyperplasia, and gastrointestinal enteropathy may be difficult to treat, leading to increased morbidity. Improved survival to prior years is likely overall in CVID, but the inflammatory complications still present additional challenges.[10] For subjects with IgG subclass defects or antibody deficiency, with immune reconstitution if required, no increased morbidity or mortality is expected.

COMPLEMENT DISORDERS

DEFINITION

The complement system is a network of proteins that both amplify and control many actions of the immune system. It is generally considered to have three main branches, the classical, alternative, and lectin pathways; deficiencies of individual components lead to increased susceptibility to infections, autoimmunity, and inflammatory diseases (Table 250-5). For further details of these disorders, see Chapter 50.

EPIDEMIOLOGY

Complement C2 deficiency is found in 1 : 10,000 white subjects and usually in subjects with a conserved major histocompatibility complex haplotype due to a founder defect; more than 95% of C2-deficient individuals are homozygous for the same *C2* mutation. The other complement component defects are rare but found in unequal distribution in selected populations; C6 deficiency is more common in persons of African descent and C9 deficiency in Asians, with an estimated incidence of 0.036 to 0.095%. Disorders of members of these pathways are discussed here; deficiency of C1 inhibitor is discussed separately.

PATHOBIOLOGY

The classical pathway is triggered by interaction of the Fc portion of an IgG1, IgG2, IgG3, or IgM antibody with C1q, which subsequently engages C1r,

TABLE 250-5 EXAMPLES OF COMPLEMENT DEFECTS

TYPE	GENES	INHERITANCE	LABORATORY FEATURES	ALTERED FUNCTIONS	DISEASE AND COMPLICATIONS
C1q, C1r, C1s deficiency	*C1qA, C1qB, C1qC; C1r, C1s*	AR	Absent CH_{50} hemolytic activity	Loss of early complement activation; impaired dissolution of immune complexes; impaired clearance of apoptotic cells	Bacterial infections; SLE-like syndrome, rheumatoid disease, multiple autoimmune diseases, infections
C4 deficiency	*C4A* and *C4B*	AR	Absent CH_{50} hemolytic activity	Loss of early complement activation	Bacterial infections
C2 deficiency	*C2*	AR	Absent CH_{50} hemolytic activity	Loss of early complement activation	Bacterial infections; SLE-like syndrome, vasculitis, early atherosclerosis, polymyositis, glomerulonephritis
C3 deficiency	*C3*	AR	Absent CH_{50} hemolytic activity	Loss of classical and alternative pathways of complement activation	Life-threatening pyogenic infections; SLE-like disease; glomerulonephritis; atypical hemolytic-uremic syndrome
C5, C6, C7, C8 deficiency	*C5*	AR	Absent CH_{50} hemolytic activity	Loss of complement activation	Neisserial infections, SLE
C9 deficiency	*C9*	AR	Reduced CH_{50} and AP_{50} hemolytic activity	Partial loss of complement activation	Some *Neisseria* infections
C1 inhibitor deficiency	C1 inhibitor	AD	Activation of complement; low levels of C4 and C2	Loss of regulation of activities of complement C1	Angioedema

AD = autosomal dominant; AR = autosomal recessive; SLE = systemic lupus erythematosus.

C1s, C2, and C3, leading to activation of C4, C5, C6, C7, C8, C9, resulting in lysis of bacteria (discussed in Chapter 50). As opsonization of bacteria is essential for antibody function, patients with these defects have infections similar to those of subjects with loss of immunoglobulin. The alternative pathway is activated in an antibody-independent manner and involves opsonization of bacteria with subsequent involvement of C3 and the alternative pathway. The lectin pathway includes other serum binding proteins that coat bacteria or fungi, leading to downstream complement activation and the assembly of the membrane attack complex, the C7, C8, C9 components responsible for microbial lysis. The genes of the complement system are located on many chromosomes, and in general, the defects are autosomal recessive in inheritance, with one exception, defects of X-linked properdin. In addition to the three pathways of activation, the complement system also includes an even larger number of control proteins that, when genetically defective, also lead to severe infections, hemolytic-uremic syndrome, severe eclampsia, glomerulonephritis, thrombosis, and macular degeneration, which are outside the scope of this chapter.

CLINICAL MANIFESTATIONS

With genetic loss of the classical and alternative pathways, severe bacterial infections are likely; this is particularly true of subjects with defects of C3, which lies at the convergence of the three pathways. For unclear reasons, with loss of C6, C7, C8, and C9 or properdin, *Neisseria gonorrhoeae* or *Neisseria meningitidis* infections are more common. More complex but equally potent is the role that the complement proteins play in immune regulation. With loss of the early components of the classical system, C1q, C1r , C1s, C2, and C4, autoimmunity, especially systemic lupus erythematosus, is common; this complication is estimated at 93% for subjects with defects of C1q and 75% for defects of C4. Complement is important for clearing immune complexes and possibly apoptotic cells, potentially explaining this observation.

DIAGNOSIS

Deficiencies of complement are diagnosed by testing total serum hemolytic complement (CH_{50}) and the alternative hemolytic complement (AP_{50}). The CH_{50} tests for deficiencies in the classical pathway by determining whether the patient's serum can lyse antibody-coated sheep erythrocytes; this will be zero if the proteins of the classical pathway are defective. The AP_{50} tests for alternative pathway activity. Further testing usually includes measurement and function of individual serum complement proteins to determine the most applicable diagnosis. (Note that the most common reason for low levels in CH_{50} and AP_{50} is improper blood handling.)

TREATMENT Rx

There are no treatments for complement deficiencies. Whereas loss of these classical components may lead to severe clinical consequences, for C2 in particular but also for C4 and C5-C9, there may be no history of illness. Prompt antibiotic therapy for acute infections and control of autoimmunity are the important therapeutics. However, periodic immunizations with pneumococcal, *H. influenzae*, and meningococcal vaccines may be helpful to boost antibody titers to enhance bacterial clearance.

PROGNOSIS

The prognosis of complement defects is highly variable because of the clinical complications; also, most of these defects have been found in healthy subjects. However, for defects of the classical pathway, prompt recognition and treatment of bacterial infections and possibly preemptive vaccination with appropriate vaccines would be important. The prognosis for subjects with autoimmunity will depend on disease manifestation and response to treatment. Whereas C2 deficiency is commonly viewed as usually asymptomatic, some data suggest a higher incidence of premature arteriosclerotic heart disease.

C1 INHIBITOR DEFICIENCY

DEFINITION

C1inhibitor (C1 INH) deficiency is discussed in detail in Chapter 252. It is classified as either genetic or acquired. The genetic form is called hereditary angioedema (HAE), due to mutations of C1 INH, inherited as an autosomal dominant trait. However, approximately 25% of patients with HAE have a spontaneous mutation in C1 INH, with no family history. C1 INH defects are classified as type I, due to loss of C1 INH protein, or type II, in which the protein is present but nonfunctional. Another inherited, estrogen-dependent form of HAE due to mutations in factor XII has also been recognized. The acquired form of C1 INH deficiency may be due to interfering autoantibodies and often clinically resembles the genetic forms, except that it usually is manifested later in life.

PATHOBIOLOGY AND GENETICS

Defects of C1 INH are inherited as autosomal dominant traits, but the outcome in families may vary considerably, from no angioedema in some members to frequent episodes in others. The C1 INH protein is the main regulator of the early activation steps of the classical complement pathway. It binds to and inactivates C1r and C1s in the C1 complex of the classical pathway, and when insufficient amounts are present, the classical pathway can be activated. C1 INH protein also inhibits proteases in the bradykinin pathways, increasing bradykinin production and leading to angioedema. With loss of C1 INH activity, fluid leaks from the vascular endothelium, leading to localized edema.

CLINICAL MANIFESTATIONS

A diagnosis of C1 INH deficiency is suggested by a history of recurrent attacks of angioedema or in some cases (25%) episodes of recurrent abdominal pain due to edema. The edema is nonpitting, nonpruritic, and localized to one regional area, such as the lips and mouth, hands, genitals, or abdomen, leading to concern for acute colitis or appendicitis. The presence of urticaria with angioedema suggests an IgE-mediated process and is not typical. As these defects are inherited as autosomal dominant defects, a family history is likely but not always identified. The hereditary forms usually become clinically apparent in early adolescence, but angioedema may occur before or after, with the first episode appearing first in adult life. Attacks may be preceded by "prodromes" of erythema, nausea, or a tingling sensation. Although the cause of an attack onset may often be unpredictable, there are certain triggers of HAE, including dental work, accidents, surgery, emotional stress, and infection. Unlike allergic angioedema, angioedema from C1 INH deficiency does not respond to treatment with antihistamines or corticosteroids and resolves slowly during 3 to 5 days. Selected medications (estrogen and angiotensin-converting enzyme inhibitors) can exacerbate or cause attacks and are to be avoided.

DIAGNOSIS

The diagnosis is suggested by a low serum C4 level. In HAE I, there is low C1 INH protein; in HAE II, there is normal C1 INH protein but a low function. The acquired form is suggested by a decreased C4 level, low C1 INH protein and function, and decreased C1q. A diagnosis of this form should prompt further evaluation of an underlying malignant or autoimmune disease. Blood tests for either HAE or the acquired form should be repeated to confirm the diagnosis because falsely low C1 INH function levels may result from improper handling of blood.

TREATMENT Rx

The treatment of hereditary C1 INH deficiency includes management of the attacks and prophylaxis against angioedema. These are described in Chapter 252.

PHAGOCYTE DEFECTS

DEFINITION

Abnormalities of the phagocytic system are presented in detail in Chapters 167 and 169. They are categorized as neutropenia, abnormal neutrophil morphology, defective cell adhesion and migration, or defective microbial killing (E-Table 250-1). Neutropenia (Chapter 167) is defined as counts of less than 1000×10^9/L.

EPIDEMIOLOGY

Whereas neutropenia is a common laboratory finding (due to conditions described in Chapter 167), genetic defects impairing neutrophil development, adhesion, locomotion, or intracellular killing are rare. The most

E-TABLE 250-1 EXAMPLES OF PHAGOCYTE DEFECTS

TYPE	GENES	INHERITANCE	LABORATORY FEATURES	ALTERED FUNCTIONS	DISEASE AND COMPLICATIONS
DEFECTS OF NEUTROPHIL DIFFERENTIATION					
Severe congenital neutropenia	*ELANE, GFI1, HAX1*	AD or AR	Neutropenia	Impaired myeloid differentiation	Susceptible to infections; myelodysplasia
Cyclic neutropenia	*ELANE*	AR	Neutropenia at 21-day intervals	Impaired and cyclic myeloid differentiation	Susceptible to infections at intervals, periodontitis
DEFECTS OF MOTILITY					
Leukocyte adhesion deficiency (types 1-3)	*ITGB2* Adhesion protein (CD18)	AR	Leukocytosis	Impaired neutrophil adherence and chemotaxis	Delayed cord separation for type 1; skin ulcers, poor wound healing, periodontitis
Shwachman-Diamond syndrome	*SBDS*	AR	Pancytopenia	Impaired chemotaxis	Exocrine pancreatic insufficiency, chondrodysplasia; risk of leukemia
Chédiak-Higashi syndrome	*LYST*	AR	Neutrophils with giant inclusions; hair: pigment clumps	Impaired chemotaxis	Partial albinism, recurrent infections, late-onset primary encephalopathy, increased lymphoma risk
DEFECTS OF RESPIRATORY BURST					
Chronic granulomatous disease	gp9 ^{phox} p22^{phox} p47^{phox} p67^{phox} p40^{phox}	XL, AR	Normal or increased neutrophil counts but loss of respiratory burst	Impaired bacterial killing	Susceptible to bacterial and fungal infections

AD = autosomal dominant; AR = autosomal recessive; XL = X-linked.

common is chronic granulomatous disease (CGD), with an estimated incidence of 1 : 100,000 to 1 : 200,000.

PATHOBIOLOGY AND GENETICS

Circulating neutrophils are attracted to sites of inflammation by complement components C5a, chemokines, and bacterial byproducts, but traveling to these sites requires migration through capillaries and into tissues. The best known diseases in which neutrophil adhesion is impaired are the leukocyte adhesion defects (LAD types 1, 2, and 3), discussed in Chapter 169. Other defects of neutrophil motility include juvenile periodontitis, Shwachman-Diamond syndrome, and the Chédiak-Higashi syndrome.

About two thirds of patients with CGD are males as they have defects in an X-linked gene encoding $gp91^{phox}$. Autosomal defects in $p47^{phox}$ are the next most common form, occurring in 20% of patients and often due to the same deletion. Other autosomal forms are due to defects in the gene encoding the $p22^{phox}$ or $p67^{phox}$ subunits (about 5% each).

CLINICAL MANIFESTATIONS

The genetic neutrophil disorders have specific clinical associations: delayed separation of the umbilical cord and poor wound healing in LAD-1; growth delay, mental retardation, and Bombay blood group in LAD-2; peripheral nerve conduction defects, pigmentary dilution with partial oculocutaneous albinism, easy bruising, and risk of hemophagocytic disease in Chédiak-Higashi syndrome; and pancreatic insufficiency (fat malabsorption), growth failure, and skeletal abnormalities in Shwachman-Diamond syndrome. For both Shwachman-Diamond syndrome and the severe congenital neutropenias, there is a risk for development of myelodysplastic disease and leukemia.

The clinical manifestations of CGD usually include bacterial or fungal infections. Males with the X-linked form will generally present in the first decade of life, whereas subjects with autosomal forms may have a later onset of symptoms (into the second decade). Regardless of the genetic cause, most patients with CGD will have one or more episodes of pneumonia; the most common causes of infection are *Staphylococcus, Burkholderia cepacia, Klebsiella, Aspergillus, Serratia,* and *Nocardia* species. Common clinical manifestations include acute or chronic lymphadenitis, colitis leading to recurrent diarrhea, *Staphylococcus* liver abscess, osteomyelitis, and rectal abscess. Patients with CGD are also prone to infections with unusual organisms, for example, *Chromobacterium violaceum, Trichosporon inkin, Francisella philomiragia,* and *Granulibacter bethesdensis*. For this reason, exposure to contaminated water or decaying plant material (compost, mulch) presents significant risk to subjects with CGD.

DIAGNOSIS

The differential diagnosis of neutropenia is presented in Table 167-4; the genetic diagnosis of congenital neutropenia syndromes, in Table 167-5; and a diagnostic approach to suspected phagocyte defects, in Figure 169-4.

TREATMENT Rx

The management of patients with neutropenia is discussed in Chapter 167. The treatment of CGD is summarized in Chapter 169.

WELL-DEFINED DEFECTS WITH SYNDROMIC FEATURES

Another group of primary immune defects are those that have distinctive systemic characteristics, aside from the obvious abnormities in the immune system (Table 250-6). The best known of these are the Wiskott-Aldrich syndrome, ataxia-telangiectasia, DiGeorge syndrome, hyperimmunoglobulin E (Buckley-Job) syndrome, and cartilage-hair hypoplasia. As these are distinct from each other, they are discussed separately.

Wiskott-Aldrich Syndrome

DEFINITION AND EPIDEMIOLOGY

Wiskott-Aldrich syndrome (WAS) is a rare X-linked recessive disease characterized by eczema, thrombocytopenia, and immune deficiency. WAS is rare, estimated as 1 and 10 cases per million males. Ethnic differences are not known.

PATHOBIOLOGY AND CLINICAL MANIFESTATIONS

WAS is inherited as an X-linked disease, and the main manifestations in early childhood include eczema, chronic thrombocytopenia sometimes leading to bloody diarrhea, and immune deficiency with recurrent infections.[11] Not uncommonly, autoimmunity or inflammatory disease including autoimmune hemolytic anemia, splenomegaly, arthritis, inflammatory bowel disease, and vasculitis appear. There is a clear increase in the incidence of lymphoma in WAS. The syndrome is caused by mutations in the *WAS* gene, which codes for the protein called WASP, an intracellular cytoplasmic scaffold protein important for the activation and mobility of all blood cells. WASP is involved in actin polymerization and in establishing an interface between immune cells (the immune synapse). Partly depending on the location of the

TABLE 250-6 WELL-DEFINED DEFECTS OF IMMUNITY WITH SYNDROMIC FEATURES

TYPE	GENES	INHERITANCE	LABORATORY FEATURES	ALTERED FUNCTIONS	DISEASE AND COMPLICATIONS
Wiskott-Aldrich syndrome	*WAS*	XL	Thrombocytopenia, small platelets	Impaired cell activation, mobility	Eczema; lymphoma; autoimmune disease; bacterial and viral infections
Ataxia-telangiectasia	*ATM*	AR	Some have IgA deficiency; IgG defects, lymphopenia in some	Impaired DNA double-stranded break repair	Ataxia; telangiectasia; pulmonary infections; lymphoreticular and other malignant neoplasms; increased α-fetoprotein; x-ray sensitivity
DiGeorge anomaly	22q11.2 deletion; rarely a deletion in 10p	De novo (majority) or AD	Lymphopenia; low T-cell numbers; large deletion in chromosome 22 on fluorescence in situ hybridization	Impaired T-cell immunity	Cardiac abnormalities; hypoparathyroidism, abnormal facies
Hyper-IgE syndrome (Buckley-Job syndrome)	*STAT3*	AD, de novo	Eosinophilia, high IgE	Loss of normal cytokine activation, defective IL-17	Bacterial infections; eczema, distinctive facial features, osteoporosis , fractures, scoliosis, delay of shedding primary teeth, hyperextensible joints, candidiasis
Cartilage-hair hypoplasia	*RMRP*	AR	Lymphopenia, low T-cell numbers	Impaired processing of mitochondrial RNA	Short-limbed dwarfism, sparse hair, celiac disease, Hirschsprung disease, bone marrow failure, autoimmunity, susceptibility to lymphoma

AD = autosomal dominant; AR = autosomal recessive; IL = interleukin; XL = X-linked.

mutation in the *WAS* gene, milder versions are known, leading to X-linked thrombocytopenia in some cohorts. Another, much rarer version leads to X-linked neutropenia.

DIAGNOSIS

The diagnosis is commonly made in the first few years of life in males with the characteristic symptoms of eczema with thrombocytopenia leading to petechiae. Typically, IgM levels are low, whereas IgA (and sometimes IgE) levels are increased. Platelet sizes are smaller than normal, and clot retraction is poor. Family history may include male relatives with WAS or thrombocytopenia. The diagnosis can be suggested by lack of the WAS protein as detected by flow cytometry in reference laboratories, but definitive diagnosis requires gene testing.

TREATMENT Rx

Treatment strategies in WAS are diverse and usually considered on a case-by-case basis. Conservative management includes prophylactic antibiotics, immunization with conjugated polysaccharide vaccines, and intravenous or subcutaneous immune goblin for subjects with repeated infections. For eczema, standard measures are used (Chapter 438). For significant thrombocytopenia (Chapter 172), splenectomy has been performed but is discouraged as lifelong post-splenectomy sepsis poses a significant risk. For these subjects, lifelong antibiotic prophylaxis is mandatory. Platelet transfusions should be reserved for active bleeding that cannot be managed with usual methods (e.g., aminocaproic acid) and avoided for subjects for whom transplantation is considered. Autoimmunity can be difficult to control, and immune suppression should be used with caution. Treatment of lymphomas is by standard regimens (Chapter 185). Definitive treatment is by HSCT, which has proved successful in many subjects. Trials with gene therapy are also ongoing.

PROGNOSIS

The prognosis in WAS is highly heterogeneous. Some have mild thrombocytopenia leading to occasional nose bleeds, whereas other subjects have inflammatory disease or other complications that require additional, sometimes intensive medical management. HSCT (Chapter 178) offers a cure, but this is best done early and requires careful matching and standard protocols.

Ataxia-Telangiectasia

DEFINITION AND EPIDEMIOLOGY

Ataxia-telangiectasia (AT) is a rare neurodegenerative disease that leads to cerebellar atrophy, skin telangiectasia, and immune defects. AT is estimated to occur in 1 in 40,000 to 100,000 but is more common in selected isolated populations. Sexes are affected equally.

PATHOBIOLOGY

AT is due to recessive mutations in the gene that encodes the ATM protein, important in both cell division and DNA repair. With the loss of the ATM protein, DNA breakage cannot be repaired, leading to cell death.

CLINICAL MANIFESTATIONS

The clinical manifestations include progressive difficulty in walking, with ataxia beginning around the age of 5 years. Skin telangiectasias develop on the bulbar conjunctiva and behind the ears. The immune defects include IgA deficiency, IgG subclass defects, and cellular defects leading to recurring pulmonary infections and lung damage in some. Subjects with AT have radiosensitivity, and the development of lymphomas is common with increasing age.

DIAGNOSIS

The diagnosis can usually be made by the characteristic clinical phenotype, coupled with an increase in α-fetoprotein in the blood. Radiosensitivity can be assessed in vitro in fibroblast cell lines. Definitive diagnosis is by *ATM* gene sequencing.

TREATMENT AND PROGNOSIS Rx

Treatment for AT includes supportive measures and physical therapy as needed. The life expectancy for subjects with AT varies greatly, but most live into early adulthood.

DiGeorge Syndrome

DEFINITION AND EPIDEMIOLOGY

DiGeorge syndrome is an autosomal dominant defect and one of the members of the 22q11.2 deletion syndrome that includes velocardiofacial syndrome, conotruncal anomaly face syndrome, congenital thymic aplasia, and thymic hypoplasia. DiGeorge syndrome is one of the most common of the immune defects, estimated at 1 : 4000. Sexes are affected equally.

PATHOBIOLOGY AND CLINICAL MANIFESTATIONS

Although it is classified as an immune defect because of thymic hypoplasia or aplasia, patients with DiGeorge syndrome are likely also to have congenital heart disease, cleft palate or pharyngeal closure defects, characteristic facies, hypocalcemia due to parathyroid insufficiency, and learning disability. The more common cardiac defects include tetralogy of Fallot, interrupted aortic arch, ventricular septal defects, vascular rings, and anomalous return of brachial arteries. The mnemonic CATCH-22 has been applied: cardiac issues, abnormal facies, thymic aplasia, cleft palate, and hypocalcemia. With loss of thymic tissue, cellular immunity is mildly to moderately impaired, leading to recurrent infections. Hypogammaglobulinemia is not uncommon and may be associated with autoimmune cytopenias, especially thrombocytopenia.[12]

DIAGNOSIS

The diagnosis of DiGeorge syndrome for most patients is based on the genetic test fluorescence in situ hybridization, which detects the loss of the 22q11.2 gene segment or, more rarely, a loss of 10p14-p13. However, about 10% do not have a gene defect but have the syndrome due to maternal diabetes, fetal alcohol syndrome, or prenatal exposure to isotretinoin (Accutane).

TREATMENT

Treatment of DiGeorge syndrome is based on individual need and may require cardiac surgery, cleft palate repair, and calcium and vitamin D supplementation if hypocalcemia is found. Some subjects are hypothyroid, requiring thyroid supplementation. The immune defect in DiGeorge syndrome varies widely, from complete loss of thymic development with no circulating T cells to normal T-cell numbers. For most, the thymus is hypoplastic, and whereas the level of T cells may be subnormal for age, sufficient T-cell function remains and no specific treatment is needed. Withholding of live viral vaccines may not be necessary as reports of ill effects are rare and the protection afforded is likely to outweigh any risk . For complete loss of the thymus, thymic transplantation, HSCT, or, for some, infusion of HLA-matched peripheral T cells can supply sufficient reconstitution.

PROGNOSIS

For most subjects, the prognosis depends on the concomitant medical issues, such as results of cardiac surgery, surgical repair of cleft palate, management of swallowing difficulties, and resources to enhance muscle strength and to overcome speech impediments and learning disabilities. For most, the T-cell defect is a minor component and a normal lifespan is likely; but with age, autoimmunity may become more prominent.

Hyperimmunoglobulin E Syndrome

DEFINITION

Hyperimmunoglobulin E syndrome (HIES), also called Buckley-Job syndrome, is an immune deficiency syndrome characterized by eczema, skin and lung abscesses, hyperextensible joints and recurrent bone fractures, distinctive coarse facies, eosinophilia, and high levels of serum IgE.

PATHOBIOLOGY AND CLINICAL MANIFESTATIONS

Most but not all patients with HIES have an autosomal dominant defect in the gene *STAT3* encoding a transcription factor, signal transducer and activator of transcription 3. After activation by selected cytokines and growth factors, STAT3 protein is phosphorylated and translocated to the cell nucleus. Whereas loss of STAT3 signaling affects many cellular processes, the syndrome itself is often clinically recognizable from the characteristic clinical findings of eczema, recurrent skin boils, unusual facies with tubular nose, cyst-forming pneumonias often due to *S. aureus*, and increased serum IgE. Other common manifestations include a rash in the newborn period; mucocutaneous candidiasis; and skeletal abnormalities, such as scoliosis, osteoporosis, fractures with minimal trauma, and delayed shedding of primary teeth.

Features of the HIES syndrome have been found in a few patients with rare autosomal recessive defects in genes encoding tyrosine kinase 2 (Tyk2) and dedicator of cytokinesis 8 (DOCK8), but in both of these, viral infections are also prominent.

DIAGNOSIS

The diagnosis can be strongly suspected on clinical grounds, but a useful scoring system composed of a composite of laboratory and clinical characteristics has been shown to aid in the dissection of hyperimmunoglobulin E subjects from other subjects with high serum IgE levels, for example, severely atopic subjects. IgE levels may range from 1000 to 40,000 IU or more; some references note that IgE levels may normalize in older subjects. Eosinophilia is common. However, a definitive diagnosis is best confirmed by identifying a *STAT*3 mutation.

TREATMENT

Rx

There is no definitive treatment for HIES syndrome. Because of the propensity for staphylococcal infections, prophylaxis with appropriate antibiotics (trimethoprim-sulfamethoxazole, 5 mg/kg/day trimethoprim divided twice daily) is commonly used, along with oral antifungals such as itraconazole, 100 mg daily for patients aged <13 years or weighing <50 kg; 200 mg daily for those aged >13 years or weighing >50 kg. Surgical drainage of abscesses is also important, but wound healing may be poor. Skin care for eczema may include bleach baths to reduce bacterial burden and antihistamines to control pruritus. Optimization of calcium and vitamin D levels may be useful to strengthen bones.

PROGNOSIS

HIES is a lifelong disease, and infections or complications require individual care. With increasing age, increased respiratory dysfunction is likely. Recent reports note vascular, especially arterial, abnormalities, which are important to define.

Cartilage-Hair Hypoplasia

DEFINITION AND EPIDEMIOLOGY

Cartilage-hair hypoplasia (CHH) is a rare autosomal recessive form of short-limbed dwarfism associated with a variable cellular immune deficiency. In the Old Order Amish population, CHH affects 1 in 1300 newborns; for those of Finnish descent, the incidence is about 1 in 20,000. A common point mutation in the gene is prevalent in the particularly affected populations.

PATHOBIOLOGY AND CLINICAL MANIFESTATIONS

The genetic defect in CHH is in the *RMRP* gene, which encodes the RNA in a mitochondrial RNA-processing endoribonuclease that helps copy mitochondrial DNA and process ribosomal RNA. In CHH, the encoded RNA is unstable, leading to skeletal dysplasia, sparse hair, and the predominantly T-cell deficiency disease. For unclear reasons, the cellular defect is varied, ranging from mildly impaired immunity to severe defects requiring HSCT. Other clinical features of CHH include short stature, anemia, autoimmunity, celiac disease, Hirschsprung disease, and several cancers including lymphoma.

DIAGNOSIS

The diagnosis can be suspected by inheritance patterns and clinical phenotype, but definitive diagnosis is made by genetic sequencing of the *RMRP* gene.

TREATMENT AND PROGNOSIS

Rx

For patients with severe T-cell defects and infections (essentially SCID phenotype) suggesting a significantly impaired immune system, HSCT is required. Aside from the cellular defect, treatment is directed at the other presenting clinical issues. The prognosis of CHH is varied, and the prognosis depends on the depth of the cellular defect, the therapies required, and the associated clinical complications. As the defect is so variable, normal lifespans may be achieved.

IMMUNE DYSREGULATION SYNDROMES

Clustered into a separate set of immunodeficiency diseases are syndromes that have immune dysregulation as a main theme. These mostly monogenic diseases have in common lymphoid proliferation, immune activation, and inflammatory or autoimmune complications. These include the hemophagocytic lymphohistiocytosis (HLH) diseases (Chapter 169), the lymphoproliferative syndromes linked to Epstein-Barr virus (EBV) infection, autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED), autoimmune lymphoproliferative syndromes (ALPS), and defects of T-regulatory cells (Table 250-7).

EPIDEMIOLOGY

The estimated incidence of the genetic HLH syndromes is 1 : 50,000; the incidence of X-linked lymphoproliferative disease is 1 to 3 in 1,000,000; and the incidence of APECED is high in Finland (1 in 25,000) and in Sardinians and Iranian Jews (1 in 9000) but otherwise much rarer. The incidence of ALPS and defects of T-regulatory cells is unknown.

PATHOBIOLOGY AND CLINICAL MANIFESTATIONS

HLH is a form of extreme and potentially life-threatening immune activation. It is further discussed under the section Hemophagocytic Lymphohistiocytosis and Macrophage Activation Syndrome in Chapter 169. There are two forms: genetic, due to mutations in genes that control cellular cytotoxicity; and secondary, due to acute viral illnesses, autoimmune activation, or underlying malignant disease.[13] The familial form is a heterogeneous autosomal recessive disorder due to mutations in one of five genes essential for control of T-cell cytotoxicity. Immune activation leads to expansion of poorly controlled cytotoxic T cells and macrophages, leading to the release of interferon (IFN)-γ, IL-1, IL-6, and IL-10. Patients have high fevers, cytopenias, liver dysfunction, coagulopathy, and sometimes neurologic symptoms. HLH may be fatal unless it is treated with aggressive measures and may require HSCT. Life-threatening accelerated immune activation syndromes are also characteristic of other genetic defects that impair cytotoxicity, such as the Chédiak-Higashi syndrome.

Monogenic defects leading to impaired immunity to EBV produce another group of immune dysregulation syndromes. The first described (and the most common, 70 to 80%) is the X-linked proliferative disorder (XLP) due to mutations of the X-linked gene *SH2D1A*, which encodes the gene *SAP*, a signaling lymphocytic activation molecule (SLAM)–associated protein. Other genetic causes for loss of control of EBV are due to mutations in *XIAP* (20 to 30%) or, rarely, *ITK* and *CD27*. *XLP* and *XIAP* are on the X chromosome; the other defects are inherited as autosomal recessive traits. In each case, infection with EBV leads to an acute illness with lymphoproliferation, progressive but variable hypogammaglobulinemia, and lymphoma in *XLP*, *ITP*, and *CD27* defects. A unifying theme of these syndromes is loss of function of NK-T cells, a subset of T cells important in viral immunity.

A unique member of the genetic immune dysregulation diseases is APECED or autoimmune polyglandular syndrome type 1 (Chapter 231). Whereas the clinical presentation is usually due to endocrine disease (hypoparathyroidism, Addison disease, hypogonadism, and secondary amenorrhea), the disease is caused by loss of thymic recognition of self-antigens due to mutations in the autoimmune regulator gene (*AIRE*).[14] Chronic mucocutaneous candidiasis is common, probably due to circulating anticytokine antibodies (interferon and IL-17). The transcription factor encoded by the *AIRE* gene, found in thymic epithelial cells, is involved in the early negative selection of cells with autoimmune potential. Clinically, cutaneous candidiasis or the endocrine defect may be the first sign of the syndrome; for unclear reasons, chronic diarrhea with malabsorption is also common. Other autoimmune complications may include hepatitis, alopecia, vitiligo, diabetes mellitus, anemia, and pernicious anemia.

Defects in lymphocyte apoptosis lead to another form of immune dysregulation; in these subjects, because of impaired death of lymphocytes, lymph nodes and spleen enlarge and autoimmunity, especially thrombocytopenia and hemolytic anemia, occur. Together, these are commonly referred to as ALPS. The most common of these defects are due to autosomal dominant mutations in the *FAS* gene, which encodes the important FAS death receptor, and less commonly in FAS ligand. Both are dominant but have variable penetrance. Much less common forms of autoimmune lymphoproliferation are due to mutations in caspase 10 or even more rarely the oncogenes *KRAS* and *NRAS* or protein kinase Cδ.[15]

TABLE 250-7 DISEASES OF IMMUNE DYSREGULATION

TYPE	GENES	INHERITANCE	LABORATORY FEATURES	ALTERED FUNCTION	DISEASE AND COMPLICATIONS
Familial hemophagocytic lymphohistiocytosis syndromes	*PRF1, UNC13D, STX11,* and *STXBP2*	AR	Anemia, neutropenia, thrombocytopenia, abnormal liver functions, high ferritin and serum IL-2 receptor, hemophagocytosis in bone marrow and liver	Decreased to absent NK cells and cytotoxic activities	Fever, hepatosplenomegaly, cytopenias, hemophagocytic lymphohistiocytosis, neurologic disease in some
Chédiak-Higashi syndrome	*LYST*	AR	Neutrophils with giant inclusions; hair: pigment clumps	Impaired chemotaxis	Partial albinism, recurrent infections, late-onset primary encephalopathy, increased lymphoma risk
Lymphoproliferative syndromes	*SAP, XIAP* (*ITK, CD27*)	XL, AR	Epstein-Barr virus infection; decreased NK cells and $CD8^+$ CTL activation; deficient NK-T cells; anemia; hypogammaglobulinemia in some	Loss of function of NK-T cells leading to impaired viral control	Clinical and immunologic features triggered by Epstein-Barr virus infection; lymphoproliferation, lymphoma
Autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy	*AIRE*	AR	Endocrine dysfunction; hepatitis	Loss of thymic self-tolerance	Autoimmunity leading to hypoparathyroidism, hypothyroidism, diabetes, adrenal and gonadal dysfunction; cutaneous candidiasis; hepatitis
Autoimmune lymphoproliferative syndrome	*FAS*, FAS ligand; (caspase 10; *KRAS; NRAS;* protein kinase Cδ)	AD	Increased double-negative T cells ($CD4^-/CD8^-$), increased serum B_{12}	Defects in lymphocyte apoptosis	Splenomegaly, lymphadenopathy, autoimmune cytopenias; increased risk of lymphoma
Genetic defects of T-regulatory cells	*FOXP3* (CD25, *STAT5B* and *ITCH, STAT1*)	XL, AR	Diabetes, anemia, eosinophilia, high serum IgE, hyperglobulinemia, loss of *FOXP3* expression in the XL form	Lack of (or impaired function of) $CD4^+$, $CD25^+$, $FOXP3^+$ regulatory T cells (Tregs)	Enteropathy, dermatitis, eczema, early-onset diabetes, thyroiditis, hemolytic anemia, thrombocytopenia, elevated IgE and IgA

AD = autosomal dominant; AR = autosomal recessive; CTL = cytotoxic T lymphocyte; IL = interleukin; XL = X-linked.

The defects of T-regulatory cells are the final member of this set of genetic defects leading to loss of regulation.[16] The first to be described was the immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) syndrome, a generally lethal disease in males, characterized by early-onset insulin-dependent diabetes mellitus, enteropathy with severe diarrhea, and eczema-like dermatitis. Other manifestations include anemia, thrombocytopenia, and neutropenia as well as liver or kidney autoimmune disease. The defect is generally due to mutations of the X chromosome forkhead box protein 3 (*FOXP3*) gene, a gene essential for the development of regulatory T cells. However, other genetic defects may lead to a similar clinical syndrome.[16]

DIAGNOSIS

The diagnosis of these syndromes may be suspected from the clinical manifestations, family history, and laboratory grounds, but genetic validation is required for definitive diagnosis.

TREATMENT

Rx

For the HLH diseases and related syndromes, prompt immune suppression by established protocols and intense supportive care are necessary. For the genetic forms, HSCT is often required. The lymphoproliferative syndromes associated with EBV are similar in that prompt supportive care is required and transplantation is potentially curative. Rituximab has been used in these defects to reduce B-cell numbers and EBV burden if infection occurs. Treatment of the cytopenias in ALPS includes corticosteroids, rapamycin, and other agents. For unclear reasons, rituximab may lead to permanent hypogammaglobulinemia in ALPS, and splenectomy is to be avoided. Patients with APECED usually require endocrine and possibly nutritional management as well as treatment for cutaneous candidiasis. For the defects of T-regulatory cells due to mutations in IPEX, HSCT is the only curative measure.

PROGNOSIS

The diseases of immune dysregulation have a varied prognosis. For the genetic HLH syndromes, EBV-related lymphoproliferative diseases, and IPEX, immune reconstitution is required. Because of the broad spectrum of manifestations for ALPS and APECED, management of the clinical issues may be sufficient.

DEFECTS OF INNATE IMMUNITY THAT LEAD TO SELECTED INFECTIONS

DEFINITION

As opposed to the adaptive immune system (in which a previous exposure is required to form immune memory; Chapter 46), many components of the immune system function quickly with no pre-exposure. These components of the innate immune system (Chapter 45) include, for example, complement, phagocytic cells, and natural killer cells. Screening of large populations for selected microbial diseases has revealed a number of novel defects of innate immunity. Some of these defects are discussed here (Table 250-8).

PATHOBIOLOGY AND CLINICAL MANIFESTATIONS

Innate defects appear to be rare and the incidence is not known. One of the first recognized was anhidrotic ectodermal dysplasia with immunodeficiency, a syndrome due to mutations in the *IKBKG* gene that encodes nuclear factor κB (NF-κB) essential modulator (NEMO). This is an X-linked disease and was first assigned to the category of hyper-IgM syndromes. However, the actual phenotype is broad due to impairment of NEMO, which is essential for both cytokine and toll-like receptor signaling pathways. Impairment in this gene leads to severe bacterial infections and mycobacterial disease as well as to the characteristics of ectodermal dysplasia: sparse hair, abnormal tooth development, and lack of sweat glands. After NEMO defects were recognized, a series of other genetic defects in toll-like receptors and their signaling

TABLE 250-8 EXAMPLES OF DISEASES OF INNATE IMMUNITY

DISEASE	GENES	INHERITANCE	LABORATORY FEATURES	ALTERED FUNCTION	ASSOCIATED FEATURES
Anhidrotic ectodermal dysplasia with immunodeficiency	*NEMO* (*IKBKG*), *IKBA*	XL, AD	Variable hypogammaglobulinemia for NEMO with increased IgM in some; lack of antibody response to polysaccharides	Defective NF-κB signaling pathway	Bacterial and mycobacterial infections Ectodermal dysplasia, hair loss, heat intolerance due to loss of sweat glands Tooth abnormalities
IRAK4 deficiency	*IRAK4*	AR	Impaired cytokine responses to toll receptor activators	Defective TIR-IRAK signaling pathway	Bacterial infections, especially *Staphylococcus* and *S. pneumoniae*
MyD88 deficiency	*MYD88*	AR	Impaired cytokine responses to toll receptor activators	Defective TIR-MyD88 signaling pathway	Bacterial infections, especially *Staphylococcus* and *S. pneumoniae*
Herpes simplex encephalitis	*TLR3* *UNC93B1* *TRAF3*	AD AR	Impaired cytokine responses to TLR3 activators	Defective IFN-α, IFN-β, and IFN-γ induction	Herpes simplex virus 1 encephalitis
Predisposition to fungal diseases	*CARD9*	AR	Fungal cultures positive	Defective CARD9 signaling pathway	Invasive candidiasis and other fungal diseases
Chronic mucocutaneous candidiasis	*IL17RA* *IL17F* *STAT1*	AR, AD	Fungal cultures positive	Defective IL-17R signaling pathways	Mucocutaneous candidiasis
IL-12, IL-23 receptor deficiency	*IL12RB* *IL12* *IL23*	AR	Mycobacterial cultures positive	Defective cytokine receptor binding and signaling	Mycobacterial and salmonella infections
IFN-γ receptors 1 and 2 deficiency	*IFNGR1* *IFNGR2*	AR	Mycobacterial cultures positive	Defective IFN-γ binding and signaling	Mycobacterial and salmonella infections
GATA2 deficiency	*GATA2*	AR, AD	Multilineage cytopenias; very low monocyte numbers		Infections with mycobacteria, papillomaviruses, histoplasmosis, alveolar proteinosis, but also myelodysplasia and leukemias

AD = autosomal dominant; AR = autosomal recessive; IFN = interferon; IL = interleukin; IL-17R = interleukin-17 receptor; NF-κB = nuclear factor-κB; TIR = intracytoplasmic Toll and IL-1 receptor; TLR = toll-like receptor; XL = X-linked.

pathways have been recognized, for example, autosomal recessive defects in IRAK4 and MyD88, both of which lead to severe pneumococcal and staphylococcal infections. In contrast, effects of the TLR3 pathway lead to early herpes simplex encephalitis. Much more clinically heterogeneous are the genetic defects that lead to chronic mucocutaneous candidiasis. These defects may be autosomal dominant or recessive and lead to simple onychomycosis in some to invasive fungal infections in others. Patients of any age may have defects in these pathways. The pathogenesis of some of these includes genes that disrupt the dectin-1 pathway. Dectin-1 is a surface lectin receptor that recognizes the β1-3 glucan of fungi; downstream mutations in *CARD9* impair the secretion of IL-17A, IL-17F, and IL-22, cytokines that are essential in fungal clearance.[17]

A separate and unique category of innate defects are the cytokine/receptor mutations that impair the functions of cytokines IL-12, IL-23, and IFN-γ, which are needed for control of mycobacterial and other intracellular infections, such as salmonella. Chronic mycobacterial infections may also occur in patients with autosomal recessive mutations in the gene for signal transducer and activator of transcription 1 (*STAT1*), a gene downstream of both IFN-γ and IFN-α receptors. However, as the functions of both cytokines are impaired, these patients may also have severe viral or fungal infections. On the other hand, dominant (activating) mutations in *STAT1* may lead to simple cutaneous candidiasis or more complex clinical outcomes in others. More complex is the syndrome of GATA2 deficiency, in which mycobacterial disease may also develop, but other organisms (papillomaviruses, fungi) and serious complications (cytopenias, myelodysplasia, pulmonary alveolar proteinosis, peripheral edema) may be foremost. Whereas *GATA2* defects are dominantly inherited, members of the same family with the same mutations may have very different clinical manifestations.

DIAGNOSIS

The diagnosis of innate defects is first based on exclusion of other causes and then confirmed by genetic testing. The family history may be helpful, but for patients with mutations in *STAT1* or *GATA2*, although dominant inheritance is likely, the extreme range of clinical phenotypes may obscure easy recognition.

TREATMENT AND PROGNOSIS

Rx

The treatment of innate defects includes antimicrobial therapy to clear active infections and, probably, relevant prophylactic therapy on an ongoing basis. For the more severe defects, HSCT is required.

REVIEW QUESTIONS

1. A 30-year-old man has had episodes of chronic diarrhea for several years. He is thin and has had a 10-pound weight loss during the previous year. He has had an extensive gastrointestinal evaluation for Crohn disease, but the biopsies were inconclusive; however, villous blunting and a lack of plasma cells were noted in the intestinal mucosa. Which of the following might be appropriate?

A. Test for anti-endomysial antibodies.
B. Treat with steroid.
C. Test for serum IgG, IgA, and Ig.
D. Test for stool parasite.
E. Order computed tomography of the abdomen with contrast enhancement.

Answer: C Loss of plasma cells in the gastrointestinal mucosa is a signal that there is a profound lack of B-cell development. This is a characteristic in common variable immune deficiency in general in those with or without gastrointestinal disease and would be expected to be associated with low serum levels of IgG, IgA, and IgM. Whereas celiac disease, for which testing for anti-endomysial antibodies would be sensitive and specific, is also characterized by villous atrophy, intestinal biopsy in this disease demonstrates increased lymphocyte and plasma cell infiltration, not absence of plasma cells.

2. A 64-year-old man goes to an allergist with chronic sinusitis for 3 years but no other significant illnesses aside from onychomycosis of several fingernails. Skin test results for allergy to aeroallergens are negative, and the allergist tests quantitative immunoglobulins. These show an IgG level of 160 mg/dL (normal, 700 to 1600 mg/dL), IgA level of 7 mg/dL (normal, 40 to 250 mg/dL), and IgM level of 12 mg/dL (normal, 50 to 300 mg/dL). Which of the following is the next step?

A. Give an antifungal cream.
B. Test serum Ig.
C. Culture the sinuses.
D. Order computed tomography of the chest.
E. Request a bone marrow examination.

Answer: D This is likely to be Good syndrome, thymoma with hypogammaglobulinemia (or agammaglobulinemia). The main characteristics are the later onset and the observation of nail fungus. For diagnosis of this syndrome, computed tomography (or magnetic resonance imaging) of the chest is needed. The loss of antibody will require immunoglobulin replacement.

3. A 21-year-old woman comes to the emergency department with 4 days of chest pain, some blood-stained sputum, and a low-grade fever for 2 days. Her medical history includes severe eczema since infancy, an abscess on her buttock that required in-hospital surgical drainage, and a wrist fracture on closing a file cabinet. Aside from the fairly severe eczema, she does not appear ill; her white blood cell count is 9400 with 70% neutrophils and 10% eosinophils. Which of the following is the next step?

A. It is likely a viral syndrome and she can be discharged.
B. Give her a prescription for an antibiotic for 5 days
C. Get a chest radiograph.
D. Treat the eczema more aggressively.
E. Evaluate her for asthma with pulmonary function tests.

Answer: C With the clinical history, this may be hyperimmunoglobulin E syndrome (HIES). Pneumonias in HIES often lead to fewer clinical signals of toxicity; her past history of eczema since infancy, a significant abscess requiring drainage, and a fracture with minimal trauma suggest this diagnosis. A white blood cell count may not show neutrophilia, but eosinophilia is common. She needs a chest radiograph and, if it is abnormal, computed tomography to demonstrate the infection. At least 80% of HIES patients have had one or more pneumonias, often with mild symptoms; these lead to cysts and lung cavities.

4. A 29-year-old software designer was referred for evaluation of hypogammaglobulinemia. Recent evaluation for an enlarged spleen had revealed low serum levels of all immunoglobulins, including an IgG level of 251 mg/dL, IgA level 10 mg/dL, and IgM level 39 mg/dL. At the age of 15 years, he was febrile, anemic, and thrombocytopenic and developed splenomegaly and lymphadenopathy. He had a bone marrow that showed normal hematopoiesis, but the stain for Epstein-Barr virus (EBV)–encoded RNA (EBER) was positive. He was diagnosed with mononucleosis and recovered. His complete blood count is normal. Which of the following should be considered?

A. HIV test
B. Bone marrow examination
C. Monospot
D. Protein loss in the intestinal tract
E. X-linked lymphoproliferative disease

Answer: E The X-linked proliferative disorder (XLP), due to mutations of the X-linked gene *SAP*, leads to a significant infection with EBV with lymphoproliferation, progressive but variable hypogammaglobulinemia, and, in some, lymphoma. This is the most common genetic disease leading to loss of control of EBV.

5. JF is a 27-year-old man who is referred because of the possibility of food allergy. For the past 5 years, he has had recurrent episodes of abdominal pain with nausea and vomiting and has concluded that he must be allergic to a common food ingredient. On one occasion, he had such severe abdominal pain that he went to the emergency department, where acute food poisoning and appendicitis were excluded. His father had a long history of "colitis" with intermittent abdominal pain and diarrhea. Which of the following tests might be helpful?

A. Serum tryptase
B. Serum C4
C. Total hemolytic complement
D. Computed tomography of abdomen with contrast enhancement
E. Serum Ig

Answer: B With the severity of the pain and family history of a first-degree relative with an unexplained but somewhat similar abdominal pain, a C1 inhibitor defect is possible. The abdominal pain may be due to angioedema of the intestine. The best screening test would be serum C4, and if the level is low, one would proceed to test the C1 inhibitor protein and function.

251 ALLERGIC RHINITIS AND CHRONIC SINUSITIS

LARRY BORISH

ALLERGIC RHINITIS

Allergic rhinitis (AR) refers to the nasal and ocular symptoms that result from an inflammatory hypersensitivity reaction to aeroallergens deposited on the nasal mucosa and conjunctiva.

EPIDEMIOLOGY

AR, the most common chronic disease in the United States, affects between 10 and 30% of adults and up to 40% of children. Each year, nearly 80 million people in the United States experience 7 days or more of nasal or ocular

symptoms as a result of AR. Although it is not a severe disorder, the socioeconomic costs of AR are substantial. AR is one of the chief reasons for visiting a primary care physician; it adversely affects work productivity and school performance, and it limits socialization. The impact of AR also reflects its association with a variety of comorbid conditions, including asthma (Chapter 87), acute and chronic sinusitis, nasal polyposis, secretory otitis media, and sleep disorders. Adequately addressing AR requires a thorough understanding of its pathophysiology, its relation to these comorbid conditions, and the effects of various therapeutic options on AR and its associated comorbidities.

PATHOBIOLOGY

Airborne Allergens

Allergic respiratory diseases result from a hypersensitivity immune reaction to airborne allergens. These include the pollens and molds that are responsible for seasonal AR (SAR) and the indoor allergens, such as dust mites, indoor molds, and animal proteins, that are responsible for perennial AR (PAR) (Table 251-1).

In any area, the specific pollens that are likely to cause symptoms can be predicted from the number of days a pollen is airborne in large numbers. All these pollens use a wind-borne mechanism to achieve fertilization. Insect-borne pollens, specifically those produced by flowers, are not significantly airborne and therefore are not inhaled in sufficient concentrations to generate immune responses. In the United States, grass pollens (May to June) and ragweed (mid-August to October) are the most important causes of SAR. Tree pollens vary locally but typically start in late February and continue through April. The major trees implicated in allergy include birch in the North, oak in the mid-Atlantic region, live oak in the South, and mountain cedar in the Southwest. In addition to pollens, outdoor molds, particularly *Alternaria* and *Cladosporium*, can produce symptoms. These molds have variable seasons, depending on the weather; high levels of airborne fungi may be common at any time between March and October. In recent years, climate change has influenced both the length and the region of pollen seasons.

TABLE 251-1 ALLERGENS CAUSING ALLERGIC RHINITIS

COMMON NAME	SEASON
SEASONAL ALLERGENS	
Trees	
Birch	March–May
Cottonwood	April–May
Elm	February–May
Cedar	March–May
Oak	May–June
Maple	March–May
Grasses	
Kentucky blue	Mid-May–June
Timothy	Mid-May–June
Orchard	Mid-May–June
Sweet vernal	Mid-May–June
Fescue	Mid-May–June
Bermuda	Mid-May–June
Weeds	
Ragweed	August–September
Kochia	July–September
Russian thistle	July–September
Sage	July–September
Marsh elder	July–September
English plantain	July–September
Outdoor Molds	
Alternaria	Spring–fall
Cladosporium	Spring–fall
PERENNIAL ALLERGENS	
Household Allergens	
Cockroaches (German and American)	
Dust mites: *Dermatophagoides farinae, D. pteronyssinus, Blomia tropicalis*	More active in summer and humid months
Other insects (spiders, ladybugs)	
Animals	
Cats	
Dogs	
Other pets (guinea pigs, ferrets, hamsters, horses)	
Rodents	
Indoor Molds	
Aspergillus	
Cladosporium	
Penicillium	

PAR may occur year-round, but the term is applied to any rhinitis that does not have a clearly defined seasonal association. The most common causes include (1) indoor fungi, which are related to periods of high indoor humidity; (2) animal danders, particularly cats, but rodents (mice, rats, guinea pigs, ferrets, hamsters), rabbits, dogs, and birds may also be significant; (3) dust mites of the genus *Dermatophagoides*, which grow in bedding and pillows and are semiseasonal, with maximal levels from August to December; and (4) other insects (the best studied is the cockroach, but gypsy moths, crickets, ladybugs, spiders, and beetles may be locally important). Dust mites and cats produce the most important indoor allergens. Dust mites grow well only with a relative humidity higher than 50%. Dust mite allergy is probably relevant in all areas with more than 6 humid months in the year.

Immunoglobulin E, Mast Cell, and Basophil Activation

The traditional view is that AR is caused by the triggering of mast cell degranulation resulting from the cross-linking of surface-bound immunoglobulin (Ig) E molecules by the aeroallergen. As with all antibody-mediated immune responses, the initial exposure to the antigen results in B-lymphocyte secretion of low-affinity IgM antibodies. Subsequent exposure to the allergen in genetically predisposed subjects leads to a secondary immune response characterized by the isotype switch to IgE. The specific mechanisms underlying isotype switching to IgE are controversial, including the exact location where this occurs and the extent to which this requires an IgG intermediate. Similarly, the relative production of IgE-producing long-lived B cells or plasma cells is very poorly understood, although experience with bee stings and drug allergy suggests ongoing IgE synthesis for up to 10 years after an isolated allergenic exposure.[1] The resulting release of IgE antibodies into the circulation does not cause allergic symptoms; only after these IgE antibodies bind to their high-affinity receptors on basophils and mast cells do symptoms develop with subsequent allergen exposure. It takes the cross-linking of approximately 300 IgE receptors and cells to stimulate degranulation; therefore, and with the large number of mast cells scattered through virtually all tissues, it often requires several allergy seasons before sufficient numbers of allergen-specific IgE molecules are present on the surface of a given mast cell to drive its degranulation. This means that the development of symptomatic AR is a protracted process, generally requiring at least three or four exposures. As a result, SAR is generally not observed in children until they are approximately 4 years of age. Similarly, in adults, symptomatic responses to local allergens may not develop until approximately 4 years after moving to a region. PAR, however, can develop much faster.

Within minutes of allergen exposure, IgE-sensitized mast cells degranulate and release preformed and newly synthesized mediators, including histamine, proteases (tryptase and chymase), cysteinyl leukotrienes, prostaglandins, platelet-activating factor, and cytokines. Some of these mediators produce the characteristic early-phase symptoms of AR, namely, sneezing, pruritus, rhinorrhea, and, to some extent, congestion. Other mediators stimulate infiltration of the nasal mucosa with inflammatory cells, including basophils, eosinophils, neutrophils, additional mast cells, and mononuclear cells. This infiltration of inflammatory cells and their subsequent release of a secondary wave of mediators sustain the inflammatory reaction and produce the late-phase response of AR. This slowly developing inflammatory response is characterized primarily by nasal congestion. The inflammation that develops during the course of an allergy season is associated with an approximately 10-fold increase in the number of mast cells present in nasal epithelial and submucosal tissue. This reflects the migration of preexisting mast cells into the epithelium and the differentiation and influx of newly synthesized mast cells under the influence of cytokine growth factors. During the course of chronic allergen stimulation, these mast cells also display increased *priming*, which reflects increases in the number of IgE receptors and surface-bound IgE as well as enhancement of signal transduction pathways. As a result, as the allergen season progresses, less and less allergen (engagement of fewer and fewer IgE receptors) is required to trigger mast cell degranulation.

Antigen-Presenting Cell and Helper T-Lymphocyte Activation

In addition to their interaction with mast cells, allergens behave like any other foreign antigen and are processed and presented by antigen-presenting cells

to helper T (T_H) lymphocytes. Activation of these antigen-presenting cells, including mononuclear phagocytic cells, B lymphocytes, and especially dendritic cells, is an important source of cytokines, especially those associated with innate immunity, such as interleukin (IL)–1, IL-6, and tumor necrosis factor-α (TNF-α). Recent understanding of the molecular mimicry of allergens has increasingly expanded our understanding of the role of pathogen-associated molecular patterns receptors in dendritic cell activation, such as the engagement of toll-like receptor 4 by *Dermatophagoides* and similarly engagement of the lectin receptor dectin-2 by *Aspergillus*.[2] Engagement of these receptors promotes an inflammatory response to these otherwise innocuous inhaled particles. With the ensuing development of allergic inflammation, there is an increased presence of B cells expressing allergen-specific surface immunoglobulin and dendritic cells expressing surface-bound IgE. These antibodies can function as receptors that "capture" allergen and increase these cells' effectiveness in antigen processing. The newly activated T lymphocytes tend to resemble T_H2 cells, characterized by the production of IL-4, IL-5, IL-9, IL-13, and granulocyte-macrophage colony-stimulating factor (GM-CSF). These cytokines are also major components of the inflammatory response in AR and contribute to the increased production, recruitment, and activation of eosinophils, mast cells, and basophils. A milieu rich in IL-4 and IL-13 drives the IgE isotype switch and contributes to the further production of allergen-specific IgE. IL-13 also drives the metaplastic differentiation of nasal epithelial cells into goblet cells that are characterized not only by production of mucus but, importantly, also by chemokines such as CCL5, CCL11, CCL24, and CCL26 that further mediate basophil and eosinophil chemotaxis.

Innate Lymphoid Type 2 Cells as Additional Sources of Type 2 Signature Cytokines

An additional cell type, the type 2 innate lymphoid cell (ILC2), having features of NK cells and sharing with the NK cell the absence of a T-cell receptor, has recently been defined and distinguished by its secretion of preformed IL-5 and IL-13.[3] ILC2s can be activated through several pathways, but it is increasingly appreciated that nasal epithelial cells themselves respond to allergens to secrete two cytokines, IL-25 and IL-33, that are central to this process. This cellular mechanism defines a pathway linking allergen engagement of receptors on epithelium that drives their secretion of IL-25 and IL-33, leading in turn to an allergic inflammatory milieu driven by ILC2–derived IL-5 and IL-13. This provides a parallel pathway for development of allergen-induced inflammation that does not require engagement of the adaptive immune system (i.e., allergen-specific IgE or allergen-targeting T effector cells).

Through these mechanisms, during the seasonal course of allergen exposure, rhinitis evolves and becomes more dependent on mediators associated with the infiltration of eosinophils, basophils, neutrophils, mononuclear cells, and T_H lymphocytes as well as the increasingly primed mast cells. The symptoms of acute rhinitis, such as sneezing, itching, and rhinorrhea, largely reflect vasoactive mediator release, especially histamine. As SAR or PAR persists, however, these infiltrating cells continue to produce cytokines and other inflammatory mediators, leading to mucus hypersecretion, tissue edema, goblet cell hyperplasia, and tissue damage that become the primary sources of allergy patients' symptoms. As the role of histamine diminishes with AR progression (discussed later), antihistamines become less and less effective.

Eosinophils represent an important component of the inflammation that develops in AR. Eosinophils release a wide variety of proinflammatory mediators, including cysteinyl leukotrienes (leukotrienes C4, D4, and E4), eosinophil cationic protein, eosinophil peroxidase, major basic protein, IL-3, IL-4, interferon-γ, GM-CSF, and platelet-activating factor. Eosinophil-derived mediators are major components of the chronic allergic response and produce many of the symptoms of AR, especially nasal congestion. The natural history of AR is for symptoms to worsen inexorably during several weeks in the presence of ongoing allergen exposure. Symptoms often do not peak until well after the peak in pollen counts, and then they persist after pollen counts have declined. These observations reflect the time frame of the onset of nasal inflammation and tissue damage. The influx of eosinophils into the nasal mucosa correlates with the development and progression of symptoms. In summary, the natural history of AR represents an evolution from an acute, primarily mast cell–mediated process that is responsive to antihistamines to a chronic inflammatory process that is primarily eosinophil mediated and is much less responsive to antihistamines.

CLINICAL MANIFESTATIONS

The diagnosis of AR is based on a history of sneezing, which is often paroxysmal; rhinorrhea with clear, watery secretions; nasal congestion; and itching in the nares and palate. These symptoms are generally associated with allergic conjunctivitis manifested by ocular itching, lacrimation, and conjunctival injection. Severe conjunctivitis is less common in PAR than in SAR. The best explanation for this difference is that pollen grains affect the eyes when they are blown into them. With the exception of cat-derived allergens, which have a strong tendency to remain airborne, indoor allergens including those derived from dog and dust mites are less likely to be blown into the eyes because these allergens are on heavy particles that do not remain airborne. Instead, these indoor aeroallergens are drawn into the nose by breathing.

What is less well appreciated—in the literature but certainly not in AR sufferers—is that AR is a systemic disease associated with circulating activated T lymphocytes and mononuclear phagocytic cells. The activation of these cells is demonstrated by their production of cytokines associated with innate immunity, such as IL-1, TNF-α, and IL-6. These cytokines are responsible for the lethargy, fatigue, arthralgias, myalgias, and cognitive impairment that frequently accompany AR. These systemic symptoms, which are often the chief complaints of allergy sufferers, contribute to a diminished quality of life and are often severe enough to make normal activities difficult, including work or school.[4] Although fever is not a feature of AR, it is intriguing that the lay term for this condition is *hay fever*, a designation reflecting the pronounced influenza-like nature of this disease.

DIAGNOSIS

AR is primarily a clinical diagnosis based on symptoms and exposure history. It is a complex genetic disorder, and affected patients generally give a positive family history. Vasoactive mediators induce glandular secretions and vascular leakage along with engorgement of capacitance nasal venous sinusoids. Physical examination therefore reveals the nasal mucosa to be cyanotic and swollen, with clear secretions. Smears of nasal secretions (Hansel stains) are seldom required, but when they are performed, they typically reveal eosinophils.

The diagnosis of AR is confirmed by the demonstration of specific IgE antibodies reactive to the relevant allergen through either positive allergy skin test responses or IgE immunoassays (Video 251-1). Identification of the specific triggering allergen is essential for the institution of appropriate environmental controls. Prick skin testing is safe, specific, and rapid, and it is the diagnostic test of choice for identifying relevant allergens. A positive intradermal test response in the presence of a negative prick skin test response is often a false-positive result. Intradermal testing is therefore rarely indicated and is associated with potentially life-threatening systemic reactions. If prick skin testing is not available or if the test cannot be performed (e.g., in patients with eczema or dermatographism or in those using antihistamines or antipsychotic agents), IgE immunoassays are an appropriate alternative. As with prick skin tests, positive IgE immunoassays correlate with symptoms caused by natural exposure, establish the diagnosis of AR, and can form the basis for environmental therapy; these assays should therefore be used extensively by primary care physicians who manage patients with AR. However, a negative IgE immunoassay with a strong clinical suspicion suggests the need for referral.

Differential Diagnosis

Other causes of rhinitis are shown in Table 251-2. The approach to patients with sneezing and rhinorrhea is illustrated in Figure 251-1.

Viral rhinitis may be difficult to distinguish from SAR. Viral rhinitis is not associated with the release of mast cell mediators. The main mediators present in nasal secretions from patients with the common cold are kinins; histamine and cysteinyl leukotrienes are less prevalent. In contrast to the pervasive eosinophilia in AR, infectious rhinitis is defined by the presence of polymorphonuclear leukocytes, reflecting in large part the secretion of IL-8 by infected epithelium. The presence of these different mediators is in keeping with the observation that pruritus, paroxysmal sneezing, and clear secretions help distinguish SAR from viral rhinitis, along with the distinct recurrent, seasonal nature of SAR. Viral rhinitis produces thicker, purulent secretions, with neutrophils present on the nasal smear. Conjunctival symptoms are less pronounced, and on physical examination, the nasal mucosa is erythematous and swollen.

Hormonal influences that may produce chronic nasal congestion and rhinorrhea include hypothyroidism, birth control pill use, pregnancy, and menopause. Abuse of topical nasal decongestants (e.g., oxymetazoline), with chronic reflex vasodilation, has historically been the most common cause of rhinitis medicamentosa; however, cocaine and nasal narcotic abuse is another frequent cause of this condition. Chronic unilateral nasal blockage suggests an anatomic defect, typically a deviated or fractured septum, but such

blockage can also result from polyps, foreign bodies, and tumors, which can be malignant. This history necessitates referral for rhinoscopy (Video 251-2) and possibly computed tomography (CT) of the nose and sinuses. Nasal septum deviation is an unlikely cause of bilateral nasal congestion, and surgical therapy has little role in the treatment of rhinitis that is producing symptomatic congestion.

TABLE 251-2 DIFFERENTIAL DIAGNOSIS OF RHINITIS

ALLERGIC
Seasonal allergic rhinitis (SAR)
Perennial allergic rhinitis (PAR)
INFLAMMATORY
Infectious rhinitis (viral)
Nonallergic rhinitis with eosinophilia syndrome (NARES)
Chronic sinusitis with or without nasal polyposis
Laryngopharyngeal reflux
HORMONAL
Pregnancy, oral contraceptives, perimenopause
Hypothyroidism
Hyperthyroidism
RHINITIS MEDICAMENTOSA
Topical or, less commonly, oral decongestants
Antihypertensives
Antidepressants
Cocaine
VASOMOTOR
Irritant induced (pollution, cigarette smoke)
Cold air induced
Gustatory (food induced)
ANATOMIC
Nasal septal deviation
Tumor, neoplasm
Foreign body
Cerebrospinal fluid leak
Atrophic (postsurgical or trauma)

An abnormal neurogenic response to irritants (e.g., cold air, pollutants, cigarette smoke, strong odors, alcohol, foods) is the predominant feature of vasomotor rhinitis. This disorder is characterized by nasal autonomic nerve dysfunction. Patients with vasomotor rhinitis typically have chronic nasal congestion and posterior pharyngeal drainage, but they lack the paroxysmal sneezing, rhinorrhea, pruritus, conjunctivitis, and systemic complaints typical of patients with AR. In addition, eosinophils are absent in their nasal mucus. Topical antihistamines (nasal azelastine, olopatadine) are often effective in vasomotor rhinitis. Patients with this condition also respond to therapy with topical corticosteroids but also to atropine (nasal ipratropium).

An increasingly recognized cause of perennial nasal congestion and posterior pharyngeal drainage that often occurs in association with cough and hoarseness can be ascribed to laryngopharyngeal reflux. These patients are often otherwise asymptomatic from ("silent") gastroesophageal reflux, making recognition challenging. Intra-arytenoid erythema on laryngoscopy is traditionally ascribed to reflux; however, the specificity of this finding has never been determined, and other causes of chronic cough may produce identical findings. Because symptoms may not resolve until after several months of aggressive reflux treatment and because proton pump inhibitors by themselves may not prevent reflux of digestive enzymes (e.g., pepsin) or other stomach-derived irritants, proper diagnosis can be daunting. More recent techniques, including esophageal impedance testing and laryngeal smears for pepsin, are promising diagnostic advances.

Chronic sinusitis (see next section) with or without nasal polyposis can produce a spectrum of symptoms, including rhinorrhea, mucopurulent posterior pharyngeal drainage, and nasal congestion, that can be mistaken for PAR. However, chronic sinusitis, particularly when it is eosinophilic (discussed later), is often asymptomatic, and a reduced or absent sense of smell may be the only complaint. In contrast to acute (infectious) sinusitis, headaches are an unusual manifestation of either perennial rhinitis (allergic or nonallergic) or chronic sinusitis, and virtually all patients who complain of "sinus headaches" suffer from atypical migraines or other headache syndromes.[5] Atypical migraines routinely produce headaches that occur in a bilateral distribution involving the maxillary or ophthalmic branches of the

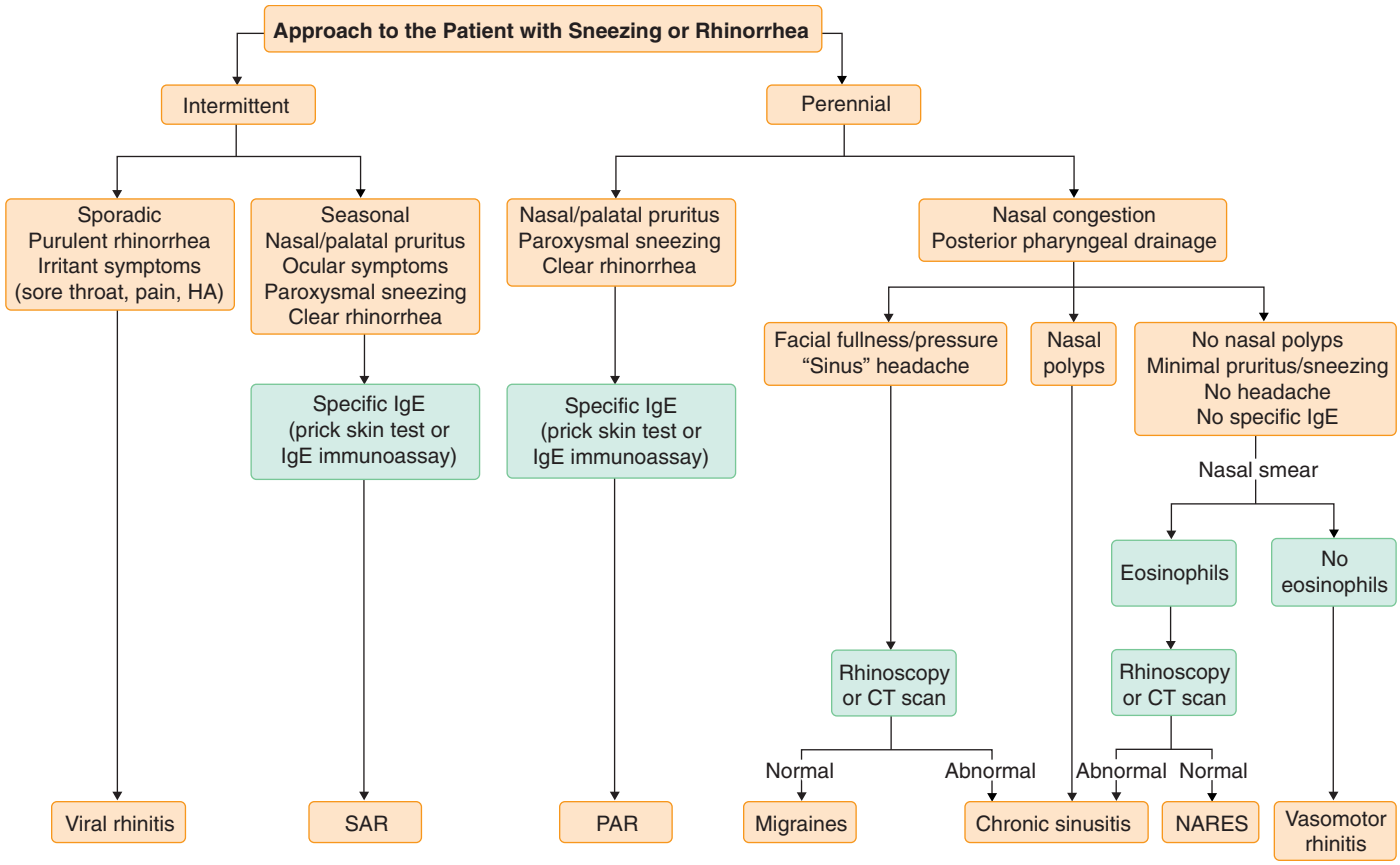

FIGURE 251-1. Approach to the patient with rhinitis symptoms. CT = computed tomography; HA = headache; IgE = immunoglobulin E; NARES = nonallergic rhinitis with eosinophilia syndrome; PAR = perennial allergic rhinitis; SAR = seasonal allergic rhinitis.

trigeminal nerve; this distribution, especially when it is combined with vasomotor symptoms such as nasal congestion, rhinorrhea, and conjunctival injection, often leads to misdiagnosis as chronic sinusitis or rhinitis. This complex becomes even more confusing with the recognition that vasoactive mediators released in association with allergic (or nonallergic) rhinitis (e.g., histamine) can trigger migraines. Because of this overlap in symptoms among chronic sinusitis, perennial rhinitis, and atypical migraines and their synergistic influences on each other, objective evaluation with either CT or rhinoscopy is usually required to establish the diagnosis of chronic sinusitis.

Atrophic rhinitis is characterized by atrophy of the nasal epithelium and is associated with complaints of nasal congestion and a perceived bad odor. It is observed in elderly patients, but the most common cause is devascularization secondary to nasal surgery or trauma.

Finally, a nonallergic nasal disease characterized by prominent eosinophilic inflammation has been described and termed non-AR with eosinophilia syndrome (NARES). On further analysis, many of these patients prove to have chronic sinusitis and nasal polyps. Patients with NARES present with symptoms similar to those of vasomotor rhinitis. NARES is diagnosed by performing a nasal smear (Hansel stain) for eosinophils; however, a CT scan or rhinoscopy is required to rule out chronic sinusitis or nasal polyposis because these conditions may be minimally symptomatic. In contrast to vasomotor rhinitis, NARES is more responsive to intranasal cromolyn and intranasal corticosteroids.

CHRONIC SINUSITIS

Chronic sinusitis represents many disease processes, including those caused by chronic bacterial infections, cystic fibrosis, immotile cilia syndrome, immune deficiencies, nonspecific inflammation, hypersensitivity to colonized fungi (allergic fungal sinusitis), aspirin-exacerbated respiratory disease (Samter's triad), and a disorder termed chronic hyperplastic eosinophilic sinusitis (CHES) (Table 251-3).[6] In the absence of immunodeficiency or cystic fibrosis, infection is a *very* unusual cause of chronic sinusitis. Noneosinophilic forms of chronic sinusitis most often reflect congenital anatomic variants or acquired nasal disorders (e.g., allergic rhinitis) that lead to ostial occlusion, with the secondary development of frequent, protracted acute infections. This ultimately produces tissue remodeling within the sinuses (with or, more often, without nasal polyps). These patients typically respond to surgical interventions that address the underlying anatomic precipitant.

TABLE 251-3 HETEROGENEITY OF CHRONIC SINUSITIS

PHENOTYPE	CHARACTERISTIC
Infectious	Very unusual as a cause of chronic sinusitis Occurs in association with cystic fibrosis, immune deficiency, ciliary dyskinesis
Inflammatory	Reflects remodeling secondary to frequent, recurrent acute sinusitis Develops secondary to anatomic obstruction of the sinus ostia; often resolves after surgical correction Pathologic examination demonstrates dense collagen fibrils, goblet cell metaplasia, and glandular hypertrophy and a chronic mononuclear infiltrate, with or without neutrophils Bacterial biofilms contribute to presence and severity Less often associated with nasal polyps
Hyperplastic eosinophilic	Prominent eosinophilic infiltrate with systemic eosinophilia Pathologic examination demonstrates edema, subbasement thickening Frequent association with allergies and asthma Usually associated with nasal polyps
Allergic fungal	Often unilateral; presents as expansive, dense infiltrate on CT scan Associated with elevated total IgE and specific IgE to colonizing fungi
Aspirin-exacerbated respiratory disease (Samter's triad)	Intense eosinophilic infiltrate Usually associated with nasal polyps and asthma Exacerbations of upper and lower respiratory disease (asthma) after ingestion of aspirin and nonselective COX1 inhibitors

COX1 = cyclooxygenase 1; CT = computed tomography; IgE = immunoglobulin E.

CHES, which more often occurs in association with nasal polyposis, is an inflammatory disorder characterized by the accumulation of eosinophils, fibroblasts, mast cells, other stromal cells, and T_H2-like lymphocytes along with goblet cell metaplasia and mucous gland hypertrophy. The prominent accumulation of eosinophils, however, is the diagnostic feature of this condition. The inflamed tissue expresses cytokines responsible for eosinophil hematopoiesis (IL-5), survival (IL-3, IL-5, and GM-CSF), recruitment (CCL11 [eotaxin]), and activation (CCL11, CCL5 [RANTES], IL-3, IL-4, IL-5, GM-CSF, and TNF-α). This histologic appearance and immune profile of CHES bears striking similarity to asthma. Indeed, approximately half of patients with CHES have asthma, and virtually all asthmatics have some component of CHES. Together, these observations suggest that CHES and asthma are similar diseases affecting the upper and lower portions of the airway (the "unified" airway concept). Whereas surgery may be a useful therapeutic adjuvant, as with asthma, treatment requires lifelong anti-inflammatory therapy. Therapies useful in asthma, such as topical corticosteroids and biotherapeutics that target IgE and IL-5, also appear useful in CHES.[7,8]

PREVENTION

Avoidance and Environmental Control

When it is feasible, avoidance or elimination of the source of the allergen is the treatment of choice for patients with AR. Avoidance studies in AR are limited, and the amount of allergen reduction needed to alleviate symptoms is unknown. Avoidance studies in asthma (Chapter 87) provide compelling evidence of a beneficial effect on bronchial hyperreactivity, symptom severity, and need for β-agonist rescue therapy.

Dust mite avoidance involves four principles: (1) remove reservoirs for mite growth (i.e., use allergen-impermeable mattress and pillow covers), (2) keep the relative humidity lower than 50%, (3) wash bedding in hot water (130° F) to kill mites, and (4) wear a simple mask when dust is being disturbed. Many of the measures suggested for mites are also helpful for fungi, especially dehumidification. Windows, shower curtains, and indoor plants are important sites for fungal growth and can be treated with mild fungicides (dilute household bleach).

In some houses, and particularly urban apartment blocks, large numbers of cockroaches are present, and IgE sensitivity is common. Although it may be difficult to kill cockroaches in an apartment, it is usually possible to keep a house clear of cockroaches by using chemical sprays and traps. Care must be taken in using chemical sprays because they can be an irritant to asthmatic patients.

Air-conditioning with closed windows is useful for reducing seasonal allergens, and the dehumidification provided by air-conditioning also mitigates the mite and indoor mold load.

Pets, especially cats, are the most preventable source of allergic diseases. Animal dander accumulates in houses during a prolonged period and takes many months to eliminate after the pet is removed. Although it is difficult to persuade patients to get rid of their animals, it may be possible to move the pet outside into the garage or to restrict the pet's access to certain parts of the house. Dogs kept outside and allowed into the house only occasionally do not appear to be an important cause of symptoms. Cat allergy is a much more serious problem because a single cat can deposit a huge concentration of allergen, and cat allergen remains airborne for prolonged periods. Cat owners, in turn, deposit sufficient concentrations of allergen in classrooms and work environments to induce symptoms in their allergic colleagues. The dominant rodent allergen is a urinary protein, and rodents, like cats, can deposit large quantities of allergen in a house.

TREATMENT

Rx

Although avoidance interventions can reduce allergen levels, they often fail to produce clinically significant improvement. As a result, pharmacotherapy is frequently required.

Antihistamines

Antihistamines are the oldest drugs used to treat AR and are considered first-line therapy. Antihistamines compete with histamine for the H_1-receptor sites that contribute to sneezing, itching, rhinorrhea, and conjunctivitis. Oral antihistamines ameliorate these symptoms of AR but generally do not improve nasal congestion. They also inhibit mast cell activation as manifested by diminished histamine, cysteinyl leukotrienes, and mast cell tryptase secretion. First-generation antihistamines cross the blood-brain barrier and have significant

sedative and anticholinergic effects. In addition to causing sleepiness, they interfere with school, work, driving, or use of machinery, and as such, the use of these drugs is no longer recommended. Second-generation antihistamines have a longer duration of action, do not cross the blood-brain barrier, and are nonsedating. These agents include cetirizine, levocetirizine, fexofenadine, descarboxyloratadine, and loratadine. Although less sedating than their parent compound hydroxyzine, cetirizine and levocetirizine may occasionally produce sedation. The intranasal antihistamines azelastine and olopatadine have a more rapid onset of action than oral antihistamines, and reflecting the high local concentrations they are able to achieve, they do have decongestant efficacy. They are also distinguished from oral antihistamines in being effective for nonallergic forms of rhinitis. No studies have convincingly demonstrated the superiority of one antihistamine over another.

As discussed earlier, the role of histamine diminishes during the course of an allergy season or with PAR, making antihistamines less effective. Antihistamines are effective for acute allergic reactions that are mediated predominantly by mast cell–derived histamine; as such, they are most beneficial in patients with intermittent allergen exposures, such as occasional outdoor exposure during pollen season. In patients with continuous allergen exposures, however, such as PAR caused by indoor allergens or after several days of continuous exposure to seasonal allergens, these drugs often prove to be little better than placebo.

Decongestants

Decongestants such as pseudoephedrine treat nasal stuffiness but are mild stimulants and even in oral formulations may produce rebound congestion and headaches. These drugs are usually used in combination with antihistamines to control the full spectrum of AR symptoms. Antihistamines and decongestants alone generally do not provide satisfactory relief in patients with moderate to severe AR.

Leukotriene Modifiers

Leukotriene modifiers (zileuton, zafirlukast, montelukast) have a confirmed efficacy in AR that is comparable to that of antihistamines but do significantly improve sneezing, rhinorrhea, nasal congestion, ocular symptoms, and quality of life in patients with both SAR and PAR. This efficacy reflects the presence and importance of these proinflammatory vasoactive mediators in AR.

Nasal Cromolyn

Nasal cromolyn stabilizes mast cells and mediates additional anti-inflammatory activities. Although it is not as effective as intranasal corticosteroids, cromolyn provides relief in patients with mild to moderate symptoms. The value of cromolyn is mitigated by the need for frequent doses (four times/day), a lack of efficacy in approximately 30 to 40% of recipients, and the superior efficacy of intranasal corticosteroids in controlled studies. Cromolyn may be especially useful preventively (e.g., immediately before cat exposure). Ocular cromolyn has been especially useful in the treatment of allergic conjunctivitis. No significant side effects are associated with its use.

Intranasal Corticosteroids

Intranasal corticosteroids (fluticasone [Flonase, Veramyst], beclomethasone [Qnasl], triamcinolone [Nasacort], flunisolide [Nasarel], budesonide [Rhinocort], mometasone [Nasonex], and ciclesonide [Omnaris]) are the most effective AR treatments and are considered the treatments of choice for patients with moderate to severe SAR or PAR.[A1] Comparative studies of antihistamines and intranasal corticosteroids consistently favor the corticosteroids.[A2] In well-performed placebo-controlled studies, intranasal corticosteroids provided a 50 to 90% reduction in symptoms (compared with 20 to 30% for antihistamines). In contrast to oral antihistamines, topical corticosteroids reduce nasal congestion in addition to relieving itching, rhinorrhea, sneezing, *and* allergic conjunctivitis.[9] Few studies have directly addressed the influence of corticosteroids on the systemic effects of AR—including missed work and school, poor productivity, reduced cognition, and fatigue—that are often the dominant complaints of patients with AR; however, intranasal corticosteroids significantly improve quality of life, reflecting relief from these complaints. Although they are slower in onset than antihistamines, intranasal corticosteroids produce some clinical improvement as quickly as 6 to 8 hours and achieve full effectiveness after several days.

Topical corticosteroid therapy does not inhibit IgE synthesis or mast cell degranulation, traditionally considered the two determinants for the development of AR. However, corticosteroids do inhibit T-lymphocyte proliferation, chemokine and cytokine production, recruitment of eosinophils and basophils, mucus secretion, vascular permeability, and mast cell proliferation. Intranasal corticosteroid use is therefore associated with diminished nasal eosinophilia, mast cell numbers, and cytokine expression. The efficacy of intranasal corticosteroids emphasizes the importance of these nonhistamine mechanisms to the pathophysiologic process of AR.

Several intranasal corticosteroid preparations are currently available and differ according to dose, approval age, and propellant (Table 251-4). No studies have demonstrated superior efficacy for any of the nasal corticosteroid preparations. Clinical experience with asthma (Chapter 87) suggests that patients refractory to one intranasal corticosteroid may be switched to a higher-potency corticosteroid; however, the best evidence is that all these agents are comparably valuable when patients are willing to comply with their use. Choices should be based primarily on the patient's preference.

TABLE 251-4 INTRANASAL CORTICOSTEROIDS*

GENERIC NAME	DOSE (PER ACTUATION)	MINIMUM APPROVED AGE	USUAL DOSING
Beclomethasone AQ	42 µg	6 yr	Twice daily
Beclomethasone HFA	80 µg	12 yr	Once daily
Flunisolide	25 µg	6 yr	Twice daily
Triamcinolone	55 µg	2 yr	Once daily
Budesonide	32 µg	6 yr	Twice daily
Fluticasone furoate	27.5 µg	2 yr	Once daily
Fluticasone propionate	50 µg	4 yr	Once daily
Mometasone	50 µg	2 yr	Once daily
Ciclesonide	50 µg	6 yr	Once daily
Ciclesonide HFA	37 µg	12 yr	Once daily

*Intranasal corticosteroids are generally administered at 2 sprays per nostril.

There is no convincing evidence of clinically significant systemic absorption or systemic side effects from intranasal corticosteroids. Given these drugs' hydrophobicity, local metabolism, and lack of absorption from lung tissue, clinically meaningful systemic absorption from the nasal passages is unlikely. Intranasal corticosteroids, even at greater than recommended doses, do not significantly suppress serum or urinary cortisol levels. There is a small but statistically significant effect on short-term growth velocity in children with PAR but minimal or no impact on ultimate adult height. Nasal corticosteroids cause minimal topical side effects, including local irritation, dryness, and epistaxis. Nasal perforation has been reported, but primarily in the setting of underlying devascularization (previous trauma, surgery, or cocaine abuse).

Immunotherapy

The clinical efficacy of subcutaneous immunotherapy for AR caused by grass, ragweed, many other pollens, cat and dog dander, and dust mites has been categorically established in innumerable well-designed, controlled studies.[10] Immunotherapy decreases the severity of AR, reduces the need for pharmacotherapy, and significantly improves quality of life. In patients with severe AR and conjunctivitis poorly controlled by antihistamines and intranasal corticosteroids, immunotherapy can reduce allergen sensitivity by more than 10-fold as well as significantly decrease total symptoms and reduce total antiallergic drug use. Efficacy depends on delivery of the correct antigen, regular injections for 3 to 5 years, and administration of an adequate dose of the allergen (10 to 15 µg, a dose much higher than that used historically).

Immunotherapy is indicated primarily in patients with refractory rhinitis or in those experiencing unacceptable side effects from standard medications. Because intranasal corticosteroids are not universally effective and do not provide complete relief in all patients, consideration of immunotherapy is necessary. In addition, despite the excellent safety profile of intranasal corticosteroids, many patients are reluctant to use them. Patients should normally go through at least one full pollen season before considering immunotherapy. Immunotherapy is the only treatment that produces long-term immune modulation. Both avoidance and pharmacotherapy are effective only if they are sustained. The effects of immunotherapy, in contrast, persist for many years after a 3- to 5-year course of treatment has been discontinued, and they could be lifelong. As such, a 5-year course of immunotherapy has cost advantages over lifelong pharmacotherapy. Many patients are attracted to immunotherapy by this potential for long-term immune modulation, remission of symptoms, and ability to discontinue daily pharmacotherapy.

Immunotherapy is associated with a small risk of fatal anaphylaxis (about 3 fatalities/year in the United States, of 2 million people receiving this form of treatment). Because of this risk, immunotherapy must be administered only in a facility where resuscitation equipment and trained personnel are available. Asthmatic patients are uniquely at risk for fatal anaphylaxis, so immunotherapy should be recommended with caution in these patients.

Because of the risk for anaphylaxis and the inconvenience of having to receive subcutaneous immunotherapy in a facility where evaluation and treatment of anaphylaxis are available, there is increasing enthusiasm for alternative forms of immunotherapy, specifically, sublingual immunotherapy. Sublingual immunotherapy has been extensively studied and proved to provide significant clinical benefit along with reduced need for pharmacologic therapy for numerous allergens including grass, ragweed, and dust mites.[A3-A6] In comparison to subcutaneous administration, sublingual immunotherapy is sufficiently

safe to permit home administration. As with subcutaneous immunotherapy, long-term clinical benefits are observed after it is discontinued, although recurrences are common after 5 to 10 years. Whereas few direct comparative studies have been performed, the preponderance of evidence suggests that subcutaneous immunotherapy does provide greater and longer lasting benefits.[11]

Summary

Many patients have multiple antigen sensitivities, and specific immunotherapy at effective doses may not be practical. Furthermore, immunotherapy has poor efficacy for many antigens, such as molds. These issues have led to a search for new immune-based therapies capable of attenuating allergic inflammation. Many experimental approaches being developed for asthma, including various anticytokine therapies, may have efficacy for AR.

In general, however, currently available therapies provide adequate relief for virtually all AR sufferers. The persistence of nasal symptoms in the face of adequate AR-directed pharmacotherapies should suggest the diagnosis of an alternative form of rhinitis (see Fig. 251-1) or the presence of sinusitis or—especially if headaches are present—atypical migraines and rebound headaches. Given the high frequency of AR in the population (and the even higher prevalence of allergic sensitization), treatment becomes particularly challenging when a patient presents with nonallergic nasal symptoms and either concomitant AR or clinically innocuous allergic sensitization (positive skin test responses or IgE immunoassays) occurring in the absence of actual AR.

REVIEW QUESTIONS

1. A patient presents with a chief complaint of recurrent, protracted headaches that occur bilaterally in a maxillary distribution and are associated with nasal congestion and ocular tearing. These episodes occur spontaneously throughout the year. The most common cause of this condition is

A. Allergic rhinitis
B. Chronic sinusitis
C. Migraine
D. Nasal polyps
E. Rebound headache

Answer: C The most common cause of "sinus" headache is migraine. Whereas acute sinusitis is often painful, chronic sinusitis is virtually never a source of pain. Migraines routinely occur in a maxillary distribution, are often bilateral, and often are inappropriately ascribed to sinusitis when they are associated with vasomotor symptoms such as nasal congestion and ocular tearing. Allergic rhinitis may trigger migraines and acute sinusitis but by itself would be an unusual cause of headaches. Nasal polyps do not produce pain. Rebound headaches most commonly occur in the setting of caffeine or short-acting nonsteroidal anti-inflammatory drugs.

2. A 55-year-old women presents with a chief complaint of continuous nasal congestion and posterior pharyngeal drainage. Symptoms are present year-round and interfere with her sleep and quality of life. Blood tests demonstrate specific IgE to cottonwood trees, *Alternaria*, and ragweed. The most likely explanation for this syndrome is

A. Allergic rhinitis
B. Chronic sinusitis
C. Atypical migraine
D. Nonallergic rhinitis
E. Nasal polyps

Answer: D Nonallergic rhinitis most often is manifested with the combination of nasal congestion and posterior pharyngeal drainage. The absence of typical allergy symptoms of paroxysmal sneezing, pruritus, clear anterior secretions, and concomitant allergic conjunctivitis argues against allergic rhinitis as a cause. Allergic sensitization (presence of specific IgE by blood or skin testing) is common, is often not associated with symptoms on natural exposure, and therefore should not by itself be used to diagnose an allergic disease. In addition, the absence of sensitization to perennial allergens that can explain a year-round syndrome rules out an allergic etiology in this case. Whereas chronic sinusitis (with or without associated nasal polyps) can produce similar symptoms, these patients typically have additional complaints, such as "pressure" or "fullness" in a sinus distribution and reduced sense of smell. Migraines are episodic and are usually associated with headaches.

3. A 21-year-old patient presents with allergic rhinitis each spring, lasting continuously from early March through the end of June, that is associated with numerous pollen sensitizations. The most effective therapeutic intervention for this patient would be

A. Oral antihistamines
B. Intranasal cromolyn
C. Intranasal corticosteroids
D. Leukotriene modifiers
E. Immunotherapy

Answer: C Intranasal corticosteroids are the most effective treatment for allergic rhinitis and are compellingly superior to antihistamines, leukotriene modifiers, and cromolyn in well-performed trials. Antihistamines are effective in mild intermittent disease, but once symptoms persist for more than a few days or weeks, they may prove little better than a placebo. Cromolyn and leukotriene modifiers are not as effective as corticosteroids. Immunotherapy may be effective, especially for grass pollen. It may be difficult to treat the patient for all of the pollinating trees present in her environment. In general, however, immunotherapy is reserved for patients who fail to respond to pharmacologic treatments.

4. A college student presents with a chief complaint of seasonal allergies that occur every year in late spring (May-June). Of the following, which is the most likely allergen explaining this history?

A. Birch pollen
B. Timothy grass pollen
C. Ragweed pollen
D. Dust mite (*Dermatophagoides pteronyssinus*)
E. *Alternaria*

Answer: B Early spring allergic rhinitis is triggered by trees. Grasses pollinate in late spring and are what is driving this patient's symptoms. Ragweed pollinates in late summer and autumn. *Alternaria* is an outdoor mold that is also particularly prevalent in the autumn. Whereas dust mites are often considered a perennial allergen, they are particularly active during periods of high humidity and as such often present as "seasonal" allergens with worse symptoms in the summer.

5. Left untreated, allergic rhinitis may contribute to the development of which of the following medical conditions?

A. Benign nasal tumors
B. Atypical migraines
C. Eosinophilic granuloma (Langerhans cell histiocytosis)
D. Eosinophilic esophagitis
E. Chronic inflammatory (noneosinophilic) sinusitis

Answer: E Chronic rhinitis of any cause, including allergic rhinitis, occludes the sinus ostia. This can lead to frequent, persistent sinus infections and ultimately the remodeling of sinus tissue that characterizes chronic inflammatory sinusitis. Chronic sinusitis may be associated with extrusion of sinus tissue into the nasal air space, a condition referred to as nasal polyps. However, neither chronic sinusitis nor persistent allergic rhinitis produces nasal tumors. Similarly, allergic rhinitis produces a local (nasal) eosinophilic inflammatory process but not either eosinophilic esophagitis or eosinophilic granuloma. Although allergic rhinitis may trigger a migraine, it is not a cause of headaches, atypical or otherwise.

URTICARIA AND ANGIOEDEMA

STEPHEN C. DRESKIN

URTICARIA

Urticaria (hives) consists of pruritic, edematous, erythematous, blanching papules that are round or oval; have pale, raised centers (wheals); are several millimeters to a few centimeters in size; and are transient, lasting minutes to days (Fig. 252-1). Angioedema appears as a brawny, nonpitting edema, typically without well-defined margins and without erythema. Angioedema can be accompanied by a sense of burning, pressure, or aching but not pruritus; it is distinguished from other edematous states by its frequent involvement of the lips, tongue, eyelids, hands, feet, or genitalia and its rare occurrence in dependent areas of the body. Episodes (daily or almost daily symptoms) of recurrent hives or angioedema during a period of less than 6 weeks are considered acute, and those lasting longer are said to be chronic. Patients typically present with urticaria alone or urticaria with angioedema. Rarely, patients present with angioedema alone, and this becomes a diagnostic dilemma because angioedema as an isolated finding may be due to activation of the kinin system or may be due to activation of mast cells (see later). The terms *urticaria* and *urticaria/angioedema* are used interchangeably here to refer to illnesses characterized by urticaria or angioedema in which mast cells are activated.

EPIDEMIOLOGY

Urticaria/angioedema occurs in 15 to 25% of individuals at some time during their lives and can affect both genders and all races. Acute urticaria is more common in young adults and children. Chronic urticaria is more common in adults, affecting women (75% of cases) more often than men.[1]

PATHOBIOLOGY

Mast cells, the primary effector cells in urticaria/angioedema, are found in high numbers throughout the body, particularly within the subcutaneous tissue. After activation of mast cells, there is a rapid (<10 minutes) release of histamine, leukotriene C_4, and prostaglandin D_2, leading to vasodilation, subcutaneous and intradermal leakage of plasma from postcapillary venules, and pruritus. In addition, there is the delayed (4 to 8 hours) production and secretion of inflammatory cytokines such as tumor necrosis factor-α, interleukin-4, and interleukin-5, leading to an inflammatory infiltrate and perpetuation of longer-lived lesions. Angioedema is formed by a similar extravasation of fluid, not superficially in the skin but in deeper dermal and subdermal sites.

Lesions of acute urticaria typically show subcutaneous edema with widened dermal papillae, swollen collagen fibers, and rare inflammatory cells. Most episodes of acute urticaria/angioedema are caused by immediate hypersensitivity reactions to drugs or foods or result from inflammatory processes initiated by viral illnesses. The most common drugs that cause acute urticaria/angioedema are penicillins, sulfonamides, muscle relaxants, diuretics, and nonsteroidal anti-inflammatory drugs (NSAIDs), although any drug acting as a hapten can generate an allergic response. The predominant allergenic foods are milk, eggs, and peanuts for children and peanuts, tree nuts, fish, and shellfish for adults, although sensitization can occur to many other foods as well. These allergens cross-link immunoglobulin (Ig) E bound to the high-affinity receptor for IgE (FcεRI), leading to activation of mast cells. Some drugs (e.g., opioids, vancomycin, NSAIDs) and radiocontrast dye can activate mast cells by an IgE-independent (pseudoallergic) mechanism. Ingestion of fish contaminated with bacteria that produce histamine leads to hives as part of a toxic reaction to the histamine (scombroid food poisoning).

Lesions of chronic urticaria are characterized by similar edematous findings, with the addition of a dense perivascular inflammatory infiltrate

consisting of $CD4^-$ and $CD8^+$ T lymphocytes, eosinophils, basophils, and neutrophils. A minority of patients exhibit urticarial vasculitis, with lesions characterized by vascular destruction with leukocytoclasis.

The largest subgroup of chronic urticaria/angioedema is idiopathic urticaria, accounting for approximately 70 to 80% of cases. Recently, an effort has been made to replace the term *chronic idiopathic urticaria* with the more descriptive term *chronic spontaneous urticaria*. These patients have symptoms in the absence of a specific physical trigger, allergen exposure, or coexistent disease. Half the patients with idiopathic urticaria have evidence of autoimmunity based on the presence of IgG antibodies that can cross-link FcεRI or antithyroid antibodies. Some experts consider these patients to have a separate entity called autoimmune urticaria, whereas others consider these patients to have idiopathic urticaria with evidence of autoimmunity.[2]

Physical stimuli activate mast cells by unknown mechanisms and account for about 20 to 30% of cases of chronic urticaria. The most common of the physical urticarias is dermographism (also called dermatographism), in which wheals can be "written on the skin" by simple stroking or scratching. Cholinergic urticaria is a physical urticaria in which the trigger leading to mast cell activation is related to cholinergic stimuli occurring after exposure to heat or after exercise. Other physical stimuli can cause urticaria, including cold, solar radiation, pressure, vibration, and water. Cold-induced urticaria is rarely caused by cryoglobulins. Cold-induced urticaria needs to be distinguished from the cryopyrin-associated periodic fever syndromes that include familial cold autoinflammatory syndrome and the Muckle-Wells syndrome (see later and Chapter 261).

In approximately 1-2% of patients with chronic urticaria/angioedema, symptoms appear to be caused by ingestants (e.g., foods, medications, dietary supplements), contactants (e.g., soaps, detergents, cosmetics, hair or nail products, latex), concomitant infections, hormonal changes, or systemic illnesses. A food must be consumed regularly to cause chronic urticaria. Wheat is rarely found to be a trigger. Multicellular parasites (e.g., those causing strongyloidiasis or filariasis) elicit strong IgE responses and are important causes of chronic urticaria in endemic areas. Rare patients report that their urticaria occurs only during menses or is worsened by menses. Although hormonal variation often is associated with worsening of urticaria, a detailed history may reveal ingestion of NSAIDs taken for uterine cramping. Chronic urticaria/angioedema can be associated with flares of rheumatic conditions, other autoimmune conditions (including Hashimoto thyroiditis), or neoplastic conditions. Occult neoplasia is exceedingly unlikely to be the cause of chronic urticaria.

TABLE 252-1 CLASSIFICATION OF URTICARIA AND ANGIOEDEMA

I. Acute urticaria/angioedema
  A. Hypersensitivity reactions
    1. Drug allergy
    2. Food allergy
    3. Insect allergy
  B. Idiopathic
  C. Pseudoallergic reactions
    1. Drugs
    2. Radiocontrast dye
  D. Toxic reactions
  E. Immune complex
    1. Serum sickness
    2. Transfusion related
    3. Postviral
II. Chronic urticaria/angioedema
  A. Idiopathic
    1. Autoantibody associated
      a. Anti-IgE receptor (FcεRI)
      b. Anti-IgE
      c. Antithyroid
      d. Other
    2. Not associated with autoantibodies
  B. Physical
    1. Dermographism
    2. Cholinergic
    3. Delayed pressure
    4. Solar
    5. Cold
    6. Vibratory
    7. Aquagenic
  C. Immune complex
    1. Urticarial vasculitis
    2. Collagen vascular disease associated
III. Urticaria pigmentosa and systemic mastocytosis
IV. Complement-related and kinin-mediated angioedema
  A. Hereditary angioedema
  B. Acquired angioedema
  C. Angiotensin-converting enzyme inhibitor–induced angioedema
  D. Renin inhibitor–induced angioedema
V. Urticaria pigmentosa and systemic mastocytosis

CLINICAL MANIFESTATIONS

Patients often report that the first sensation of urticaria is poorly localized pruritus that quickly develops into the typical lesions of urticaria. The intensity of the pruritus varies from a minor inconvenience to an unbearable sensation that can lead to self-inflicted abrasion of the skin. Groups of hives often appear together during a short period, and episodes of hives can come in waves starting several times a day. Patients with cholinergic urticaria usually have a distinctive clinical presentation of diffuse urticarial lesions measuring a few millimeters in diameter on exertion sufficient to cause sweating. The pruritus is particularly intense, and all the symptoms are generally limited to the skin. A self-rated quality-of-life survey of patients with chronic urticaria revealed dramatic impairment in terms of loss of sleep, fatigue, and emotional discomfort. Angioedema can originate near a wheal or independently in other parts of the body. Symptoms vary from minor discomfort to an intense sense of pressure and may lead to other symptoms, such as severe shortness of breath if there is compromise of the airway. Rarely, patients report angioedema beginning 4 to 6 hours after application of local pressure, and this is called delayed pressure urticaria. This is a debilitating condition that is often difficult to treat.

DIAGNOSIS

The first episode of acute urticaria/angioedema may occur in the absence of an identifiable stimulus. If hives occur 5 to 30 minutes after ingestion of a drug or a food, the patient often can identify the association. If a physician is consulted, the best approach is to take a careful history, with attention to ingestants and intercurrent illnesses. Unnecessary drugs and food supplements should be discontinued, and any recently added medication should be changed to a structurally different agent. Most often, no causative agent is identified, and the hives are treated symptomatically (see the later discussion) for days or weeks before they resolve spontaneously.

Differential Diagnosis

The differential diagnosis of chronic urticaria/angioedema includes the subgroups of urticaria discussed earlier: idiopathic, autoimmune, physical, ingestant mediated, and associated with a variety of systemic illnesses.[3] Other conditions that can be confused with chronic urticaria/angioedema include diffuse pruritus complicated by dermographism, flushing disorders, urticarial vasculitis, urticaria pigmentosa, systemic mastocytosis, exercise-induced anaphylaxis, exercise-induced food-associated anaphylaxis, idiopathic anaphylaxis, hereditary angioedema, acquired angioedema, and angioedema associated with angiotensin-converting enzyme (ACE) inhibitors (Table 252-1).

Approximately 95% of patients with urticaria/angioedema are not reacting to an ingestant and do not have another illness that is causing their hives. However, it is sometimes difficult for patients (and some physicians) to accept this fact, prompting an extensive, invasive, expensive, and unnecessary investigation. The best "test" to identify patients with a specific underlying cause (i.e., physical trigger, autoimmune condition, allergen, or systemic disease) is a careful and detailed history and physical examination by a specialist knowledgeable in urticarial disease.

A good place to begin is by excluding possible physical triggers. Specific tests are available to establish the diagnosis of most physical urticarias, including scratching the skin and exposing the skin to heat, ice, vibration, pressure, ultraviolet radiation, or water. Cold urticaria must be distinguished from cryopyrin-associated periodic fever syndromes that are characterized by a cold-induced papular rash (not urticaria) and are now classified in the family of hereditary periodic fever syndromes. Solar urticaria must be distinguished from other types of light sensitivity, including metabolic abnormalities (e.g., erythrogenic porphyria) and photosensitivity due to drugs.

Even though foods and drugs are infrequent causes of chronic urticaria, many patients focus on ingestants and are not satisfied until these causes are ruled out. As in the evaluation of acute urticaria, the patient should discontinue all food supplements and medications that are not absolutely necessary and, if possible, change essential medications to structurally unrelated compounds. The patient then keeps a food diary to identify suspect foods that can be eliminated. Some allergists use skin tests with foods to identify "suspects" (Chapter 249), but this approach is unproven. For highly motivated patients, 2 weeks of a severely restricted diet, often based on lamb and rice, is recommended. Antihistamines and other medications used to control the urticaria must be discontinued. If the urticaria resolves, it is critical to reintroduce foods in a controlled fashion to identify the specific food causing the urticaria and to reinstate a healthy diet.

Chronic infections, including sinus infection, dental abscess, *Helicobacter pylori* gastric infection, cholecystitis, onychomycosis, and tinea pedis, have been associated with urticaria. Case reports indicate the resolution of urticaria after treatment of these infections, although rigorous proof of an association is lacking. The natural history of chronic urticaria probably accounts for coincidental spontaneous improvement after treatment of these conditions, at least in some cases.

Laboratory evaluation in a patient with typical urticaria should always include a complete blood count with differential, basic metabolic panel, liver enzymes, and urinalysis. Specialists are not in full agreement about the necessity of additional laboratory testing. Levels of thyroid-stimulating hormone and antithyroid antibodies may be measured in otherwise euthyroid-appearing patients to screen for subclinical Hashimoto thyroiditis. Skin tests for immediate hypersensitivity to foods may be ordered for patients with a suggestive history. Some specialists order no screening tests at all. As in vitro tests for anti-FcεRI autoantibodies have become more widely available, some specialists will perform this test. A positive test response for anti-FcεRI autoantibodies is useful because this reassures the patient that the urticaria is being driven by an internal process and is not caused by an ingestant or occult illness. Other tests should be ordered only as a result of positive findings in the history and physical examination.[4]

Although it is not routinely indicated in every case of chronic urticaria, a skin biopsy can provide useful information. The most common indication for this procedure is to rule out urticarial vasculitis when the hives are more painful than pruritic, last longer than 24 hours, or leave discolored skin. The presence of vascular destruction, fibrinoid necrosis, and immune complex deposition on microscopic examination (including immunofluorescence) should lead to a consideration of the specific causes of urticarial vasculitis (e.g., systemic lupus erythematosus) and the rapid initiation of more aggressive treatment.

Primary mast cell disorders rarely manifest as chronic urticaria (Chapter 255). Systemic mastocytosis is a very rare condition characterized by increased numbers of atypical mast cells in the bone marrow, skin, and other organs. Levels of tryptase (an enzyme specific for mast cells) are usually elevated in the serum. This condition is frequently accompanied by episodic flushing, urticaria pigmentosa, prominent gastrointestinal symptoms, neuropsychiatric symptoms, or recurrent anaphylaxis. Urticaria pigmentosa is characterized by distinctive pigmented cutaneous lesions containing nests of mast cells and is not easily confused with urticaria/angioedema.

Hereditary angioedema, acquired angioedema, and angioedema associated with ACE inhibitors are discussed later in this chapter. Briefly, these syndromes are characterized by episodic swelling without urticaria and are best identified by a careful history, physical examination, and focused laboratory evaluation.[5] An approach to the evaluation and treatment of patients with urticaria or angioedema is summarized in Figure 252-2.

TREATMENT

Rx

Acute urticaria is usually self-limited and responds well to histamine$_1$ (H_1)–type antihistamines. Antihistamines work better if they are taken prophylactically rather than after histamine has been released and is bound to the receptor. Patients often self-medicate with or are prescribed diphenhydramine (25 to 50 mg every 6 hours) or hydroxyzine (25 to 50 mg every 6 hours), but they may experience significant sedation. Second-generation antihistamines such as cetirizine (10 mg nightly at bedtime), fexofenadine (180 mg/day), and loratadine (10 mg/day) are much better tolerated and can be effective, although doses up to four times the standard doses are sometimes necessary.

On occasion, a brief course of corticosteroids is warranted to control severe symptoms. Epinephrine (0.3 mL of 1:1000 intramuscularly) quickly (but transiently) reverses the signs and symptoms of urticaria and angioedema. Patients who have experienced potentially life-threatening angioedema or anaphylaxis should have ready access to self-injectable epinephrine and be knowledgeable about its indications, administration, and brief duration of action. β-Blockers not only can aggravate urticaria but also can interfere with the action of epinephrine. NSAIDs and codeine can lead to IgE-independent mast cell activation. These medications should be discontinued if it is clinically safe to do so.

H_1 antihistamines are also the cornerstone of therapy for chronic urticaria/angioedema but are frequently inadequate to control symptoms. Certain H_1 antihistamines have been proposed as "preferred" for particular subtypes of chronic urticaria, such as hydroxyzine (25 to 50 mg three to four times daily) for cholinergic urticaria or cyproheptadine (2 to 4 mg every 6 hours) for cold-induced urticaria. Some have advocated using multiple H_1 antihistamines, changing or "rotating" agents, or using them in dosages well above those approved by U.S. Food and Drug Administration (FDA) labeling procedures.[6]

Approximately 15% of histamine receptors in the skin are of the H_2 subtype; therefore, the addition of an H_2 antihistamine, such as ranitidine (150 mg twice daily) or famotidine (20 mg twice daily), is a logical adjunct to H_1 antihistamine therapy, providing additional clinical benefit. The tricyclic antidepressant doxepin (10 to 100 mg nightly at bedtime) has highly potent H_1 and H_2 antihistamine activity, with an H_1-receptor affinity almost 800 times that of diphenhydramine and an H_2-receptor affinity 6 times that of cimetidine, but its use can be limited by significant sedation and its tendency to stimulate the appetite, leading to significant gain of weight.

Symptoms often persist despite the use of maximal or supramaximal doses of antihistamines. This is not surprising, considering the number of vasoactive and pruritogenic mediators released by mast cells, of which histamine is only one. Antileukotriene medications, such as montelukast (10 mg/day) or zafirlukast (20 mg twice daily), can be added to antihistamines, with some success. Especially severe symptoms may require systemic corticosteroids (prednisone 10 to 60 mg/day) to achieve symptomatic control, but strong concerns about side effects limit their usefulness.

Refractory symptoms have been treated with a wide variety of other medications. Some of these medications (adrenergic agents, calcium-channel blockers) are thought to decrease the ability of mast cells to release mediators. Others drugs are anti-inflammatory (hydroxychloroquine, sulfasalazine, dapsone, colchicine), immunomodulatory (cyclosporine, tacrolimus, mycophenolate), or antimetabolic (azathioprine, cyclophosphamide, methotrexate). Other treatments of refractory autoimmune chronic urticaria include intravenous immune globulin, plasmapheresis, and omalizumab (anti-IgE).

Evidence-Based Treatments

Multiple randomized, placebo-controlled studies of chronic urticaria/angioedema have shown the efficacy of both sedating and nonsedating antihistamines.[7] If sedating antihistamines must be used, doxepin is more effective than diphenhydramine, but it must be titrated carefully to avoid significant sedation. H_2-receptor antagonists alone are ineffective, but a meta-analysis of four studies with a total of 144 subjects demonstrated that they are effective when combined with H_1-receptor antagonists. Prednisone is generally accepted as a mainstay of therapy in difficult cases but has not been formally studied. Cyclosporine (4 mg/kg/day) was shown to be effective in a randomized, placebo-controlled, parallel study of 30 patients with autoimmune urticaria.[8] Leukotriene C_4 receptor antagonists (montelukast, zafirlukast) do not provide any incremental benefit when added to an antihistamine. Omalizumab (a humanized monoclonal antibody that binds and inactivates IgE; 300 mg SQ every 4 weeks) has been shown to be effective in a large randomized placebo-controlled trial. Although well characterized by described in case studies and used by experts, sulfasalazine, hydroxychloroquine, dapsone, colchicine, methotrexate, azathioprine, and intravenous gamma globulin are immunomodulatory agents that appear to be effective but have not been formally studied.

PREVENTION

It is essential to encourage patients with chronic urticaria to accept the chronicity of their illness and to focus on achieving reasonable symptomatic control with effective treatments that cause the fewest side effects. Many patients with physical urticaria can learn to avoid or to minimize triggers. The few patients for whom chronic urticaria is a feature of systemic illness may find relief if the underlying condition is appropriately treated. An excellent example is that chronic urticaria in patients with clinically apparent thyroid disease often resolves once the thyroid disease is treated. For many patients, other factors that exacerbate their specific symptoms can be identified, including stress or anxiety, hormonal fluctuations, aspirin and other NSAIDs,

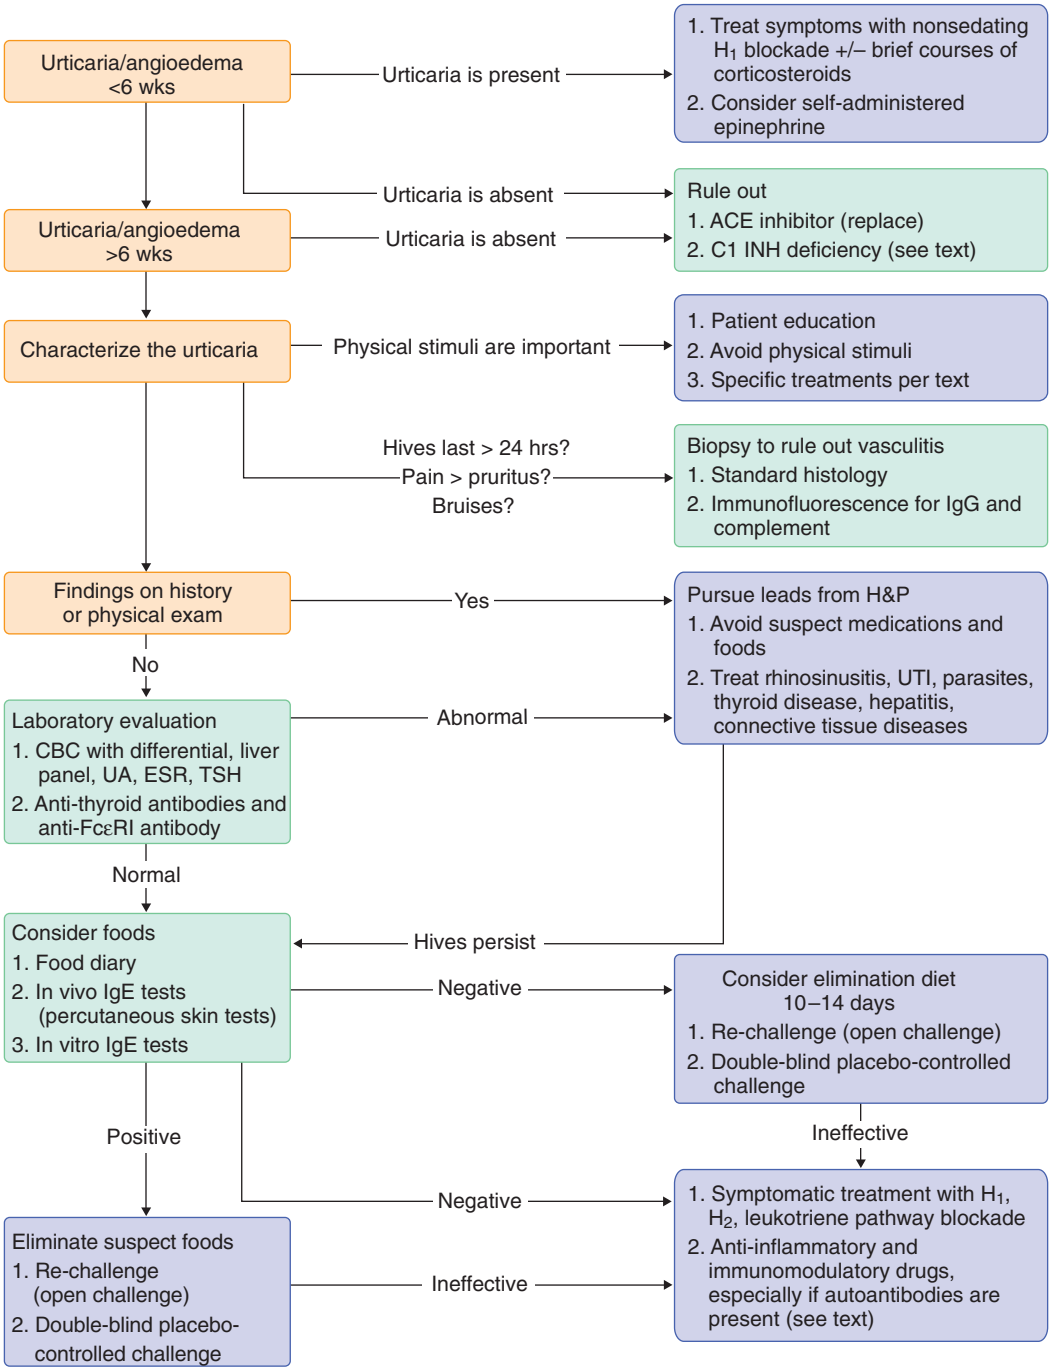

FIGURE 252-2. Evaluation and treatment of urticaria/angioedema. Treatment of urticaria with or without angioedema (AE) can be similar. However, treatment of AE without urticaria depends on the cause. If the AE is caused by an angiotensin-converting enzyme (ACE) inhibitor, discontinuation of the medication is required. Treatment of AE caused by a deficiency or dysfunction of C1 inhibitor (C1 INH) is discussed in the text. Idiopathic AE often responds to treatments described for urticaria/angioedema. CBC = complete blood count; ESR = erythrocyte sedimentation rate; FcεRI = high-affinity receptor for IgE; H & P = history and physical examination; H_1 = histamine$_1$-receptor antagonist; H_2 = histamine$_2$-receptor antagonist; IgE = immunoglobulin E; IgG = immunoglobulin G; TSH = thyroid-stimulating hormone; UA = urinalysis; UTI = urinary tract infection.

and agents that cause cutaneous vasodilation (e.g., alcohol, hot baths or showers, exercise, heated waterbeds). Psychosocial stress is a commonly reported trigger of worsening symptoms. A plausible biochemical mechanism may include increased release of cutaneous neuropeptides known to lower the threshold for mast cell degranulation.

PROGNOSIS

The prognosis for most patients with chronic urticaria/angioedema is excellent. Spontaneous resolution occurs within 12 months in 50% of patients and within 5 years in an additional 20%. However, 10 to 20% of patients, particularly those with physical or autoimmune urticaria, continue to have symptoms for as long as 20 years. Patients who had one episode of chronic urticaria that lasted for months or years and then resolved may experience one or more similar recurrences later in life.

FUTURE DIRECTIONS

The current trend in the treatment of urticaria/angioedema is to use multiple antihistamines and other agents that block the actions of the mediators produced by mast cells. In the near future, it is likely that patients will be treated earlier with anti-inflammatory and immunomodulatory drugs. Some agents under development for asthma and rhinitis may be useful for the treatment of urticaria/angioedema, including 5-lipoxygenase inhibitors, prostaglandin D_2-receptor antagonists, and more potent nonsedating antihistamines. Agents that decrease the sensitivity of mast cells to degranulation, such as phosphodiesterase 4 inhibitors and spleen tyrosine kinase (Syk) inhibitors, may also find a role in the treatment of this condition. In spite of the fact that chronic urticaria/angioedema is not thought to be an IgE-mediated disease, as mentioned before, omalizumab (anti-IgE) has been shown to be very

effective. This may be due to unexpected effects of IgE on mast cell activation. This finding could have a significant impact on future therapies.[9]

HEREDITARY ANGIOEDEMA AND RELATED DISEASES

DEFINITION

Hereditary angioedema (HAE) and related illnesses are characterized by recurrent attacks of angioedema mediated by vasoactive peptides such as bradykinin.[10]

EPIDEMIOLOGY

HAE affects approximately 1 in 50,000 people. It is an autosomal dominant disease and therefore affects 50% of offspring of both genders. Frequently, a history of several generations with this disease is obtained, but new mutations do occur, and a negative family history is not uncommon. Acquired angioedema (AAE) is more rare, affecting older persons who often have a monoclonal gammopathy or a malignant disease such as lymphoma. Angioedema associated with ACE inhibitors occurs in 0.1 to 0.2% of treated patients.[11]

PATHOBIOLOGY

HAE and AAE are caused by either low levels or abnormal function of a regulatory protein in the plasma, C1 inhibitor (C1 INH deficiency), which exerts control of the complement, fibrinolytic, and kinin-generating pathways. Because there is one normal gene, levels of C1 INH are detectable but, because of the abnormal gene, are not sufficient to control the generation of kinins. The C1 esterase enzyme, when activated, cleaves two complement products, C4 and C2. Without proper inhibition, this leads to low levels of circulating C4 and C2. C1 INH is also a critical modulator of the bradykinin pathway, and decreased C1 INH function leads to increased levels of bradykinin. Increased generation of bradykinin, not mediators from mast cells or activation of complement, leads to capillary leakage and angioedema. Changes in levels of C4 and C2, although not important in the pathophysiologic mechanism of the disease, are useful diagnostically.[12]

In HAE type I (85% of patients), the abnormal gene does not produce C1 INH. In HAE type II (15%), an antigenically detectable C1 INH protein is produced, but it is not functional. In HAE type III (very rare), C1 INH is present and functional, but there is a yet-to-be-defined abnormality in the generation of vasoactive compounds. In AAE, unknown factors activate C1 and deplete the C1 INH activity in plasma, or there is an autoantibody to C1 INH that interferes with its function. ACE inhibitor–associated angioedema is due to unintended inhibition of the enzyme that inactivates bradykinin; the complement pathway is unaffected.

CLINICAL MANIFESTATIONS

Children with HAE can have attacks shortly after birth, but these tend to be mild. For most patients, the severity of the attacks worsens at puberty, with episodes of swelling that can affect any external body surface, including the genitalia. Mucosal surfaces are also affected, and patients can have life-threatening swelling of the uvula and posterior pharynx, leading to asphyxiation. Swelling of the submucosa of the gastrointestinal tract can cause symptoms of an "acute abdomen," leading to unnecessary exploratory laparotomy. About half of patients report that trauma, particularly trauma associated with local pressure, precipitates an attack, and about half note an increased frequency of attacks during times of emotional stress. Attacks in patients with AAE are clinically similar to those in patients with HAE. In patients taking ACE inhibitors, angioedema may be manifested as severe swelling or simply as a chronic cough beginning days to months after ACE inhibitor therapy is initiated.

DIAGNOSIS

The best tests to support the diagnosis of HAE or AAE are measurements of C1 INH levels, C1 INH function, and C4 levels, particularly during an attack. The distinguishing features of AAE are onset later in life and the presence of a malignant disease or paraproteinemia. However, in addition to having low levels of C2 and C4, patients with AAE can have profound depressions in the level of C1, a protein that is commonly normal in HAE. Patients with ACE inhibitor–associated angioedema can present within hours after initiation of therapy or after many months and even years. The angioedema seen in urticaria/angioedema is distinctive in that it is usually associated with a pruritic urticarial rash, laboratory evaluation is normal, there is no history of treatment with an ACE inhibitor, and it responds to antihistamines, steroids, and epinephrine.

TREATMENT

Rx

Acute Attacks of Hereditary Angioedema

C1 INH concentrate purified from human plasma (Berinert; 20 units/kg intravenously), icatibant, a bradykinin receptor 2 antagonist (Firazyr; 30 mg SC), and ecallantide, a kallikrein inhibitor (Kalbitor; 30 mg SQ), are all FDA approved for acute attacks of HAE. If these agents are not available, treatment of angioedema of the airway should include racemic epinephrine (1:1000) delivered in the airway by nebulization and by intramuscular injections (0.2 to 0.3 mL of 1:1000 at intervals of 20 to 30 minutes). The addition of antihistamine for sedation may be helpful. Treating physicians must be prepared to perform nasotracheal intubation, preferably in the operating room under conditions in which tracheostomy can be performed if needed. Acute attacks can be terminated by administration of 2 units of fresh-frozen plasma (FFP) to supply the missing C1 INH; but in rare instances, patients may become more edematous, presumably reflecting the increased availability of substrates for the generation of kinins. Therefore, although FFP can be useful for treatment of non–life-threatening acute attacks, it is not recommended for life-threatening laryngeal edema.[13]

Long-term Treatment of Hereditary Angioedema

Attenuated androgens, such as danazol (50 to 200 mg up to twice daily), increase the production of C1 INH and lead to a marked amelioration of symptoms in patients with HAE. Masculinizing side effects are usually mild but can be problematic. These drugs are absolutely contraindicated in pregnancy. C1 INH concentrate (Cinryze; 1000 units IV every 3 to 4 days) is approved for long-term treatment. Many patients with relatively mild disease or infrequent attacks are treated with "on-demand" therapy with either C1 INH, icatibant, or ecallantide.[14]

Prophylaxis

Patients should be treated prophylactically before dental work or other procedures that involve trauma to tissue. Those treated with attenuated androgens, antifibrinolytic agents, FFP (2 units intravenously), or C1 INH concentrate (500 units subcutaneously) have fewer attacks.

Acquired Angioedema

Treatment of AAE is similar to that of HAE, but definitive treatment requires amelioration of the underlying disease.

ACE Inhibitor–Associated Angioedema

Treatment of angioedema associated with the use of an ACE inhibitor includes antihistamines, epinephrine, or both, as appropriate, and discontinuation of the ACE inhibitor. The direct renin inhibitor aliskiren is also associated with a significant risk of angioedema. Rare patients develop angioedema when taking angiotension receptor blockers. These patients are more likely to have idiopathic angioedema than angioedema due to the angiotension receptor blocker.

Evidence-Based Treatments

Current therapy for HAE in the United States includes both prophylactic treatment and on-demand, patient-centered treatment of attacks. Prophylactic administration of anabolic steroids and of C1 INH concentrate has been shown in a double-blind, placebo-controlled trial to significantly reduce the number of acute attacks. On-demand treatment for acute attacks has been shown to be effective with C1 INH, icatibant, and ecallantide. Ecallantide provides only marginal benefit for treating acute ACE inhibitor-induced angioedema in the emergency department setting.

PROGNOSIS

The long-term outlook for patients with HAE is largely dependent on the phenotype of the illness (frequency of laryngeal attacks), the ability of the patient to tolerate attenuated androgens, and the patient's access to C1 INH concentrate, icatibant, or ecallantide. Repeated use of these medications for recurrent acute episodes appears to be safe and effective.[15] For most patients, life expectancy should be normal. AAE usually resolves with treatment of the underlying condition, but the ultimate prognosis depends on the nature of that illness. Angioedema associated with the use of an ACE inhibitor can be fatal but usually resolves after the medication is removed.

FUTURE DIRECTIONS

In the last several years, there has been dramatic progress in the availability of medication for HAE.[16] In the near future, the focus will be on tailoring therapy to individual patients and controlling costs.

REVIEW QUESTIONS

1. A 27-year-old woman wakes up with hives and appears in your office the same day for an urgent visit. On examination, she is not in acute distress but has multiple raised pruritic papules that blanch. The first medication you should prescribe is

A. First-generation type 1 antihistamine
B. Second-generation type 1 antihistamine
C. Type 2 antihistamine
D. Leukotriene pathway inhibitor
E. Corticosteroid

Answer: B Second-generation type 1 antihistamines (cetirizine, fexofenadine, and loratadine) are better tolerated than the first-generation type 1 antihistamines. Often, the first generation antihistamines (e.g., diphenhydramine) are prescribed for breakthrough symptoms.

2. A 45-year-old man has had hives daily for 8 weeks. A combination of antihistamines (types 1 and 2) at high doses plus prednisone 20 mg daily controls the hives. What is the next step?

A. Perform extensive testing to discover the offending food.
B. Continue prednisone after documenting a discussion of possible side effects.
C. Explain the importance of adherence to prescribed medications.
D. Discuss adding an immunomodulatory drug.
E. Initiate a work-up for systemic lupus erythematosus.

Answer: D This patient has failed to respond to conservative medical management. Chronic urticaria is a life-altering disease, and chronic steroid use is often associated with significant side effects. Current literature suggests that some immunomodulatory drugs, such as cyclosporine, can result in remission of the disease.

3. A 20-year-old man appears in your emergency department with acute abdominal pain. He has presented in this way in the past, without a definitive diagnosis. Examination now reveals a tender, swollen abdomen without bowel sounds. What is your next step?

A. Laparotomy
B. Appendectomy
C. Narcotics
D. Discharge secondary to malingering
E. Take a detailed personal and family history

Answer: E Attacks of abdominal angioedema in patients with hereditary angioedema can mimic an acute abdomen. Also, these patients often seek pain relief and are incorrectly labeled "drug seeking." A detailed personal and family history may reveal a pattern of swelling of the bowels or other parts of the body in either the patient or his immediate relatives. This will lead to appropriate laboratory studies and medical management.

4. A 50-year-old man carries the diagnosis of hereditary angioedema. He has been intubated twice and has minor episodes of swelling monthly. A trial of an attenuated androgen resulted in severe acne. Therapeutic options at this time include

A. C1 INH twice weekly
B. On-demand C1 inhibitor
C. On-demand icatibant
D. On-demand ecallantide
E. All of the above

Answer: E All of these options are possible. Patients now have multiple options for management of hereditary angioedema, and these should be instituted on the basis of the needs of each patient.

5. A 10-year-old girl presents with a history of a hive-like rash that occurs when she is exposed to cold weather. Further questioning reveals that this is sometimes associated with myalgias and arthralgias and that several first-degree relatives have similar complaints. What is the most likely diagnosis?

A. Chronic spontaneous urticaria
B. Cholinergic urticaria
C. Familial cold urticaria
D. Familial cold autoinflammatory syndrome
E. Systemic lupus erythematosus

Answer: D This uncommon disorder is often mistaken for familial cold urticaria, another unusual disease, and must be differentiated from common conditions such as chronic urticaria and systemic lupus erythematosus.

SYSTEMIC ANAPHYLAXIS, FOOD ALLERGY, AND INSECT STING ALLERGY

LAWRENCE B. SCHWARTZ

DEFINITION

Systemic anaphylaxis, a form of immediate hypersensitivity, arises when mast cells and possibly basophils are provoked to secrete mediators with potent vasoactive and smooth muscle contractile activities that evoke a systemic response. Although mast cells in any organ system may be involved, depending on the distribution of the instigating stimulus, the principal targets are the cardiovascular, cutaneous, respiratory, and gastrointestinal systems, sites where mast cells are most abundant. Systemic anaphylaxis can occur when these cells are activated by allergen that binds immunoglobulin E (IgE), or classic immediate hypersensitivity, and by alternative pathways.

EPIDEMIOLOGY

Assessments of the annual incidence of systemic anaphylaxis and the prevalence of those at risk for systemic anaphylaxis are compromised by imprecise diagnostic measures. Approximately 1500 to 2000 deaths in the United States per year are attributed to systemic anaphylaxis. The incidence of nonfatal cases has been estimated to be between 10 and 100 cases per 100,000 person-years. A random public telephone survey of 1000 adults conducted in 2011, designed to estimate the lifetime prevalence of systemic anaphylaxis, elicited a positive personal history in 7.7% of the participants, which was lowered to 1.6% using stringent criteria based on severity (hospitalization and "felt their life was in danger") and at least two organ systems being involved, including either respiratory or cardiovascular or both.[1] In children and adolescents,[2] because food allergy is more common, the incidence of anaphylaxis is likely to be higher. A separate survey of about 1000 at-risk patients also was conducted, focusing on subjects who had a history of some type of generalized allergic reaction, identifying systemic anaphylaxis in about one third. In both public and patient surveys, respiratory or cutaneous symptoms each occurred in more than 50%, whereas cardiovascular, neurologic, or gastrointestinal symptoms were recognized in less than 50%. Among patients, medications were the most common trigger, followed by insect stings, foods, environmental allergens, and latex, but the list of offending agents was lengthy and in some cases was unknown. About half of the reactions occurred at home, 14% at a hospital or clinic, and 6 to 7% at a family member's or friend's home, at work, or at a restaurant. Among adolescents, it has been estimated that one in four first-time reactions occurs outside the home, and therefore training of school and college staff also is essential.[2] Antibiotics and radiocontrast media are the most common triggers in hospitals. In the perioperative setting, systemic anaphylactic reactions occur with a frequency of about 1 in 3500, muscle relaxants being the most common, but antibiotics, latex, induction drugs, and other drugs can also be the culprit.[3]

Anaphylaxis to foods and insect stings each account for about 100 deaths per year. Most fatal anaphylactic reactions to injected venom proteins begin within 30 minutes after the sting. Most fatal food and insect sting reactions and many drug reactions are preceded by a mild immediate hypersensitivity reaction to the same allergen. Recognition of these earlier events as an important risk factor for future fatal anaphylaxis should lead to implementation of an action plan to prevent and deal with such reactions.

Food allergy is found in about 6% of children younger than 3 years of age and in half that percentage of adults, and these individuals are at risk for food-induced anaphylaxis. Most children lose their allergic sensitivities to cow's milk, egg, wheat, or soy by 5 years of age, whereas sensitivities to peanut, tree nuts, or seafood are typically long lasting. About 20% of children lose peanut sensitivity by school age, but a small portion of these regain peanut sensitivity later in life, particularly if they continue to avoid this food.

Latex provokes anaphylaxis in a small but significant group of individuals, particularly patients who have undergone multiple surgical procedures early in life, such as those with spina bifida or congenital urinary tract disorders, and those with frequent exposure later in life, such as medical personnel. Estimates of the prevalence of latex hypersensitivity range from 1 to 6% in the general population and about 10% among regularly exposed health care workers. Over a 5-year period, the U.S. Food and Drug Administration (FDA) collected approximately 1100 reports of latex-induced anaphylaxis, including 15 deaths. Elimination of powder latex gloves and availability of nonlatex gloves has diminished the prevalence of this problem. Contact hypersensitivity is diagnosed by patch testing, and immediate hypersensitivity by latex-specific IgE tests performed in vitro. Latex allergen skin test reagents have not yet received FDA approval.

PATHOBIOLOGY

Etiology

The mediators produced by activated mast cells and basophils initiate many of the signs and symptoms of anaphylaxis. These cells constitutively express the high-affinity receptor for IgE, FcεRI, on their cell surfaces. Consequently, these cells will always be armed with antigen-specific IgE, which is produced by sensitive individuals and enables cells to respond to antigens that aggregate IgE-FcεRI complexes on their surfaces. Therapeutic interventions aim to prevent the activation of these cells and to block the production or actions of their mediators. Cells other than mast cells and basophils also undoubtedly participate in systemic anaphylaxis, particularly those expressing FcεRI. Eosinophils, monocytes, antigen-presenting cells, and epithelial cells may be induced to express this receptor and thereby affect the intensity, duration, or character of anaphylactic reactions.

Most IgE-dependent mast cell activation events occur at local sites and result in local disease. For example, allergic conjunctivitis, allergic rhinitis, or allergic asthma typically occurs when allergen lands on the corresponding mucosal surface of a sensitive individual and diffuses into the tissue where mast cells reside. Systemic anaphylaxis presumably requires the allergen (or nonallergen agonist) to distribute systemically to activate mast cells at remote sites. This is more likely to occur when allergen is administered parenterally and is less likely after oral ingestion, inhalation, or cutaneous or ocular topical contact. Activation of mast cells in perivascular locations should have the greatest effect on systemic vascular responses. Additionally, the responsiveness of various organ systems to mast cell mediators may be influenced by local factors. Although mediators released at one tissue site could, in theory, spill into the circulation and affect remote sites, most vasoactive mediators are rapidly metabolized.

Allergens

The most common allergens causing systemic anaphylactic reactions include drugs, insect venoms, foods, radiocontrast media, allergen immunotherapy injections, and latex (Table 253-1). Most allergens are typically proteins or glycoproteins that serve as complete antigens, having at least two epitopes recognized by different IgE antibodies, and thereby capable of eliciting immediate hypersensitivity reactions in a sensitized subject without further processing. The protease activity of some allergens, such as house dust mite Der

TABLE 253-1 CAUSES OF SYSTEMIC ANAPHYLAXIS

IgE-MEDIATED	NON–IgE-MEDIATED
Insect stings	Aspirin

IgE = immunoglobulin E.

p1, may facilitate their penetration at mucosal sites. Others have lipid-binding domains, such as Der p2, that increase their antigenic potency. Anaphylactic reactions to a humanized monoclonal antibody, cetuximab, can occur on first exposure, owing to IgE against a nonhuman carbohydrate moiety, alpha-gal, which was made by the animal cells and conjugated to the recombinant humanized antibody being expressed. This IgE antibody seems to form against alpha-gal in tick secretions, also causing delayed (3 to 6 hours) anaphylactic reactions after ingestion of red meats, which contain alpha-gal.

In contrast to complete antigens, most drugs act as haptens. They become covalently linked to self-proteins in the circulation, in tissues or on cells, emerging as multivalent allergens. Multivalency is important for immediate hypersensitivity because cross-linking of at least two IgE molecules on the surface of cells aggregates FcεRI molecules, which then transmit an activating signal into the cell. Monovalent antigens fail to elicit mediator release because they bind IgE molecules without cross-linking them.

An allergen exposure must lead to sensitization before an immediate hypersensitivity reaction can occur. This process, which takes at least 1 week, involves antigen processing by antigen-presenting cells, which then present peptide antigens to T_H2 cells (helper T lymphocytes), which in turn select, nurture, and instruct allergen-specific B cells to switch from production of allergen-specific IgM or IgG to IgE. Production of interleukin-4 (IL-4) or IL-13 by T_H2 cells and binding of T_H2 CD40 ligand to B-cell CD40 are essential for this antibody class switch. Consequently, anaphylaxis does not typically occur on first exposure to an allergen (sensitization phase) because the antigen is likely gone by the time antigen-specific IgE is made, but it may occur after subsequent exposures.

Food

Most cases of *food-induced anaphylaxis* in children occur in response to egg, peanut, cow's milk, wheat, or soy, whereas peanuts, tree nuts, and seafood account for most reactions in adults. Reactions to seeds such as sesame seem to be growing in importance, and a variety of different foods have proved to be important allergens in specific individuals. Some patients have the *oral allergy syndrome*, which typically occurs in subjects sensitive to pollen allergens, their pollen-specific IgE cross-reacting to certain food allergens, such as ragweed with melon or birch with peach or apple. Also, the food epitopes involved are typically conformational (rather than linear), are therefore more easily destroyed by heating (cooking), by acid in the stomach, or by proteases in the intestines, and thus rarely progress to systemic reactions.

Food allergy-associated exercise-dependent anaphylaxis occurs when a sensitive subject exercises within several hours after eating the food to which they are sensitive, but not when eating the food without exercise. Shrimp and wheat are most commonly implicated. Exercise appears to increase intestinal permeability to food antigens, which then enter into the systemic circulation. Aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) also act to increase intestinal permeability. Avoiding the implicated food for 4 to 6 hours before exercise is recommended.

Insect Sting

Hymenoptera families primarily responsible for anaphylactic reactions include the Apidae (honey bees and bumble bees), Vespidae (hornets, yellow jackets, and paper wasps), and Formicidae (fire ants). Major allergens of honeybees include phospholipase A_2 (Api m 1), hyaluronidase (Api m 2), and melitin (Api m 4). Bumblebee venom proteins exhibit immunologic cross-reactivity with those of the honeybee, even though melitin is lacking. Vespid venoms cross-react among themselves and include proteins named antigen 5, phospholipase, and hyaluronidase, the latter allergen cross-reacting with bee hyaluronidase. Fire ant venom toxicity is caused principally by various alkaloids, which are not allergenic. Immediate hypersensitivity reactions to fire ant venom target a phospholipase that cross-reacts with the comparable vespid enzyme and various other proteins that are unique antigens. Allergens in fire ant venom cross-react with those in scorpion venom. A person may exhibit an anaphylactic reaction on first exposure to an insect's sting if previously sensitized to cross-reactive venom from a different insect. In contrast to stinging insects, allergens from biting insects of the Diptera order (mosquitoes, gnats, midges, true flies) are salivary in origin and do not cross-react with Hymenoptera venom allergens. Anaphylaxis to these salivary proteins appears to be uncommon, but precise epidemiologic data are problematic because people are often unaware of an ongoing mosquito bite, and commercial diagnostic reagents of high quality are not yet available.

Latex

Latex allergens are derived from the rubber tree, *Hevea brasiliensis.* Irritant dermatitis is the most frequent contact reaction and does not involve acquired immunity. Contact hypersensitivity, which results from cell-mediated immunity to haptenic chemicals added to latex during processing, produces a poison ivy–like local reaction that may appear the day after a sensitive subject is exposed. In contrast, immediate hypersensitivity occurs when IgE is made against proteins naturally found in this plant-derived product. Cutaneous (elastic materials), mucosal or intravascular (catheters), oral (balloon), and inhaled (powdered latex gloves) routes of exposure have been well documented and generally elicit signs and symptoms within minutes of exposure. IgE-mediated cross-reactivities between latex proteins and allergens in certain fresh foods such as banana, chestnut, avocado, kiwi, peach, bell pepper, and tomato have been reported and may necessitate avoidance of these foods.

Non–IgE-Dependent Agonists

Most foreign agents that trigger non–IgE-dependent anaphylaxis do not require antigen processing and can elicit a mast cell activation response on first exposure. These include radiocontrast dyes, narcotics such as codeine and morphine, and vancomycin (see Table 253-1). The dose and rate of administration and individual variations in sensitivity are determinants of severity. For radiocontrast dyes, media of low ionic strength and iso-osmolarity are less likely than those of high ionic strength and hyperosmolarity to elicit a systemic reaction. Vancomycin produces a non–IgE-dependent mast cell activation event known as *red man syndrome*, typically involving flushing and sometimes urticaria, but without cardiovascular compromise unless infused too rapidly; and these reactions usually can be avoided by reducing the rate of administration of the antibiotic, thereby reducing peak levels.

Endogenous mast cell activators include neuropeptides such as substance P, neurokinin A, calcitonin gene–related peptide, and the complement anaphylatoxins C3a and C5a. Whether a magnitude of mast cell activation sufficient to cause systemic anaphylaxis can result from endogenous secretion or generation of these peptides by themselves is unproved. For example, an anaphylactic shock–like syndrome occurred in hemodialysis patients exposed to a contaminated hemodialysis membrane that was associated with complement activation without detectable mast cell activation, and infusion of heparin contaminated with oversulfated chondroitin sulfate caused shock by activating the contact pathway and presumably generating bradykinin.

Aspirin and NSAIDs

Aspirin hypersensitivity typically manifests as either a respiratory or a cardiovascular reaction, although sometimes overlap is observed.[4] Respiratory reactions include bronchospasm, nasal congestion, and rhinorrhea and may extend beyond the respiratory tract to include abdominal cramping, watery diarrhea, and urticaria. Cardiovascular reactions that are identical clinically to allergen-induced systemic anaphylaxis and shock also can occur. In most cases, such reactions appear to be pharmacologically (not IgE) mediated, and in sensitive subjects they can occur in response to any of the cyclooxygenase 1 (COX1) inhibitors. Although cyclooxygenase inhibitors may shunt arachidonic acid metabolism to the lipoxygenase pathway, a mechanism to explain mast cell activation has not yet emerged. COX2-selective inhibitors appear to be relatively safe in aspirin-intolerant asthmatic patients but may still cause cardiovascular reactions in those who present with this manifestation. Less commonly, sensitivity occurs to only one of the drugs within this class and is caused by IgE against an associated unique chemical moiety on that particular drug. Human mast cells also express the low-affinity IgG receptor, FcγRIIa, which when aggregated by IgG immune complexes is capable of activating mast cells, and, at least in theory, may contribute to some episodes of anaphylaxis.[5]

Physical Stimuli

Physical stimuli may precipitate systemic anaphylaxis in certain individuals. Episodes can occur in response to exercise, heat, solar radiation, vibration, pressure, or cold. Exercise-dependent anaphylaxis is sometimes associated with ingestion of any food, regardless if sensitivity to the food can be documented, occurring within several hours of ingestion, and it might be avoided by delaying exercise until several hours after eating.

Autoimmunity and Activating Kit Mutations

Some patients experience spontaneous bouts of anaphylaxis without an obvious stimulus. Those with systemic mastocytosis (Chapter 255) are particularly prone to systemic anaphylaxis, perhaps because they have too many mast cells and because the mast cells they do have harbor a somatically acquired activating mutation of Kit tyrosine kinase that primes their activation status.[6] A corollary of this is that systemic anaphylaxis to an insect sting may be a presenting manifestation of mastocytosis, particularly if a baseline serum tryptase level is elevated (see later).[7] A related disorder, *mast cell activation syndrome*, includes patients with clonal mast cell disease, reflected by these same Kit mutations, who have recurrent bouts of anaphylaxis, but who either do or do not meet diagnostic criteria for systemic mastocytosis.[8] A cohort of patients, described in 2014, had elevated baseline serum tryptase levels, atopy and connective tissue disorders, and either spontaneous anaphylaxis or anaphylaxis triggered by heat, exercise, vibration, emotional stress, nonspecific foods, or minor physical trauma, inheriting this phenotype in an autosomal dominant pattern, but having no discernible mutations in their *c-Kit* gene, suggesting that mutation in other genes might increase the risk for anaphylaxis.

Some cases of chronic urticaria are known to be associated with IgG and IgM antibodies against FcεRI or IgE.[9] In such cases, complement activation leading to the generation of complement anaphylatoxins at the surface of mast cells has been postulated to synergize with FcεRI-mediated activation. These reactions may occur preferentially in the skin because of the expression of anaphylatoxin receptors on the type of mast cell that predominates in the skin but not on the type that predominates in lung. An analogous, albeit speculative, autoimmune process might activate mast cells localized in blood vessel walls, the result being anaphylaxis.

Autoimmune progesterone-mediated anaphylaxis, *catamenial anaphylaxis*, which tends to occur just before menses, is uncommon but well documented and may respond to medical or surgical interventions that prevent menses.[10]

Pathophysiology

Mast cells participate in both acquired and innate forms of immunity (Chapter 255). They develop in peripheral tissues from bone marrow progenitors, primarily under the influence of stem cell factor, the ligand for the tyrosine kinase receptor called Kit. Armed with allergen-specific IgE, mast cells are activated by multivalent allergens that cross-link IgE and aggregate FcεRI molecules on the cell surface. This may be important in the defense against certain parasites that elicit a strong IgE response. Experiments performed in rodents suggest that mast cells can be directly activated by microbial products, leading to the secretion of mediators that recruit neutrophils. This innate immune response may restrain bacterial dissemination until a more potent acquired immune response develops. Activation of mast cells by endogenous peptides such as substance P or calcitonin gene–related peptide may influence basic biologic processes such as wound healing and angiogenesis. Whether human mast cells have a critical, nonredundant role in these biologic and immunologic processes remains controversial. However, their central role in immediate hypersensitivity is clear.

Mediators released by mast cells include preformed mediators stored in secretory granules, some of which are preferentially or exclusively made by mast cells, newly generated lipid products, which are not precise biomarkers for mast cells and include metabolites of arachidonic acid, and an array of cytokines and chemokines. Histamine, formed from histidine by histidine decarboxylase, is the sole biogenic amine stored in all granules of human mast cells and basophils. Histamine released by mast cells or basophils diffuses freely and interacts with H_1, H_2, H_3, and H_4 receptors. H_1 receptors are found on endothelial cells, smooth muscle cells, and sensory nerves; when stimulated, bronchial and gastrointestinal smooth muscle contraction, vascular smooth muscle relaxation, increased permeability of postcapillary venules, coronary artery vasoconstriction, and pruritus can occur—signs and symptoms often associated with systemic anaphylaxis. In the central nervous system (CNS), blockade of H_1 receptors appears to cause drowsiness. H_2 receptors reside on gastric parietal cells and at lower levels on inflammatory cells, bronchial epithelium, and endothelium and in the CNS. H_2-receptor–mediated increased acid production in the stomach may occur transiently during systemic anaphylaxis, but it is more likely to become clinically significant if histamine levels are chronically elevated, as occurs with systemic mastocytosis. H_3 receptors are found primarily on cells in the CNS. H_4 receptors are found on hematopoietic cells, such as mast cells, basophils, eosinophils and lymphocytes, and may modulate certain aspects of inflammation, such as eosinophil recruitment, as well as pruritus. Histamine, after its secretion from mast cells and basophils, is rapidly metabolized to inactive methylhistamine and methylimidazole acetic acid.

Prostaglandin D_2 (PGD_2) is the principal COX-catalyzed product of arachidonic acid secreted by activated mast cells, but it is not made by basophils. It binds to the G protein–coupled receptors, CRTH2 and DP. Both COX1 and COX2 are involved in PGD_2 production by mast cells. Consequently, a COX inhibitor that is bipotent might be better than one that is selective at blocking PGD_2-mediated responses during anaphylaxis, which may include hypotension, bronchospasm, inhibition of platelet aggregation, and prolonged asymptomatic cutaneous erythema.

Leukotriene C_4 (LTC_4) is released by both mast cells and basophils after its formation from arachidonic acid and glutathione; its formation is sequentially catalyzed first by 5-lipoxygenase together with 5-lipoxygenase–activating protein and then by LTC synthase. Conversion to LTD_4 and LTE_4, which also are bioactive, occurs in the extracellular space. These sulfidopeptide leukotrienes bind to the G protein–coupled receptors cysteinyl leukotriene 1 ($CysLT_1$), on bronchial smooth muscle, epithelial and endothelial cells, and leukocytes, and $CysLT_2$, on vascular smooth muscle, endothelial and epithelial cells, leukocytes, and heart muscle. LTE_4 may have selective affinity for the P2Y receptor, gpr99. Sulfidopeptide leukotrienes cause bronchoconstriction, mucus secretion, eosinophil recruitment, vasopermeability, diminished cardiac contractility, vasoconstriction of coronary and peripheral arteries, vasodilation of venules, and a burning cutaneous wheal-and-flare response. Antagonists of $CysLT_1$ (montelukast, zafirlukast), but not of $CysLT_2$, as well as a 5-lipoxygenase inhibitor (zileuton), are currently available to patients.

Platelet-activating factor (PAF) is generated from 2-lyso-glycero-3-phosphorylcholine when an acetyl group is placed on the sn-2 carbon of glycerol by acetyltransferase. PAF activates platelets but also is a potent vasoactive mediator that enhances vasodilation and vasopermeability and a smooth muscle constrictor that is capable of inducing bronchospasm. PAF is generated by both mast cells and basophils, as well as by other cell types. Elevated levels of PAF and low levels of circulating PAF acetylhydrolase, which converts PAF back to inactive lyso-PAF by removing the sn-2 acetyl moiety, have been associated with more severe food-induced systemic anaphylaxis. Sphingosine-1-phosphate (S1P) is generated from sphingosine by sphingosine kinase in activated mast cells, as well as in other cell types, and may enhance the vascular response during systemic anaphylaxis.

Mast cells also are the sole or principal source of heparin proteoglycan and certain proteases. All express β-tryptase, and a subset also expresses chymase, mast cell carboxypeptidase, and cathepsin G (like neutrophils and monocytes). Mast cells that express only tryptase are called MC_T cells; those that also express the other proteases are called MC_{TC} cells. Mature tryptase is stored in the secretory granules of all mast cells and is released during degranulation of activated cells; acute levels in serum serve as a clinical biomarker for mast cell activation. In contrast, precursor forms of tryptase (protryptase) are spontaneously secreted by mast cells at rest; baseline levels in serum reflect the total body burden of mast cells, serve as a minor diagnostic criterion for systemic mastocytosis, and serve as a biomarker for anaphylactic risk in allergen-sensitized subjects. MC_{TC} but not MC_T cells express CD88, the C5a receptor, and therefore are activated by complement C5a. Basophils are relatively deficient in these proteases but likewise express CD88.

Cytokines (tumor necrosis factor-α [TNF-α]; IL-4, -5, -6, -8, -13, and 16; granulocyte-macrophage colony-stimulating factor [GM-CSF]; basic fibroblast growth factor [bFGF]; vascular endothelial growth factor [VEGF]) and chemokines (IL-8, monocyte chemotactic protein-1, monocyte inflammatory protein-1α) represent another dimension of the mediators released by mast cells and basophils. Although these mediators are not selectively produced by these cell types, their vasoactive and inflammatory potential could affect the severity and duration of anaphylaxis. As selective antagonists of the relevant cytokines and chemokines become available and are tested for therapeutic benefits, the roles of these mediators in the pathogenesis of anaphylaxis will be better understood.

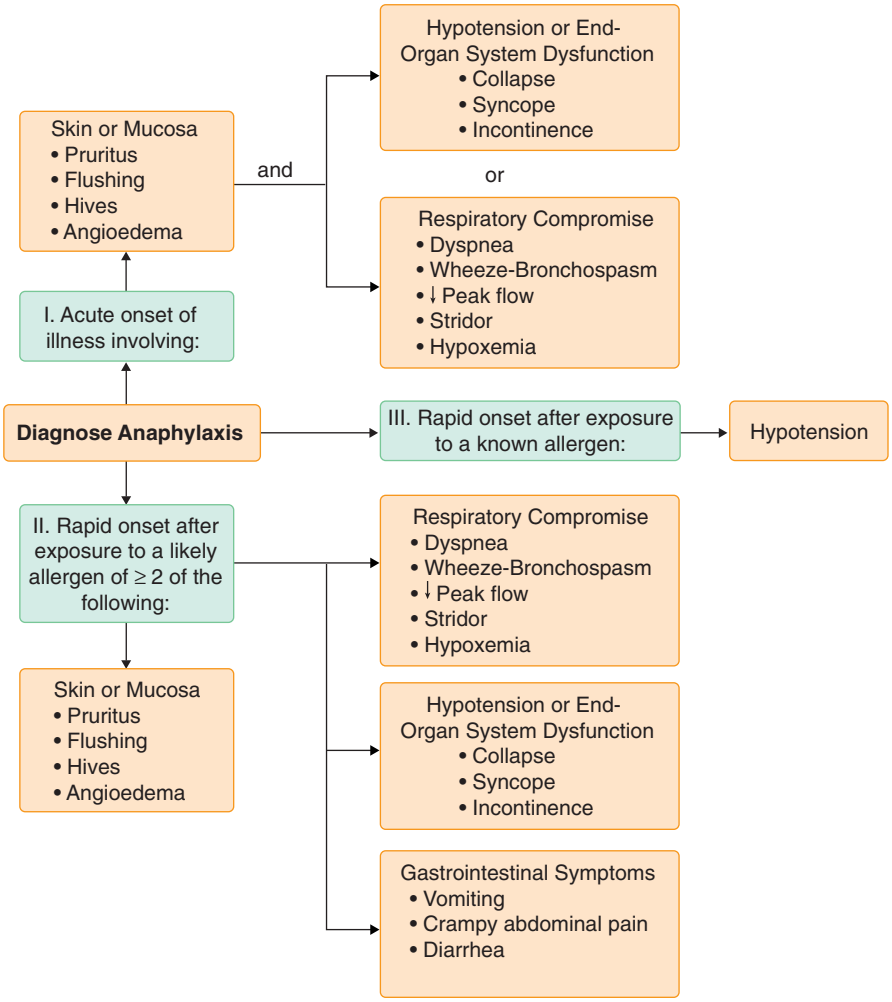

FIGURE 253-1. Clinical diagnosis of systemic anaphylaxis. Acute onset of systemic anaphylaxis in the apparent absence of allergen exposure means that the signs and symptoms develop over minutes to several hours, while rapid onset after exposure to a likely or known allergen means that these signs and symptoms begin to occur within minutes to several hours after that exposure. This is based on the Second National Institute of Allergy and Infectious Disease/Food Allergy and Anaphylaxis Network Symposium (From Sampson HA, Muñoz-Furlong A, Campbell RL, et al. Second symposium on the definition and management of anaphylaxis: summary report—second National Institute of Allergy and Infectious Disease/Food Allergy and Anaphylaxis Network symposium. *J Allergy Clin Immunol*. 2006;117:391-397).

DIAGNOSIS

Systemic anaphylaxis can be diagnosed clinically in real time by consensus criteria outlined in Figure 253-1.[11-13] Acute onset of cutaneous signs of immediate hypersensitivity along with either hypotension or respiratory compromise in the apparent absence of allergen exposure, rapid onset of hypersensitivity signs involving at least two organs from among cutaneous, gastrointestinal, respiratory and cardiovascular systems after exposure to a likely allergen, or rapid onset of hypotension after exposure to a known allergen can be used to diagnose systemic anaphylaxis—which sometimes can be precisely confirmed in the laboratory by demonstration of antigen-specific IgE (sensitization) and an acute serum level of total (mature plus pro) tryptase (mast cell activation) that is greater than a baseline level obtained at least 24 hours after all signs and symptoms have resolved. Skin testing or in vitro measurements of antigen-specific IgE should be delayed for at least 2 weeks after the precipitating event to prevent false-negative results. Insect venom allergies also have been assessed by experimental sting challenges, but these are not recommended for routine evaluations. For food allergies, larger wheal-and-flare responses to prick skin tests and higher IgE titers to specific allergens are associated with more severe reactions. Oral food challenges are performed under certain circumstances, taking care to minimize the risk for systemic anaphylaxis. These food-allergic reactions involve IgE sensitization and IgE-dependent mechanisms and should be distinguished from a variety of other types of adverse food reactions, including lactose intolerance due to a deficiency in lactase, food-induced enterocolitis in infants (in reaction to cow's milk, soy, or grains), and celiac disease associated with ingestion of gluten in wheat and other grains.

An increased level of total tryptase in acute (over baseline) serum, which peaks 15 to 60 minutes after the onset of the signs or symptoms of anaphylaxis and then declines with a half-life of about 2 hours (normal baseline levels ranging from 1 to 11 ng/mL), indicates that mast cell activation has occurred. During a study of experimental insect sting–induced anaphylaxis, the increased level of tryptase correlated closely with the drop in mean arterial pressure, indicating that the magnitude of mast cell activation is a primary determinant of clinical severity. Although an increased serum total tryptase level during putative systemic anaphylaxis may be useful for distinguishing anaphylaxis from other conditions in the differential diagnosis, elevations may not be detected after anaphylaxis triggered by food ingestion, or, in general, if anaphylactic severity is either modest (no hypotension) or local (laryngeal edema), or if the acute sample was collected outside of the optimal time. Whether there are anaphylactic IgE-dependent pathways that do not require mast cell activation, but instead involve basophil activation, is unknown but has been considered for anaphylaxis triggered by food allergen ingestion. Plasma histamine, because it is rapidly metabolized, is not as practical as serum or plasma tryptase for detecting anaphylaxis. However, urinary histamine or methylhistamine levels also may reflect overall levels of released histamine, accumulating in urine during anaphylaxis and stored in the bladder until micturition; but levels are affected by ingested histamine-containing foods, histamine-producing mucosal bacteria, and variability in histamine metabolism. PGD_2, which is made by several cell types, including activated mast cells, is rapidly metabolized to $PGF_{2\alpha}$, and urinary levels of this metabolite should be elevated in urine formed during anaphylaxis.

An elevated baseline level of serum total tryptase also appears to be a risk factor for increasing severity of insect venom-mediated systemic anaphylaxis,

perhaps in part because of an underlying clonal mast cell disorder with an activating c-kit mutation. Future studies will determine whether baseline serum tryptase levels should guide therapy for venom-sensitive subjects as well as those with other allergic sensitivities. Other risk factors for severe systemic anaphylaxis include a prior allergic event to that allergen and having high blood pressure, particularly if being treated with nonspecific β-blockers or angiotensin-converting enzyme (ACE) inhibitors.

Low serum levels of PAF acetyl hydrolase, which metabolizes PAF, and of ACE, which metabolizes bradykinin, have been associated with more severe food-induced systemic anaphylaxis. Whether slow metabolism of PAF and bradykinin might allow these mediators to play a role in such reactions and whether mediator-specific therapies would be clinically useful in such reactions remain to be determined.

Differential Diagnosis

Anaphylaxis should be distinguished from a variety of disorders with overlapping presentations. Vasovagal syncope causes diaphoresis, nausea, hypotension, and bradycardia, but without urticaria and tachycardia. Flushing disorders may be benign and unrelated to anaphylaxis, or they could be a manifestation of pathologic conditions such as the carcinoid syndrome (Chapter 232), with which urticaria and profound hypotension are not typically associated, or pheochromocytoma (Chapter 228), which causes episodic hypertension. Precise detection of these latter conditions is beyond the scope of this chapter. Panic attacks and vocal cord dysfunction can be a challenge to distinguish from anaphylaxis, especially by history alone, but nevertheless must be considered. Acute attacks of hereditary and acquired angioedema (Chapter 252) caused by C1 esterase inhibitor deficiency are not associated with pruritus or urticaria and persist longer than attacks of anaphylaxis. Shock due to complement activation by contaminated hemodialysis tubing, leading to the generation of C3a and C5a anaphylatoxins, or to activation of the contact system by an oversulfated chondroitin sulfate contaminant in heparin preparations, leading to the production of bradykinin, can occur without involving mast cell activation. Scombroidosis (histamine fish poisoning) occurs 5 to 90 minutes after ingestion of histamine, typically in poorly stored fish, and manifests with flushing, palpitations, headache, and gastrointestinal symptoms. The condition lasts several hours, both duration and severity depending on the amount of histamine ingested, and usually responds to H_1-receptor and H_2-receptor antihistamines, but occasionally requires epinephrine and intravenous fluids. Acute serum sickness, various cell activation syndromes, endotoxin-mediated septic shock, and superantigen-mediated toxic shock syndromes manifest with fever, which is not characteristic of anaphylaxis by itself. Also, hypoglycemia, seizure, and primary pulmonary or cardiac events should be considered.

In some cases, systemic anaphylaxis occurs together with another disorder. For example, a 65-year-old man, after being stung by a wasp, complained of dizziness and shortness of breath, was hypotensive with urticaria, and responded to treatment with intramuscular epinephrine, but also complained of chest pressure; electrocardiography indicated an inferior wall infarction. Acute serum levels of both tryptase and cardiac enzymes were elevated, indicating that both anaphylaxis and myocardial infarction had occurred.

Systemic mastocytosis (Chapter 255) is an important condition to consider in the setting of anaphylaxis. In adults, a somatic activating mutation in the gene for Kit in mast cell progenitors results in an excessive body burden of mast cells. The disease may regress spontaneously in children with this disorder, but this is uncommon in adults. Patients with too many mast cells are at increased risk for anaphylaxis, and anaphylaxis may be a presenting manifestation of systemic mastocytosis. For example, anaphylaxis in response to an insect sting, particularly in the absence of venom-specific IgE (due to direct mast cell agonists), should raise the possibility of systemic mastocytosis. Diagnostic tests for systemic mastocytosis might include a lesional skin biopsy when urticaria pigmentosa is suspected and a bone marrow biopsy, each stained for mast cells by antitryptase and anti-Kit (CD117) immunohistochemistry. Findings of mast cell granulomas (major criterion) and numerous spindle-shaped mast cells (minor criterion) in the bone marrow biopsy, along with mast cells that express CD2 or CD25, a D816V Kit mutation, and an elevated baseline level of serum total tryptase (>20 ng/mL) during a clinically quiescent interval (minor criteria) are used to diagnose systemic mastocytosis. One major and one minor, or three minor, criteria are recommended by the World Health Organization for diagnosis. Mast cell activation syndrome can be diagnosed when spontaneous anaphylaxis occurs in association with only two of these minor criteria.

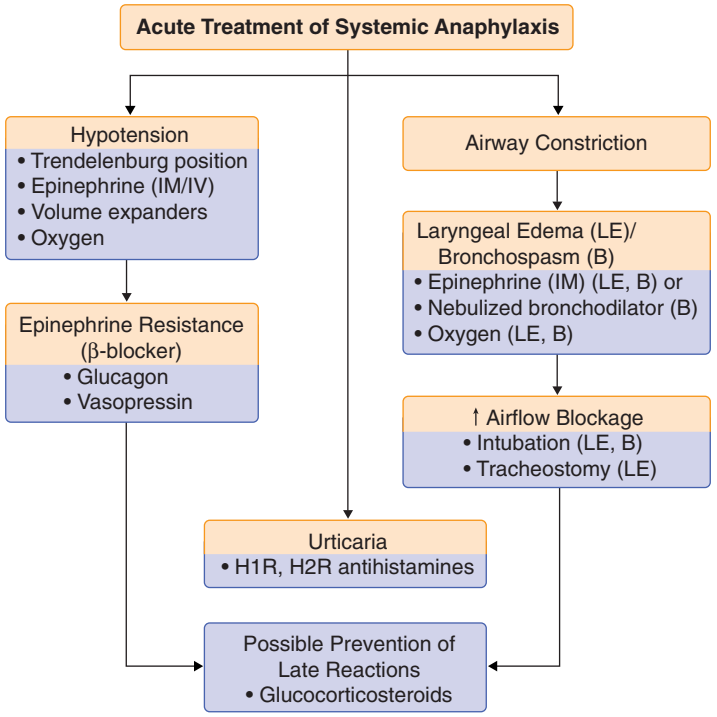

FIGURE 253-2. Acute treatment of systemic anaphylaxis. B = bronchospasm; H1R = histamine-1 receptor; H2R = histamine-2 receptor; IM = intramuscular; LE = laryngeal edema.

TREATMENT

Rx

Fatal outcomes in anaphylaxis are principally the result of either airway constriction or hypotension. Accordingly, the acute treatment of systemic anaphylaxis requires that airway patency, blood pressure, and cardiac status be addressed (Fig. 253-2).[14] Epinephrine, intubation, tracheostomy, volume expanders, and vasopressors may be needed. Patients exhibiting any signs or symptoms of hypotension should immediately assume the Trendelenburg position, which may prevent progression to anaphylactic shock or what has been called in postmortem examinations the *empty ventricle syndrome*—because almost all hypotensive anaphylactic deaths are preceded by syncope occurring in a sitting or upright posture. Epinephrine injected intramuscularly into the thigh (0.2 to 0.5 mg for adults, 0.01 mg/kg up to 0.3 mg for children, repeated every 5 to 30 minutes as indicated) is the most critical drug to administer, the earlier during the course of an anaphylactic event the better. Alternatively, intravenous administration of a solution of epinephrine (1 mg/100 mL solution starting at 30 to 100 mL/hour) and titrated to the lowest effective rate of infusion can be considered. Epinephrine relaxes bronchial smooth muscle and improves vasomotor tone and vasopermeability, thereby counteracting bronchospasm, hypotension, and tissue edema. However, the benefits of epinephrine need to be weighed against its disadvantages in elderly subjects and in those with cerebrovascular or coronary artery disease, hypertension, diabetes, hyperthyroidism, cardiomyopathy, or narrow-angle glaucoma, in whom adverse events such as myocardial infarction, stroke, or pulmonary edema can be precipitated. Also, patients taking a β-blocker may be resistant to epinephrine; in such a case, glucagon (1 to 5 mg/hour intravenously [IV] in adults or 20-30 mcg/kg in children, in each case administered over 5 min or vasopressin (2 to 40 IU IV in adults) may be used. Oxygen should be administered by nasal cannula. Inhaled bronchodilators can relieve bronchospasm. Parenteral administration of H_1-receptor (diphenhydramine, 1 to 2 mg/kg up to 50 mg) and H_2-receptor (ranitidine, 50 mg in adults and 1 mg/kg in children, in each case administered IV over 5 minutes) antihistamines may prevent progression of some of the signs and symptoms, particularly urticaria and pruritus, but is not likely to reverse hypotension or tissue edema. Prednisone (20 mg orally) or Solu-Medrol (40 mg IV) may reduce the risk for a protracted reaction or the late phase of biphasic anaphylaxis but is unlikely to be of benefit acutely.

PREVENTION

Patients who have experienced an anaphylactic reaction are at greatest risk for another episode. Such individuals should wear a Medic-Alert bracelet and be instructed in the use of epinephrine (e.g., EpiPen), which they should carry. Avoidance of nonspecific β-blockers and ACE inhibitors is

recommended because either may worsen the severity of an anaphylactic episode, and β-blockers might interfere with β-agonist treatment. In subjects with recurrent anaphylaxis, prophylactic use of H_1- and H_2-receptor antihistamines is beneficial. A leukotriene antagonist and cyclooxygenase inhibitor theoretically would provide additional benefit, but this has not been well studied. Finally, cyclosporine (3 to 5mg/kg per day) might be considered in difficult cases of recurrent anaphylaxis because of its ability to inhibit mast cell activation in vitro and in vivo in chronic urticaria. Omalizumab neutralizes free IgE, and anecdotal reports show benefit in controlling both urticaria and spontaneous episodes of anaphylaxis in mastocytosis patients, but it is not currently approved by the FDA for this indication. Glucocorticosteroids do not inhibit mast cell activation in vitro or immediate skin test responses to allergens in vivo but nevertheless may be beneficial in selected patients with recurrent anaphylaxis.

Specific anaphylactic syndromes have unique considerations. Anti-IgE therapy in peanut-allergic subjects can increase the threshold of sensitivity, on average, from the equivalent of half a peanut to almost nine peanuts.[A1] Insect venom sensitivity can be selectively treated by venom immunotherapy,[A2] dramatically decreasing the risk for anaphylaxis in response to future stings.[15] Reactions to radiocontrast media can be prevented or attenuated by prior administration of prednisone and H_1- and H_2-receptor antihistamines. Patients who are hypersensitive to penicillin should avoid β-lactam antibiotics in general but can be desensitized if an antibiotic in this class is critically needed (e.g., penicillin for neurosyphilis). However, desensitization is temporary; after the drug has cleared, sensitivity is likely to return. Catamenial anaphylaxis may respond to the luteinizing hormone–releasing hormone analog, Lupron, to oophorectomy, or to conjugated estrogens. Patients with systemic mastocytosis, in addition to prophylactic pharmacologic measures, should avoid using direct mast cell agonists such as codeine, morphine, and vancomycin. Aspirin-intolerant subjects can be desensitized but then must continue to ingest a daily dose of aspirin to maintain their desensitization status, thereby benefiting from better asthma control and regression of any nasal polyps that might be present. Food- and latex-sensitive subjects must practice avoidance of the provocative agent, although preliminary data with anti-IgE neutralization therapy and oral immunotherapy indicate that these measures might provide some protection against small inadvertent food allergen exposures. Future research should yield more effective and long-lasting interventions that reduce anaphylactic risk (including better desensitization regimens) and that more effectively reverse the signs and symptoms of this potentially fatal disorder.

REVIEW QUESTIONS

1. In adults, which of the following triggers of anaphylaxis accounts for the most deaths?

A. Peanuts
B. Latex
C. Penicillin
D. Hymenoptera venom
E. Aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs)

Answer: D The most common cause of anaphylactic death reported in adults is due to stings from insects, whereas in children, food allergic reactions may be more common. Adults who have experienced anaphylaxis to an insect sting in the past should be evaluated by an allergist for current sensitivity and risk factors for severe anaphylaxis and encouraged to undergo venom immunotherapy as clinically appropriate, which can reduce the risk for severe anaphylaxis to future stings by more than 95%. The prevalence of latex allergy in general and latex-triggered anaphylaxis in particular seem to be declining now that powdered latex gloves have been removed from medical centers and latex-free products are available for almost any procedure. Medical centers and patients generally do a good job of avoiding penicillin exposure in penicillin-allergic patients, and alternatives to penicillins are available for most infections. Cardiovascular reactions associated with aspirin and NSAIDs that can mimic allergen-induced systemic anaphylaxis are, in most cases, pharmacologically (not immunoglobulin E [IgE]) mediated.

2. An anaphylactic reaction in a 45 year-old living in Virginia that occurs 3 to 6 hours after eating dinner is most likely due to which one of the following allergens?

A. Bovine serum albumin in beef
B. Tropomyosin protein in shrimp
C. Alpha-gal carbohydrate in veal
D. Penicillin in pork
E. Melon in salad

Answer: C Particularly in the Southeastern and Mid-Atlantic states, perhaps due to exposure and sensitization to alpha-gal during Lone Star tick bites, IgE antibodies form against this antigen. Sensitized individuals can exhibit delayed urticarial or anaphylactic responses 3 to 6 hours after eating red meats, presumably because they do not react to monovalent alpha-gal-conjugated proteins in the meat soon after ingestion, but instead require several hours for this alpha-gal to be processed and form polyvalent, haptenized antigens. Interestingly, skin testing to a beef allergen extract is typically positive with sensitivity to protein allergens but negative with sensitivity to only alpha-gal, whereas in vitro testing of serum for allergen-specific IgE is positive in both cases. Anaphylactic reactions to protein allergens such as bovine serum albumin or tropomyosin occur acutely, generally within an hour of ingestion. Penicillin in beef or pork from penicillin-fed animals can cause anaphylaxis in penicillin-sensitive patients, but is uncommon and does so in less than an hour after ingestion. Individuals with pollen allergies may have pollen-specific IgE cross-reacting to certain food allergens, such as ragweed with melon, typically causing immediate-onset pruritus, irritation, and swelling around the mouth ("oral allergy syndrome").

3. Which of the following drugs is likely to activate mast cells on first exposure?

A. Vancomycin
B. Penicillin
C. Phenytoin
D. Bactrim

Answer: A Vancomycin directly activates mast cells on first and subsequent exposures, without involving the IgE-FcεRI pathway, but instead activating a G protein–coupled receptor. When peak levels of vancomycin are modest, red man syndrome results; hypotensive anaphylaxis can occur if the drug is infused too rapidly. Penicillin, phenytoin, and Bactrim (sulfamethoxazole and trimethoprim) can each haptenize proteins, elicit an IgE antibody response during a sensitization period, and then cause anaphylaxis with a subsequent exposure.

4. Mastocytosis, a clonal mast cell disorder that increases the risk for anaphylaxis, should be suspected if which of the following is elevated in serum taken from a patient at a time when their medical problem is clinically quiescent?

A. Bradykinin
B. Tryptase
C. Serotonin
D. Complement C5a
E. Catecholamines and metanephrines

Answer: B Serotonin is not abundantly produced by mast cells. Bradykinin, generated extracellularly from kininogen precursors, also is not generated by mastocytosis patients during nonacute time periods. C5a is generated from C5 by proteases, typically by C5 convertases generated during activation of the complement pathways, and also by certain noncomplement pathway proteases, but is not generated during times when mastocytosis is clinically quiescent. Flushing syndromes like pheochromocytoma, which produces catecholamines and metanephrines, are only in the differential diagnosis to be distinguished from anaphylaxis. On the other hand, α- and β-protryptases are spontaneously released by mast cells at rest. Consequently, tryptase levels in serum, detecting both mature and protryptases and reflecting the increased mast cell burden and abnormal mast cell phenotype of mastocytosis mast cells, are typically elevated during nonacute periods of disease.

5. In the absence of exposure to a known allergen, the diagnosis and treatment of anaphylaxis should be most strongly considered in a patient who presents with the acute onset of which of the following signs or symptoms?

A. Vomiting and diarrhea
B. Abdominal pain
C. Flushing and diarrhea
D. Hypotension
E. Urticaria and wheezing

Answer: E Acute onset of cutaneous signs of immediate hypersensitivity along with either hypotension or respiratory compromise in the apparent absence of allergen exposure; rapid onset of hypersensitivity signs involving at least two organs from among cutaneous, gastrointestinal, respiratory, and cardiovascular systems after exposure to a likely allergen; or rapid onset of hypotension after exposure to a known allergen can be used to diagnose systemic anaphylaxis in real time. In the scenario presented, lacking exposure to a known allergen, answers A and B only involve one organ system, C does not exhibit hypotension or respiratory signs, and D lacks cutaneous signs.

254 DRUG ALLERGY

LESLIE C. GRAMMER

DEFINITION

Adverse drug reactions (ADRs) are recognized as an important public health problem as they result in both morbidity and mortality. An ADR is defined by the World Health Organization as an unintended, noxious response to a drug that occurs at a dose usually prescribed for human patients. The classic pharmacologic definition of ADRs by Rawlins and Thompson separates these into two major types: type A reactions, which are predictable and dose dependent; and type B reactions, which are unpredictable and not dose dependent. Type B reactions account for 10 to 25% of all ADRs and include drug allergy. The World Health Organization Nomenclature Review Committee defines *drug allergy* as a hypersensitivity reaction for which a definite immunologic mechanism, either a B-cell–mediated (antibody) or a T-cell–mediated process, is documented. Most published epidemiologic studies refer to ADRs in general and not to drug allergy specifically because the demonstration of drug-specific B-cell–mediated or T-cell–mediated mechanisms is often difficult, and the immunologic culprit may be a drug metabolite.

EPIDEMIOLOGY

Drug allergy is responsible for significant mortality, morbidity, and socioeconomic costs that are probably underestimated. Current data must be evaluated carefully because they involve different populations, different definitions of ADRs and drug allergy, and different methodologies, especially in terms of data analysis. The Boston Collaborative Drug Surveillance Program collected information on all ADRs in 4031 hospitalized patients during a period of 6 months. An incidence of 6.1% was reported, of which 42% were severe; 1% of the severe reactions resulted in the patient's death. Using an automatic detection system in a Salt Lake City hospital, Claussen and coinvestigators identified 731 ADRs among 36,653 hospitalized patients. Of note, only 12.3% of these were reported by physicians in the hospital. In a meta-analysis of 33 U.S. prospective studies from 1966 to 1996, Lazarou reported that 15% of hospitalized patients experienced ADRs and that the frequency of drug-related hospital admissions varied from 3 to 6%. Most other subsequent studies reported similar data.[1] Epidemiologic information on drug allergy in nonhospitalized people and in the general population is even more limited and is confined mainly to studies of antibiotics.

Risk Factors

Some risk factors have been identified for the development of drug allergy.[2] Certain drugs more commonly cause adverse reactions, and some drugs lead to more severe reactions (Table 254-1). The dosage and route of administration of a drug can also be risk factors; intermittent, repeated administrations of a drug can be more sensitizing than uninterrupted therapy. Drug allergy is more commonly reported in women and in patients with HIV infection[3] or reactivation of some herpes viruses. Some ethnic groups appear to be more prone to certain ADRs. For example, white Americans are at a higher risk than other ethnic groups for hypersensitivity reactions to abacavir, a reverse transcriptase inhibitor. For drug allergy caused by angiotensin-converting enzyme inhibitors, the more vulnerable population is African American.

In the United States, approximately 10% of individuals who seek health care have a history of penicillin allergy. However, if tested with an appropriate panel of skin tests, less than 10% of those individuals would be deemed to have a penicillin allergy. Individuals with a positive history and negative skin test results tolerate penicillin-type antibiotics at the same rate as the general population with a negative history; in addition, there is a very low rate of resensitization.

TABLE 254-1 DRUGS FREQUENTLY IMPLICATED IN ALLERGIC DRUG REACTIONS

Allopurinol
Amiodarone
Antiarrhythmic drugs (procainamide, quinidine)
Antibiotics (β-lactams, sulfas, nitrofurans)
Anticonvulsants (hydantoin, phenobarbital, carbamazepine)
Antihypertensive agents (angiotensin-converting enzyme inhibitors)
Antipsychotic tranquilizers
Antisera (antitoxins, antivirals)
Antituberculous drugs (isoniazid, rifampicin)
Aspirin and nonsteroidal anti-inflammatory drugs
Biologics (monoclonal antibodies such as anti–tumor necrosis factor and other recombinant DNA protein products)
Chemotherapy agents (cisplatin, doxorubicin, taxanes)
Enzymes (L-asparaginase, streptokinase, chymopapain)
Heavy metals (gold salts)
Muscle relaxants (rocuronium, succinylcholine)
Radiocontrast media
Vaccines (egg protein, gelatin)

PATHOBIOLOGY

Hypersensitivity reactions to drugs can be classified according to the type of immunologic reaction, as originally described by Gell and Coombs with later modifications by Janeway, Kay, and Pichler. An immunologic response to any antigen may be diverse and the resulting reaction complex; drugs are no exception. Drugs that are more frequent perpetrators of significant allergy are listed in Table 254-1.

Most pharmacologic agents are simple structures with a molecular mass of less than 1000 D. Alone, they are unable to induce hypersensitivity-type immunologic responses. However, most of these agents have the ability to covalently bind to proteins and form hapten-carrier complexes, with the low-molecular-weight agent acting as the hapten and the protein being the carrier. Hapten-carrier complexes can induce immunologic responses, with most responses being directed at the hapten. In addition to low-molecular-weight drugs acting as haptens, there is evidence that they may activate immune receptors by binding to them directly. This is known as the pharmacologic interaction with immune receptors (or the p-I) concept.[4]

A well-known example of a low-molecular-weight agent is penicillin. Benzylpenicillin has a molecular mass of approximately 300 D and is metabolized into a penicilloyl hapten moiety. The penicilloyl moiety, which constitutes about 95% of all penicillin metabolites, is referred to as the major determinant because it is the major metabolite in terms of quantity. It has been conjugated to poly-D-lysine to form penicilloyl-polylysine, which is now commercially available as Pre-Pen (ALK-Abelló, Round Rock, TX) for skin testing. The other 5% of penicillin metabolites are referred to as the minor determinants. Although they are minor in quantity, these determinants actually cause most of the immediate-type anaphylactic reactions, whereas the major determinant is associated with later and less severe reactions. Minor determinant reagents have never been commercially available in the United States. Penicillin skin testing[5] is not widely used by U.S. physicians; annually, only 40,000 doses of the major determinant are sold.

In contrast to simple low-molecular-weight drugs, therapeutic agents that are proteins with a molecular mass exceeding 5000 D can be recognized by the human immune system and can result in sensitization and hypersensitivity reactions on subsequent exposure. Because these proteins are complete antigens, they can be used as skin testing reagents or as antigens or allergens in in vitro assays. Included among therapeutic protein reagents that reportedly cause hypersensitivity are antithymocyte globulin (rabbit or equine), streptokinase, latex, and vaccines such as tetanus toxoid. Biologics, including monoclonal antibodies, are increasingly recognized causes of drug hypersensitivity. As anticipated, murine antibodies are most immunogenic, followed by chimeric and then humanized monoclonals. Unexpectedly, a variety of human recombinant proteins, including insulin and fully human monoclonal antibodies, can cause hypersensitivity reactions. In addition to hypersensitivity reactions, biologics such as monoclonal antibodies can cause other immunologic reactions (Chapter 36). One such reaction is the *cytokine release syndrome*, in which high cytokine levels result in systemic symptoms, including fever, arthralgia, and capillary leak; interleukin-2 is the original biologic agent in which this was described.[6] Immune imbalance is another immunologic reaction, exemplified by anti–tumor necrosis factor therapy that results in immune dysregulation consisting of increased susceptibility to infection or autoimmunity.

CLINICAL MANIFESTATIONS

The clinical manifestations of drug allergy often include a dermatologic component (Chapter 440). It is estimated that 80 to 90% of drug allergies result in one of the following cutaneous manifestations: exanthematous or morbilliform eruption; urticaria, angioedema, or both; contact dermatitis; fixed drug eruption; erythema multiforme–like eruption; or photosensitivity.[7] Severe cutaneous adverse reactions (SCARs) are generally induced by drugs and encompass the conditions of Stevens-Johnson syndrome and toxic epidermal necrolysis; drug-induced eosinophilia and systemic syndrome, also known as drug-induced hypersensitivity syndrome; and acute generalized exanthematous pustulosis. These conditions, although rare, cause significant morbidity and even mortality, which is why it is important for the treating physician to promptly recognize SCARs and to discontinue implicated drugs. Some features of SCARs that distinguish them from nonserious cutaneous reactions include involvement of other organs (e.g., liver, kidneys); fever; eosinophilia; mucosal involvement; and lesions that are painful, blistering, or pustular.

DIAGNOSIS

The diagnosis of drug allergy may be simple if a patient has recently started therapy with a single agent known to cause hypersensitivity, such as a β-lactam antibiotic. In contrast, in a hospitalized patient in whom multiple drugs have been started and stopped, identifying the offending drug may be difficult, requiring a complete and exhaustive history along with a physical examination. It also requires compatible clinical manifestations and temporal relationships. In vitro tests are rarely useful clinically. In vivo testing, such as cutaneous tests and provocative test dosing, may be indicated in some situations.

Differential Diagnosis

To distinguish drug allergy from other ADRs, several criteria are helpful.[8] Allergic reactions occur in a tiny fraction of individuals who receive the drug, and they cannot be predicted. The observed clinical effects do not resemble known pharmacologic actions of the drug. In the absence of prior exposure to the drug, allergic or hypersensitivity symptoms rarely appear before 1 week of continuous therapy. In general, drugs used consistently for several months or longer are rarely responsible.

Drug allergy often resembles other allergic or hypersensitivity reactions, such as anaphylaxis, urticaria, and serum sickness–like illness. Although most drug reactions include cutaneous manifestations, some involve only other organ systems, for example, pulmonary infiltrates with eosinophilia, hepatitis, and acute interstitial nephritis. A list of drugs that cause organ-specific reactions is provided in Table 254-2. Drug-specific antibodies or T-cell receptors have been identified that react with the suspected drugs or relevant drug metabolites. As with ADRs in general, the reaction often subsides after the drug is discontinued. However, a hypersensitivity reaction may persist or

TABLE 254-2 ORGAN-SPECIFIC REACTIONS AND IMPLICATED DRUGS

REACTION	IMPLICATED DRUG
PULMONARY MANIFESTATIONS	
Pulmonary infiltrates with eosinophilia	Minocycline, nitrofurantoin
Pneumonitis and fibrosis	Bleomycin, amiodarone
Noncardiogenic pulmonary edema	Hydrochlorothiazide, cocaine, heroin, methadone
AUTOIMMUNE MANIFESTATIONS	
Drug-induced lupus	Hydralazine, procainamide
DRUG-INDUCED IMMUNE CYTOPENIAS	
Thrombocytopenia	Quinidine, gold salts, sulfonamides, heparin
Hemolytic anemia	Penicillin, methyldopa
Agranulocytosis	Sulfonamides, propylthiouracil, quinidine, procainamide, phenytoin
HEPATIC MANIFESTATIONS	
Cholestasis	Aminosalicylic acid, dapsone
Hepatocellular damage	Phenothiazines, erythromycin
Mixed pattern	Halothane, isoniazid, diclofenac
	Phenytoin, sulfonamides
RENAL MANIFESTATIONS	
Nephrotic syndrome	Gold salts, captopril, NSAIDs, penicillamine
Acute interstitial nephritis	β-Lactam antibiotics, NSAIDs, sulfonamides
LYMPHOID SYSTEM MANIFESTATIONS	
Pseudolymphoma	Phenytoin
Infectious mononucleosis–like syndrome	Aminosalicylic acid, dapsone
CARDIAC MANIFESTATIONS	Sulfonamides, β-lactam antibiotics
NEUROLOGIC MANIFESTATIONS	
Peripheral neuritis	Colchicine, nitrofurantoin, sulfonamides

NSAIDs = nonsteroidal anti-inflammatory drugs.

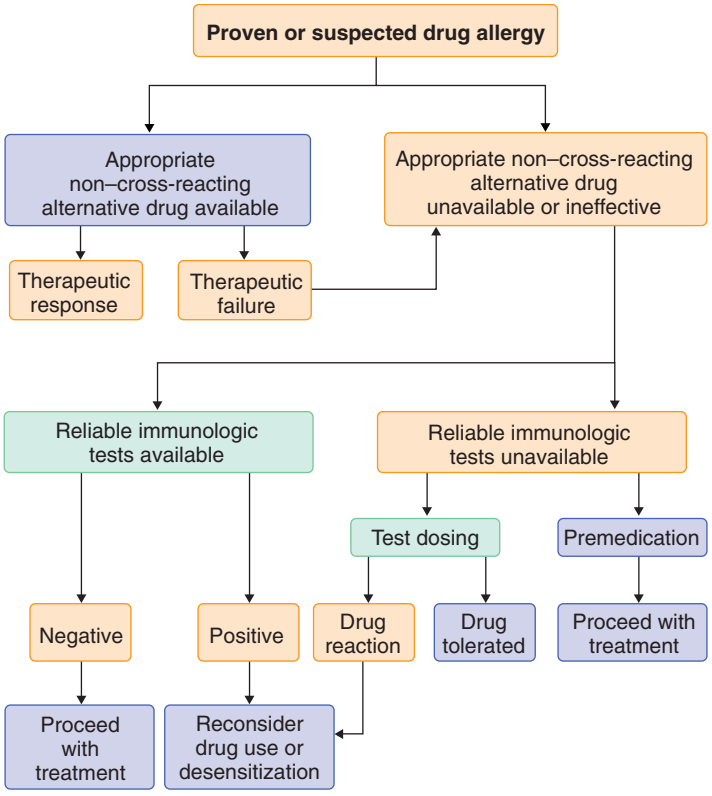

FIGURE 254-1. Guidelines for the treatment of patients with a history of drug allergy. In patients with a suspected or known drug allergy, the first choice is to use an appropriate non–cross-reacting drug. If such a drug is not available, or if the patient does not respond to it, further evaluation is based on the availability of a reliable immunologic test to detect drug hypersensitivity.

even intensify because of the formation of drug metabolites, which act as haptens and bind to carrier proteins such as human serum albumin.

TREATMENT

Evidence-Based Treatments

There is a paucity of evidence-based information regarding drug allergy, a disease that is generally iatrogenic. One study evaluated HIV patients who previously had an adverse reaction to cotrimoxazole; it was concluded that desensitization resulted in fewer adverse reactions and fewer treatment discontinuations in patients with a previous history of mild or moderate hypersensitivity.[A1] A second study, evaluating treatment for toxic epidermal necrolysis, concluded that there are no randomized controlled trials of the most commonly used therapies (i.e., systemic steroids, cyclosporine, intravenous immune globulins).

There are published clinical guidelines for the management of infusion-related hypersensitivity reactions caused by the administration of chemotherapeutic or biologic therapy. These guidelines were developed as part of a performance improvement initiative and resulted in a standardized approach to the management and reporting of ADRs.

PREVENTION

Although the outcome of ADRs is generally favorable, prevention is the obvious goal. The physician should prescribe medications only if they are clinically appropriate and, if possible, should avoid drugs that are known to produce significant hypersensitivity reactions (see Table 254-1). Before starting a medication, the patient should be asked about prior ADRs to the medication or to other pharmacologically related medications. If appropriate, oral administration is probably preferable to parenteral administration; anaphylaxis is less likely, as is sensitization. Protocols for skin testing to foreign antisera and for management of medication hypersensitivity reactions (e.g., premedication, test dosing, desensitization) are available.[9,10] Therapeutic guidelines regarding treatment of the most important and common ADRs are also reviewed in those references.[11] A general algorithm is provided in Figure 254-1.

The risk of an anaphylactic reaction to a drug such as penicillin is a function of the history of onset, severity, and proximity (Table 254-3). If an individual experienced an immediate-type reaction that was rapid in onset, involved life-threatening symptoms or signs, and occurred relatively recently, that individual is at high risk for a severe anaphylactic reaction on subsequent exposure.

TABLE 254-3 RISK OF ANAPHYLACTIC REACTION TO PENICILLIN OR OTHER PHARMACOTHERAPEUTIC AGENTS

FACTOR	LOW RISK	HIGH RISK
Onset of previous reaction	>24 hr	<30 min
Signs and symptoms of previous reaction	Morbilliform eruption Urticaria alone	Life-threatening symptoms: hypotension, upper airway angioedema, bronchospasm
Time elapsed since previous reaction	>20 yr	<1 yr

Even with a negative Pre-Pen skin test result, a patient could have reactivity against minor determinants; therefore, the approach to a patient who needs a β-lactam antibiotic depends on the risk as listed in Table 254-3. Risks and benefits should be thoroughly discussed and documented. In a high-risk individual, cautious test dosing can be performed. If a reaction occurs, desensitization can be considered if the clinical risks and benefits so warrant.

PROGNOSIS

Most drug allergies involve cutaneous eruptions that are self-limited and resolve shortly after the offending agent has been discontinued. However, severe, life-threatening reactions occur in approximately 1 in every 1000 hospitalized patients. SCARs are especially likely to cause morbidity and mortality. In 1998, the death rate for hospitalized Medicare patients was 20% higher in those who experienced an ADR. The proportion of ADRs that were allergic reactions was not determined in this study, but it can be estimated at about one fifth. The incidence of adverse cutaneous reactions to drugs is higher in women than in men. There is also an increased incidence of ADRs in the elderly.

One of the most severe reactions associated with drug allergy is anaphylactic shock (Chapter 253). It is usually immunoglobulin E (IgE) mediated, but it may occur with non–IgE-mediated reactions to drugs such as nonsteroidal anti-inflammatory drugs or radiocontrast media. It is estimated that approximately 1500 people die annually in the United States owing to anaphylaxis from medications. In the United Kingdom, drugs are the leading cause of anaphylactic fatalities.

FUTURE DIRECTIONS

Pharmacogenomics will be an important method of identifying those individuals at risk for a significant allergic reaction to a given drug.[12] Human leukocyte antigen (HLA) genotyping can reportedly identify individuals who are at increased risk for drug hypersensitivity. For example, individuals with HLA-B*5701 are at greater risk for a drug hypersensitivity reaction to abacavir, an HIV transcriptase inhibitor. Severe cutaneous adverse reactions to allopurinol are highly associated with the genetic marker HLA-B*5801. In patients of Asian ancestry, HLA-B*1508 is highly associated with development of Stevens-Johnson syndrome if carbamazepine is prescribed. Why this genetic variant is not a risk factor in patients of African or European ancestry is unclear.[13] Other avenues by which susceptible individuals may be identified include polymorphisms in genes for immune recognition molecules, drug-metabolizing enzymes, and macromolecular adduct repair systems.

REVIEW QUESTIONS

1. Which of the following drugs is *most* likely to cause drug hypersensitivity?

A. Murine monoclonal anti-CD3 antibody
B. Human insulin
C. Chimeric monoclonal anti-CD20 antibody
D. Humanized tumor necrosis factor antibody
E. Human tumor necrosis factor antibody

Answer: A Biologic proteins from most to least allergenic are murine, chimeric, humanized, and finally fully human protein. Even fully human proteins like human insulin or fully human anti–tumor necrosis factor can cause hypersensitivity. However, the most likely protein to cause drug allergy is the most foreign protein, that is, a murine protein. (See Pathobiology.)

2. Which of the following clinical characteristics is *least* concerning for a serious cutaneous adverse reaction (SCAR) to a drug?

A. Blistering lesions
B. Painful lesions
C. Pruritic lesions
D. Pustular lesions

Answer: C Some features of SCARs that distinguish them from nonserious cutaneous reactions include involvement of other organs (e.g., liver, kidneys); fever; eosinophilia; mucosal involvement; and lesions that are painful, blistering, or pustular. Pruritus is not a distinguishing feature.

3. A patient taking multiple medications develops acute interstitial nephritis with normal findings on skin examination. Which of the listed drugs is the most likely culprit?

A. Propranolol
B. Phenytoin
C. Colchicine
D. Ampicillin

Answer: D Although most drug reactions include cutaneous manifestations, some only involve other organ systems, for example, pulmonary infiltrates with eosinophilia, hepatitis, and acute interstitial nephritis. Drugs that have been described to cause acute interstitial nephritis in the absence of cutaneous involvement include sulfonamides, nonsteroidal anti-inflammatory drugs, and penicillins like ampicillin and methicillin.

4. HLA genotyping has been useful in identifying individuals at increased risk of hypersensitivity to which of the following drugs?

A. Amoxicillin
B. Minocycline
C. Ganciclovir
D. Abacavir

Answer: D Human leukocyte antigen (HLA) genotyping can reportedly identify individuals who are at increased risk for drug hypersensitivity. For example, individuals with HLA-B*5701 are at greater risk for a drug hypersensitivity reaction to abacavir, an HIV transcriptase inhibitor. At many centers, abacavir is prescribed only after the HLA genotype is determined not to be HLA-B*5701.

5. Among the following, what is the *most* significant risk factor for drug allergy?

A. Male sex
B. HIV infection
C. Atopy
D. HLA-B27 genotype

Answer: B Drug-related rashes have been estimated to be 100 times more common in HIV-positive patients than in the general population. The reasons for this are not clear but are likely to be multifactorial and include changes in drug metabolism, oxidative stress, cytokine profiles, and immune hyperactivation. (See section Risk Factors under Epidemiology.)

255

MASTOCYTOSIS

CEM AKIN

DEFINITION

Mastocytosis is a heterogeneous group of disorders characterized by pathologic accumulation of mast cells in tissues such as skin and bone marrow. According to the classification of the World Health Organization (WHO), based on clinical presentation and pathologic findings, there are seven distinct categories of mastocytosis (Table 255-1). The term *cutaneous mastocytosis* describes skin disease alone without any evidence of internal organ involvement, whereas the term *systemic mastocytosis* describes the disorder when it involves internal organs (most commonly the bone marrow) with or without skin disease.

EPIDEMIOLOGY

Mastocytosis can be diagnosed at any age.[1] Pediatric-onset and adult-onset forms are distinguished on the basis of the age of the patient at initial diagnosis. These forms display differences in their clinical course, molecular pathology, and prognosis. The most common clinical scenario leading to diagnosis in the pediatric population is a child presenting with skin lesions of cutaneous mastocytosis within the first year of life. Patients with a later onset of skin lesions are more likely to have systemic mastocytosis, as are most patients with adult-onset mastocytosis. The disease has been diagnosed in all ethnic populations. Estimates of the prevalence of patients with cutaneous mastocytosis range from 1 in 500 to 1 in 8000 patients presenting in dermatology clinics. The prevalence of systemic mastocytosis is more difficult to estimate because the diagnosis requires biopsy of an involved tissue and a high degree of clinical suspicion, especially if skin lesions are absent. Systemic mastocytosis is likely to be underdiagnosed, considering the fact that there are neither physical examination findings nor routine hematologic or chemistry laboratory abnormalities specifically associated with the disease. Consequently, it is not unusual to encounter several years' delay after the onset of symptoms in many patients before a diagnosis of mastocytosis is reached. The disease is sporadic, although rare cases of familial occurrence have been described.

PATHOBIOLOGY

Pathogenesis

The pathogenesis of mastocytosis involves the accumulation of mast cells in tissues, with mediators released by activated mast cells. The primary reason for the increased mast cell numbers in tissues appears to be defective apoptosis rather than uncontrolled proliferation. It is unusual to see increased mitotic activity in biopsy specimens from patients with mastocytosis, and, in most patients, the disease follows an indolent course. Tissue microenvironment and altered chemotaxis may also contribute to the final level of tissue mast cell burden.

Genetics

Mast cells are derived from hematopoietic progenitors (Chapter 156). Systemic mastocytosis is associated with somatic gain-of-function point mutations in the *KIT* (formerly *c-kit*) gene of the mast cell progenitor, leading to a clonal neoplastic expansion of mast cells. *KIT* encodes a transmembrane receptor (Kit) whose intracellular portion functions as a tyrosine kinase enzyme. The extracellular portion of Kit binds the cytokine stem cell factor (SCF or Kit ligand). The interaction between SCF and Kit provides the single most important growth and differentiation stimulus for mast cells from their progenitors. Under physiologic conditions, homodimeric SCF binds and cross-links two Kit receptor molecules, which leads to autophosphorylation of the tyrosine amino acids of the intracellular portion of the Kit molecule. Phosphorylated tyrosine residues in turn act as docking sites for downstream adaptor and signal transduction molecules that regulate the differentiation, proliferation, chemotaxis, and functional activation of mast cells.

The most common mutation reported in mastocytosis[2] involves codon 816 in *KIT* (located in exon 17), resulting in the replacement of an aspartic acid by a valine residue (D816V) in the Kit protein, leading to ligand-independent autophosphorylation. The D816V mutation has been shown in lesional mast cells from the skin or bone marrow tissue of more than 90% of adults and approximately 40% of pediatric patients with mastocytosis. Another 40% of pediatric patients carry *KIT* mutations in other exons, most commonly in exons 8 and 9. *KIT* mutations can be demonstrated in non–mast cell hematopoietic lineages in advanced variants of systemic mastocytosis, similar to the multilineage involvement observed in myeloproliferative neoplasms (Chapter 166). The sensitivity of detecting the mutation is much higher when a lesional tissue such as bone marrow or skin is analyzed compared with peripheral blood. Other pathogenetic factors, some yet to be determined, appear to be responsible for the final disease phenotype because the presence of the D816V *KIT* mutation alone does not explain the remarkable heterogeneity in the clinical presentation and prognosis of the disease. Molecular aberrations in *TET2*, *SRSF2*, *ASXL1*, *CBL*, *RUNX1*, and *DNMT3A* were the other most frequently identified mutations in advanced forms of systemic mastocytosis. In advanced systemic mastocytosis, most patients carry three or more mutations.

CLINICAL MANIFESTATIONS

Symptoms

The symptoms of mastocytosis are primarily related to the release of mast cell mediators and rarely by the destructive infiltration of mast cells into tissues. Mast cell activation results in the release of various preformed mediators stored in mast cell granules, de novo synthesis of sulfidopeptide leukotrienes such as LTC_4 and prostaglandins (mostly PGD_2) from membrane lipids, and cytokine synthesis. Preformed mediators stored in mast cell granules include histamine; proteases such as tryptase, chymase, and carboxypeptidase A; and proteoglycans such as heparin and chondroitin sulfate. Vasoactive mediators such as histamine, LTC_4, and PGD_2 at local or distant tissues cause vasodilation, which may lead to flushing, tachycardia, hypotension, presyncope, and syncope. Histamine also causes pruritus and stimulates gastric acid hypersecretion from parietal cells. Mast cells are rich sources of cytokines. Elevated serum levels of tumor necrosis factor-α and interleukin-6 have been found in patients with mastocytosis and may contribute to the pathophysiologic process of fatigue and accelerated osteoporosis observed in some patients. Rare aggressive categories of mastocytosis may be associated with an extensive destructive infiltration of mast cells into tissues such as the gastrointestinal tract, which may result in malabsorption, and the liver, which may cause portal fibrosis with associated portal hypertension.

Mast cell activation and mediator release may occur after triggers, such as temperature changes (e.g., hot showers), exercise, ingestion of alcohol or spicy foods, emotional stress, insect stings, and exposure to certain drugs (such as opioid analgesics, nonsteroidal anti-inflammatory drugs, or muscle relaxants), and sometimes spontaneously without an obvious trigger. The prevalence of atopic disease in patients with mastocytosis is similar to that in the general population, and the serum immunoglobulin E (IgE) level is often found to be low. However, patients with anaphylactic sensitivity to hymenoptera venoms appear to have a disproportionately high incidence of mastocytosis.[3]

Mastocytosis is a disease with protean clinical manifestations. Although in some patients the only complaint is the cosmetic appearance of urticaria pigmentosa lesions, others suffer from frequent episodes of vascular instability or have life-threatening hematologic disease. In general, patients with mastocytosis belong to one of two broad categories, according to the site of tissue involvement: those with cutaneous disease alone, or those with systemic disease with or without skin involvement. Cutaneous mastocytosis (i.e., disease limited to the skin in the absence of internal organ involvement)

FIGURE 255-1. Urticaria pigmentosa.

is commonly diagnosed in children within the first year of life, whereas systemic mastocytosis is mostly diagnosed in adults by a bone marrow biopsy and aspirate.

Cutaneous Manifestations

Maculopapular skin lesions of urticaria pigmentosa are the most common presentation of cutaneous mastocytosis (Fig. 255-1). They are also present in 50 to 90% of patients with systemic mastocytosis, depending on the disease category. Remarkably different in appearance from urticaria or hives, lesions of urticaria pigmentosa are fixed, tan- to salmon-colored lesions varying in size from a few millimeters to a few centimeters. They are most prominently observed on the trunk and extremities and tend to spare the face and the sun-exposed areas of the skin, although facial involvement may be seen in children. Blistering of the lesions may occur in children in the first 3 years of life. The lesions are generally not pruritic at rest but may urticate after exposure to a number of triggers (see Pathobiology). Many patients note that the skin lesions become more prominent after exposure to heat or after physical irritation such as rubbing. The lesions may be found concentrated in skin areas that are prone to irritation, such as the axillae and groin.

Uncommon presentations of cutaneous mastocytosis include mastocytomas, diffuse cutaneous mastocytosis, and telangiectasia macularis eruptiva perstans (TMEP). Mastocytomas are benign and generally solitary mast cell tumors, although they have been known to precede urticaria pigmentosa lesions in some cases. They occur almost exclusively in children, and physical irritation of the lesion may result in generalized flushing and other symptoms of mast cell mediator release. Diffuse cutaneous mastocytosis is another form of skin involvement seen exclusively in children. It is characterized by diffuse thickening of the skin and appendages with a peau d'orange appearance without individual urticaria pigmentosa lesions. TMEP is a rare form of cutaneous mastocytosis characterized by the presence of diffuse telangiectatic macules. Because TMEP lesions are generally seen in the presence of urticaria pigmentosa, there is debate about whether TMEP represents a distinct form of cutaneous mastocytosis.

Patients with cutaneous mastocytosis may manifest systemic symptoms, such as abdominal pain, diarrhea, and flushing.

Systemic Manifestations

Symptoms caused by mast cell degranulation may be experienced as brief, recurrent, and self-limited episodes with multiorgan manifestations or as chronic complaints during a prolonged time course. A typical mast cell degranulation episode may variably involve flushing, conjunctival hyperemia, nausea, vomiting, abdominal cramping, diarrhea, tachycardia, and lightheadedness. Hypotension may develop, and the episode may progress to full loss of consciousness in some patients. Therefore, mastocytosis should be ruled out in all patients with recurrent anaphylaxis before a diagnosis of idiopathic anaphylaxis can be made.[4] Tryptase, a protease stored in mast cell granules, may be elevated above the patient's baseline level in the serum or plasma if it is measured within 3 hours after the onset of the episode in patients with suspected mast cell degranulation or anaphylaxis, regardless of the cause. Angioedema, hives, and wheezing are uncommon in mastocytosis, in contrast to idiopathic anaphylaxis. Flushing usually involves the face and upper chest area. A consistent trigger can be identified in only a small number of patients (see Pathobiology). The episodes usually last 30 minutes to a few hours. Hypotensive episodes can be life-threatening, particularly in the presence of comorbidities, such as cardiac or pulmonary disease. Systemic mastocytosis should be suspected in all patients with systemic reactions to hymenoptera stings, especially those involving hypotensive syncope or near-syncope.

Gastrointestinal Symptoms

Gastrointestinal symptoms are observed in more than 50% of patients with mastocytosis. Epigastric pain, lower abdominal cramping, nausea, vomiting, or diarrhea can occur episodically in the context of an acute mast cell degranulation episode or on a chronic basis. Gastric acid hypersecretion induced by mast cell–derived histamine may lead to esophagitis, gastritis, and peptic ulcer disease, although measurements of basal acid output have shown great variability in different studies, ranging from hypersecretion in the range of Zollinger-Ellison syndrome to achlorhydria. Mucosal edema, thickened gastric or duodenal mucosal folds, or nodular lesions may be observed in radiographic or endoscopic evaluations. Diarrhea alternating with constipation may be seen. Severe persistent diarrhea may be complicated by clinically significant malabsorption in patients with aggressive systemic mastocytosis. Hematochezia, hematemesis, and melena are uncommon symptoms and should prompt endoscopic evaluation to rule out coexisting disease. Mast cells are constituents of the normal lamina propria in gastrointestinal mucosa, and their numbers may be increased in inflammatory states affecting the gastrointestinal tract. However, quantitation of mast cell numbers in gastrointestinal biopsy specimens is generally not helpful, and diagnosis of mast cell disease by a gastrointestinal biopsy, solely based on increased mast cell numbers without evidence for other WHO criteria, should be avoided. Mild to moderate hepatomegaly with or without abnormalities in serum transaminases may be observed, although portal hypertension and ascites are rare and indicate the presence of advanced categories of mastocytosis. Jaundice and findings on cholangiography resembling those of primary sclerosing cholangitis have been reported in some patients.

Musculoskeletal Symptoms

Musculoskeletal pain is common in patients with mastocytosis and is mostly caused by soft tissue pain resembling fibromyalgia. Accelerated osteoporosis may be seen in a subgroup of patients, particularly those with other risk factors, such as postmenopausal women, and those receiving glucocorticoid therapy. Pathologic compression fractures may be the initial finding in some patients.[5] A bone densitometry measurement should be recommended as part of the standard evaluation of women with mastocytosis and of any patient with a history of pathologic fractures. Radiographic abnormalities have been reported in up to 75% of patients with mastocytosis. In addition to generalized osteoporosis, bone surveys may show a mixture of sclerotic or lytic lesions, and skeletal scintigraphy may reveal focal or diffuse radiotracer uptake.

Hematologic Manifestations

Peripheral blood abnormalities have been noted in up to 50% of patients with systemic mastocytosis. Mild normochromic normocytic anemia is the most common abnormality, followed by thrombocytopenia, eosinophilia, monocytosis, and leukopenia. Eosinophilia in mastocytosis rarely causes organ damage, as is observed in chronic eosinophilic leukemia or idiopathic hypereosinophilic syndrome (Chapter 170). It is important to differentiate a primary eosinophilic disorder from mastocytosis with eosinophilia. Some cases of chronic eosinophilic leukemia are associated with the *FIP1L1-PDGFRA* fusion gene and respond to the drug imatinib, whereas systemic mastocytosis is associated with codon 816 point mutations of the *KIT* gene, which confers resistance to this drug.

Approximately 20% of patients with systemic mastocytosis have been reported to display evidence of another clonal non–mast cell hematologic disease. Non–mast cell clonal hematologic neoplasms associated with mastocytosis are commonly myeloid in nature (myeloproliferative neoplasms, myelodysplastic syndromes, or myeloid leukemias) but may also involve lymphoproliferative disorders, such as lymphomas, myelomas, and lymphocytic leukemias.

DIAGNOSIS

The diagnosis and classification of mastocytosis are carried out according to the guidelines published by the WHO. A suggested algorithm for the diagnosis of mastocytosis is shown in Figure 255-2.

Cutaneous Mastocytosis

Diagnosis of cutaneous mastocytosis is made by observing the typical hyperpigmented maculopapular lesions of urticaria pigmentosa and is confirmed

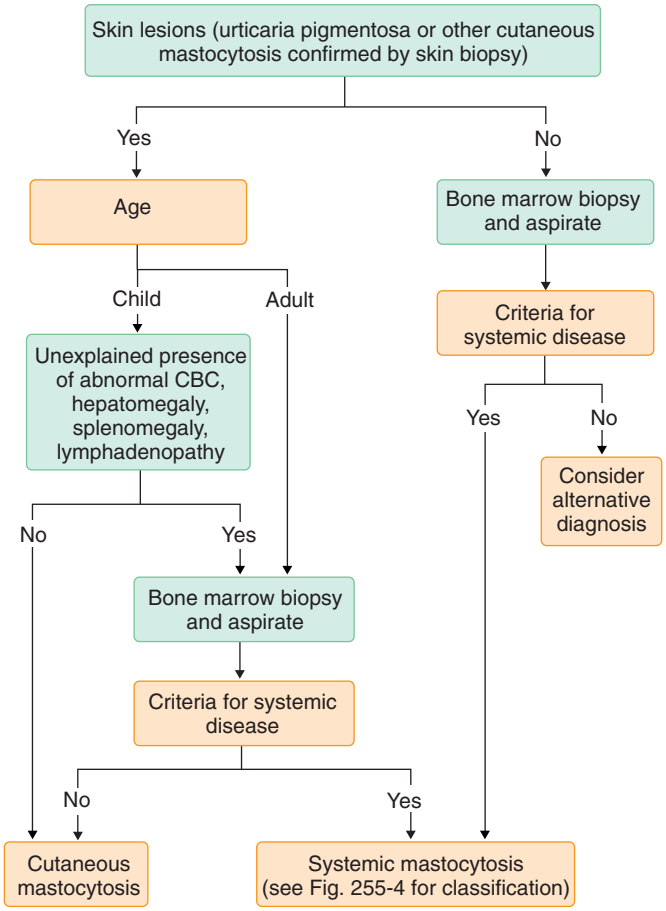

FIGURE 255-2. Suggested diagnostic algorithm for mastocytosis. CBC = complete blood count.

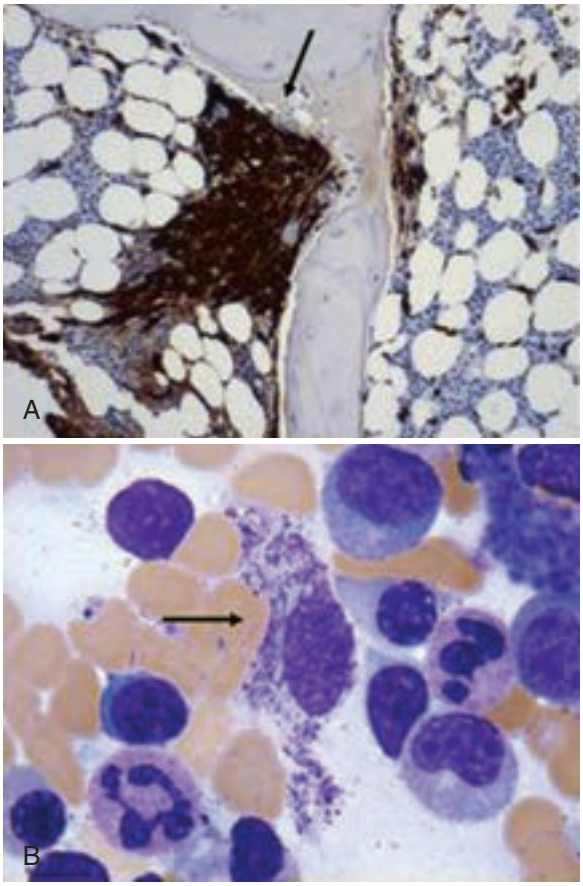

FIGURE 255-3. Diagnostic findings in the bone marrow biopsy specimen and aspirate smear. A, Characteristic mast cell aggregates on tryptase staining (major criterion) in biopsy section (*arrow*). **B,** Mast cells with atypical spindle shapes in aspirate smear *(arrow)*.

by skin biopsy, which shows infiltration of mast cells in the upper dermis, particularly in perivascular locations. Mild increases in mast cell numbers can be observed in inflammatory and neoplastic skin diseases, and establishing a diagnosis of cutaneous mastocytosis by a blind skin biopsy or biopsy of a lesion that does not have the typical appearance of urticaria pigmentosa should be avoided. A localized wheal-and-flare reaction limited to the lesional skin within a few minutes after rubbing or scratching of the skin is known as Darier's sign. Diagnosis of urticaria pigmentosa in adults should always prompt investigation of possible systemic mastocytosis.

Systemic Mastocytosis

Biopsy

The recommended diagnostic procedure to evaluate the presence of WHO diagnostic criteria for systemic disease (discussed later) is a bone marrow biopsy and aspiration. This procedure is recommended for all patients with adult-onset urticaria pigmentosa, patients with recurrent symptoms suggestive of mast cell degranulation (such as flushing and hypotension accompanied by abdominal complaints), patients with unexplained osteoporosis, and patients with suspected hematologic disease (see Clinical Manifestations). Children with an onset of lesions within the first year of life usually do not require a bone marrow biopsy unless they have abnormal blood counts, lymphadenopathy, hepatomegaly, or splenomegaly. Children with late-onset skin lesions and those who experience persistence of urticaria pigmentosa into adulthood should be considered for diagnostic evaluation for systemic disease.

World Health Organization Diagnostic Criteria

WHO guidelines for diagnosis of systemic mastocytosis consist of one major and four minor criteria (Table 255-2). Presence of the major criterion with at least one minor criterion, or demonstration of three minor criteria in the absence of the major criterion, is needed to establish a diagnosis of systemic mastocytosis and to distinguish it from reactive mast cell hyperplasia. The major diagnostic criterion is the presence of multifocal, dense aggregates of 15 or more mast cells in bone marrow or other extracutaneous tissue biopsy sections (Fig. 255-3A). Such clusters are frequently observed around blood vessels and next to bone trabeculae in bone marrow biopsy sections. Immunohistochemical staining for tryptase is the recommended method for visualization of mast cells. Routine hematoxylin and eosin or metachromatic stains such as toluidine blue are not sufficiently sensitive to demonstrate subtle mast cell infiltrates or abnormal morphologic features of mast cells within the infiltrates in decalcified bone marrow biopsy sections.

Mast cell morphology in bone marrow provides important clues to the diagnosis of systemic mastocytosis. Bone marrow mast cells in systemic mastocytosis often display atypical morphology, such as an elongated (spindle) shape, hypogranularity, and an eccentric or lobulated nucleus (Fig. 255-3B). These atypical mast cells are usually observed in close association with bone

TABLE 255-2 WORLD HEALTH ORGANIZATION DIAGNOSTIC CRITERIA FOR SYSTEMIC MASTOCYTOSIS

MAJOR
Multifocal, dense infiltrates of mast cells consisting of 15 or more mast cells in aggregates detected in sections of bone marrow and/or other extracutaneous organs, confirmed by tryptase immunohistochemistry or other special stains
MINOR
More than 25% of mast cells in biopsy sections or bone marrow aspirate smears showing spindle shape or atypical morphology
Detection of a *KIT* codon 816 point mutation in bone marrow, blood, or other extracutaneous organs
Expression of CD2 and/or CD25 by mast cells in bone marrow, blood, or extracutaneous organs
Persistent elevation of serum total tryptase >20 ng/mL*

*Criterion not valid if there is an associated clonal myeloid disorder.
From Horny HP, Metcalfe DD, Bennett JM, et al. Mastocytosis. In: Swerdlow SH, Campo E, Harris NL, et al, eds. WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues. Lyon, France: IARC Press; 2008:54-63.

marrow spicules in the aspirate smear. Mast cells in mast cell leukemia (MCL) may be very sparsely granulated.

Flow cytometric analysis of the mast cells in a bone marrow aspirate, when it is performed appropriately, is a sensitive diagnostic aid. The mean percentage of mast cells in a healthy bone marrow aspirate is approximately 0.02%, and it does not exceed 1% in most patients with mastocytosis. Therefore, to visualize the mast cell population correctly, the total cell numbers analyzed by flow cytometry should be significantly higher than those in other, more routine evaluations (e.g., leukemia phenotyping). The characteristic flow cytometric finding of systemic mastocytosis is the aberrant expression of CD25 or CD2 on $CD117^+$ mast cells. CD25 is more sensitive than CD2 as CD2 may be absent or weakly expressed in some cases of advanced mastocytosis. Aberrant CD25 expression can also be demonstrated by immunohistochemical staining of bone marrow biopsy specimens.[6] Serum tryptase level may be elevated in patients with mastocytosis.[7] Currently available commercial tryptase immunoassays measure levels of total tryptase, the sum of mature tryptase, and tryptase precursors. Mature tryptase enzyme is a serine protease stored in mast cell granules and is transiently elevated in serum or plasma after mast cell degranulation episodes, such as anaphylaxis. In contrast, tryptase precursor proenzymes (α and β protryptases) are constitutively secreted outside the cell, and their serum levels at baseline correlate with mast cell burden. The median serum tryptase level in a healthy population is approximately 5 ng/mL. A serum tryptase level higher than 20 ng/mL raises suspicion for systemic mastocytosis in the appropriate clinical setting. A normal tryptase level does not rule out a diagnosis of mastocytosis, and increased tryptase levels can be seen in other conditions, such as myelodysplastic syndromes, acute myeloid leukemias, chronic eosinophilic leukemia, and chronic renal insufficiency. Metabolites of histamine, such as *N*-methylhistamine, and prostaglandin D_2 can be elevated in a 24-hour urine specimen but are neither more sensitive nor more specific than the baseline serum tryptase measurement in mastocytosis.

Demonstration of a codon 816 *KIT* mutation (D816V) may be necessary to fulfill the diagnostic criteria in patients lacking the major criterion (see Pathobiology).[8] Examination of lesional tissues, such as skin and bone marrow, affords the highest sensitivity. Codon 816 *KIT* mutations have been detected in a variety of other neoplastic diseases, such as core binding factor acute myeloid leukemias, sinonasal lymphomas, and seminomas, in addition to mastocytosis.

A rare histologic variant with clustering of mature round mast cells without CD25 expression termed well-differentiated systemic mastocytosis has been described. These patients generally have a history of childhood-onset mastocytosis without the D816V *KIT* mutation and therefore may respond to imatinib as opposed to those with typical systemic mastocytosis carrying the D816V mutation (see Treatment).

World Health Organization Disease Categories

Each patient diagnosed with mastocytosis should be assigned a category of disease according to the WHO classification (see Table 255-1). *Cutaneous mastocytosis* in the absence of bone marrow and internal organ involvement is the most common category in patients with pediatric-onset disease.

Systemic mastocytosis is divided into the categories of indolent systemic mastocytosis, systemic mastocytosis with associated clonal hematologic non–mast cell lineage disease (SM-AHNMD), aggressive systemic mastocytosis, and MCL. An algorithm for classification of systemic mastocytosis is presented in Figure 255-4. *Indolent systemic mastocytosis* is the most common category in adults. Patients in this category usually have a normal life expectancy compared with age-matched general populations, although they experience symptoms related to release of mast cell mediators.[9] Indolent systemic mastocytosis follows a persistent course, and progression to a more advanced category is unusual (<5% of cases). *SM-AHNMD* is the second most common category in adults, and a non–mast cell hematologic disease is usually diagnosed at the time that the diagnosis of mastocytosis is made. Therefore, bone marrow biopsy and aspirate specimens should be carefully evaluated for the presence of other hematologic disease in every patient with newly diagnosed systemic mastocytosis. *Aggressive systemic mastocytosis* is a rare category characterized by the presence of organ dysfunction resulting from destructive mast cell infiltration. Aggressive systemic mastocytosis may involve the hematopoietic, gastrointestinal, and skeletal systems in the form of cytopenias, hypersplenism, malabsorption with weight loss, hepatomegaly with portal hypertension and ascites, and large osteolytic lesions with pathologic fractures; these constitute so-called C-findings as defined by the WHO criteria. MCL is characterized by 10% or more mast cells in the peripheral circulation or 20% or more mast cells in bone marrow aspirate smears, or both. To diagnose MCL, the mast cell percentage in bone marrow aspirate smears should be assessed in an area of the slide that is sufficiently distant from the spicules. *Mast cell sarcoma* and *extracutaneous mastocytoma* are rare diagnoses characterized by malignant and benign solid mast cell collections, respectively.

There is a subset of patients with recurrent idiopathic or hymenoptera venom–induced anaphylaxis who have evidence of clonal mast cells carrying the D816V *KIT* mutation or aberrantly expressing surface CD25, without fully meeting the WHO diagnostic criteria and without displaying urticaria pigmentosa skin lesions. Such patients are provisionally referred to as having a monoclonal mast cell activation syndrome.

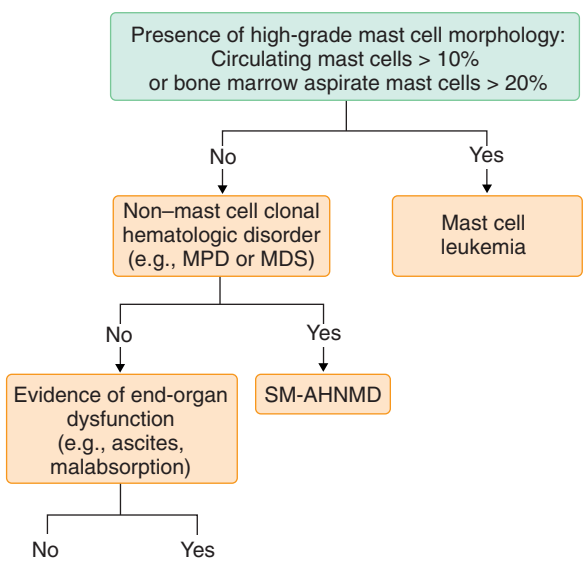

FIGURE 255-4. **An algorithm for classification of systemic mastocytosis.** ASM = aggressive systemic mastocytosis; ISM = indolent systemic mastocytosis; MDS = myelodysplastic syndromes; MPD = myeloproliferative disorders (neoplasms); SM-AHNMD = systemic mastocytosis with associated clonal hematologic non–mast cell lineage disease.

TREATMENT

Rx

The major goal of treatment for all categories of mastocytosis is symptom control. A reduction in mast cell numbers is considered only in disease categories with a poor prognosis (i.e., SM-AHNMD, aggressive systemic mastocytosis, MCL, and mast cell sarcoma).[10,11] Current treatment modalities have not been shown to change the natural course of the disease.[12]

Medical Therapy

Patients with cutaneous and indolent systemic mastocytosis are treated symptomatically. Pruritus in mastocytosis usually responds to scheduled doses of $histamine_1$-receptor blocker antihistamines, such as fexofenadine or cetirizine. Sedating antihistamines, such as hydroxyzine or diphenhydramine, may be used before bedtime. Photochemotherapy (oral psoralen plus ultraviolet A) or phototherapy may be helpful in patients with refractory pruritus; it results in symptomatic improvement and temporary fading of the pigmented skin lesions in up to 50% of patients. The side effects of phototherapy, including increased risk of skin cancer, should be taken into account when this treatment is considered.

$Histamine_2$-receptor blocker antihistamines, such as ranitidine or famotidine, are usually prescribed as a first-line treatment for patients with gastrointestinal complaints, such as heartburn, nausea, and abdominal pain. Proton pump inhibitors may be added in patients whose abdominal symptoms are refractory to $histamine_2$-receptor blockers. Oral cromolyn sodium (adult dose, 200 mg four times daily) has been effective in reducing abdominal pain, diarrhea, nausea, vomiting, and pruritus in various studies, although the beneficial effects are variable among patients. Finally, low to moderate doses of systemic glucocorticoids can be beneficial in unusual cases of aggressive mastocytosis presenting with recalcitrant diarrhea associated with malabsorption or hepatomegaly with ascites.

Cysteinyl leukotrienes, such as LTC_4, that are produced after mast cell activation are thought to contribute to symptoms in mastocytosis. Therefore, drugs targeting the synthesis or receptor binding of leukotrienes are usually added to the treatment regimens of patients who derive suboptimal relief of itching and abdominal pain from histamine receptor–blocking therapy. However, there have been no controlled studies evaluating the clinical efficacy of this class of drugs in patients with mastocytosis.

Self-administered epinephrine should be considered for all patients even if they do not have any history of hypotensive or anaphylactic episodes resulting in presyncope or syncope from acute mast cell degranulation. These episodes should be treated like systemic anaphylaxis (Chapter 253).

Cytoreductive therapy, considered in aggressive disease variants associated with poor prognosis, has yielded disappointing results thus far. Some patients with recurrent life-threatening episodes of mast cell mediator release unresponsive to conventional therapy may also be candidates for cytoreductive therapy after careful consideration of risks and benefits. Approaches to cytoreductive treatment of mastocytosis have included interferon alfa-2b and the nucleoside analogue 2-chlorodeoxyadenosine. Interferon alfa-2b (0.5 to 5 million units, three to five times per week), alone or with prednisone, has been reported to partially improve clinical and laboratory abnormalities in approximately 50% of patients with aggressive systemic mastocytosis, patients with osteoporosis and pathologic fractures, and patients with recalcitrant recurrent anaphylaxis, although complete histopathologic and molecular remissions appear to be rare. Interferon alfa is difficult to tolerate because of its many side effects, including influenza-like symptoms, bone pain, and depression. A regimen of 2-chlorodeoxyadenosine (0.10 to 0.17 mg/kg/day for 5 days, repeated at intervals of 4 to 8 weeks) has been reported to result in partial and transient responses in patients with advanced categories of disease in case reports and small series. MCL usually is treated with polychemotherapy as acute myeloid leukemia (Chapter 183), although a successful treatment regimen has not yet been identified.

Imatinib, a tyrosine kinase inhibitor with activity against wild-type *KIT*, *PDGFR*, and *abl*, has been effective in a small number of patients without D816V *KIT* mutation or with the *FIP1L1-PDGFRA* fusion gene, who present with chronic eosinophilic leukemia (Chapter 170) with a modest increase in bone marrow mast cells. However, most patients with mastocytosis have the D816V *KIT* mutation, which confers resistance to imatinib, and therefore are not appropriate candidates for this therapy.[13]

Ancillary and Other Therapies

Avoidance of the triggers of mast cell degranulation is an important adjunct to the pharmacologic treatment of symptoms. These show remarkable individual variation among patients (see Pathobiology), and the individual medical history can be helpful in identifying such triggers. General anesthesia and surgery impose an additional risk to patients with mastocytosis because several agents that are used perioperatively, such as muscle relaxants, opioid analgesics, and nonsteroidal anti-inflammatory drugs, can induce acute mast cell degranulation. Prior surgical and anesthesia records should be obtained if available, and an appropriate strategy for the anesthetic management of the patient should be determined, with close communication involving the patient, anesthesiologist, surgeon, and an allergist.

Non–mast cell clonal hematologic disorders associated with mastocytosis should be treated according to the standard-of-care guidelines for those disorders, regardless of the presence of mastocytosis. Bone marrow transplantation (Chapter 178) has yielded variable results for the treatment of mast cell disease, and occasional cases resulting in complete remission have been reported.

Venom immunotherapy is recommended for those with a history of systemic reactions to hymenoptera who have evidence of IgE-mediated sensitization (by blood or skin allergy testing). Most experts recommend the duration of the therapy to be indefinite as fatalities have been reported after discontinuation of immunotherapy.

Because of the high prevalence of osteoporosis and pathologic bone fractures in mastocytosis, bone densitometry should be considered a standard diagnostic procedure in adult patients with mastocytosis. If osteoporosis is detected, it should be treated per standard recommendations (Chapter 243).

PROGNOSIS

The prognosis for mastocytosis varies by the category of disease. At least 50% of patients with pediatric-onset cutaneous mastocytosis have complete resolution of the disease by adolescence, and the great majority of the rest of those patients experience improvement or fading of the skin lesions. Indolent systemic mastocytosis is a persistent disease but has a good prognosis without a decrease in life expectancy, and progression to a more aggressive disease category is rare.[14] Factors associated with poorer prognosis have been reported as the absence of urticaria pigmentosa, older age at onset of symptoms, elevated serum lactate dehydrogenase or alkaline phosphatase, thrombocytopenia, anemia, peripheral blood smear abnormalities, and detectability of the D816V *KIT* mutation in peripheral blood. The prognosis for SM-AHNMD is determined by the prognosis for the associated hematologic disorder. Aggressive systemic mastocytosis and MCL have poor prognoses, with median survival times of less than 3 years and less than 1 year, respectively.

REVIEW QUESTIONS

1. Which of the following markers is aberrantly expressed by mast cells in patients with systemic mastocytosis?

A. CD25
B. CD117 (Kit)
C. High-affinity IgE receptor
D. CD45

Answer: A CD25 (alpha chain of the interleukin-2 receptor) is aberrantly expressed and is a sensitive diagnostic marker in systemic mastocytosis. All others are expressed by both normal and pathologic mast cells. (Valent P, Horny HP, Escribano L, et al. Diagnostic criteria and classification of mastocytosis: a consensus proposal. *Leuk Res.* 2001;25:603-625.)

2. A 25-year-old woman has recently been diagnosed with systemic mastocytosis by a bone marrow biopsy. There was no other hematologic disease noted. She experiences pruritus of the skin in hot weather and occasional abdominal cramping but is otherwise asymptomatic. *KIT* mutational analysis reveals the D816V mutation in bone marrow. Which of the following is the most appropriate treatment?

A. Imatinib
B. H_1 and H_2 antihistamines
C. Prednisone
D. Interferon alfa
E. Bone marrow transplantation

Answer: B This patient has indolent systemic mastocytosis and should be treated symptomatically. Cytoreductive therapies such as interferon alfa are indicated in patients with aggressive mastocytosis. The patient is not a candidate for imatinib because of indolent disease and presence of D816V *KIT* mutation. The patient's symptoms do not warrant bone marrow transplantation or use of systemic glucocorticoids, which are associated with long-term adverse effects. (Valent P, Akin C, Escribano L, et al. Standards and standardization in mastocytosis: consensus statements on diagnostics, treatment recommendations, and response criteria. *Eur J Clin Invest*. 2007;37:435-453.)

3. A 35-year-old farmer with a 10-year history of mastocytosis who is otherwise healthy has recently experienced anaphylaxis with brief loss of consciousness after being stung by a honeybee. Allergy skin testing confirmed honeybee allergy. What is the most appropriate next step in management of honeybee allergy in this patient?

A. Venom immunotherapy is not recommended because of increased risk of reactions to immunotherapy due to mastocytosis.
B. Recommend venom immunotherapy for 5 years.
C. Recommend venom immunotherapy indefinitely.
D. Confirm skin test results by blood testing before recommending immunotherapy.

Answer: C Patients with mastocytosis are at increased risk for life-threatening reactions to hymenoptera stings. Fatalities have been reported in patients after discontinuation of venom immunotherapy. Therefore, most experts recommend immunotherapy when IgE-mediated sensitization is found by either skin or blood testing in these patients. Whereas the patients are also at increased risk of having a systemic reaction during immunotherapy, the risk-benefit ratio is often considered favorable to initiate immunotherapy. The patients should always continue to carry a self-injectable epinephrine as the protection is lower than for those without mastocytosis. (Niedoszytko M, de Monchy J, van Doormaal JJ, et al. Mastocytosis and insect venom allergy: diagnosis, safety and efficacy of venom immunotherapy. *Allergy.* 2009;64:1237-1245; and Alvarez-Twose I, Bonadonna P, Matito A, et al. Systemic mastocytosis as a risk factor for severe Hymenoptera sting–induced anaphylaxis. *J Allergy Clin Immunol.* 2013;131:614-615.)

4. Which of the following patients is a candidate for therapy with imatinib?

A. 30-year-old with adult-onset indolent systemic mastocytosis with D816V *KIT* mutation who remains symptomatic despite symptomatic therapy
B. 30-year-old with adult-onset systemic mastocytosis with occasional symptoms on symptomatic therapy; peripheral blood analysis negative for D816V *KIT* mutation
C. 60-year-old with systemic mastocytosis, splenomegaly, and pancytopenias; peripheral blood and bone marrow positive for D816V *KIT* mutation
D. 40-year-old with childhood-onset cutaneous mastocytosis that persisted into adulthood; patient recently developed progressive splenomegaly and anemia; mutational analysis of bone marrow shows an exon 8 *KIT* mutation

Answer: D Patients with D816V *KIT* mutation regardless of the category of mastocytosis are resistant to therapy with imatinib. Patients with cutaneous or indolent systemic mastocytosis with symptoms manageable by symptomatic therapy are not candidates for cytoreductive therapy regardless of the mutational status. Patients with well-differentiated systemic mastocytosis without codon 816 (exon 17) *KIT* mutations have a high likelihood of response to imatinib. (Akin C, Fumo G, Yavuz AS, et al. A novel form of mastocytosis associated with a transmembrane c-kit mutation and response to imatinib. *Blood.* 2004;103:3222-3225.)

5. Which of the following mast cell mediator measurements raises the greatest suspicion for mastocytosis?

A. Tryptase level of 50 ng/mL in a patient with perioperative anaphylaxis, obtained 1 hour after the event
B. Baseline tryptase level of 90 ng/mL in a patient who experiences recurrent anaphylactic episodes of unclear etiology
C. Elevated urinary *N*-methylhistamine in a patient with recurrent unexplained flushing
D. Elevated urinary prostaglandin D_2 in a patient with chronic diarrhea and osteoporosis

Answer: B Urinary metabolites of mast cell mediators are neither more sensitive nor more specific than measurement of baseline tryptase in diagnosis of systemic mastocytosis. Tryptase levels increase (usually within 4 hours) after an anaphylactic event regardless of whether it is associated with mastocytosis. Some patients with recurrent unexplained anaphylaxis who may have been previously diagnosed with idiopathic anaphylaxis may have mastocytosis as an underlying disorder (especially if the anaphylactic episodes involve hypotension and syncope rather than urticaria or angioedema). The diagnosis should be confirmed by a bone marrow biopsy in the patient in option D. (Akin C, Scott LM, Kocabas CN, et al. Demonstration of an aberrant mast-cell population with clonal markers in a subset of patients with "idiopathic" anaphylaxis. *Blood.* 2007;110:2331-2333; and Akin C, Metcalfe DD. Surrogate markers of disease in mastocytosis. *Int Arch Allergy Immunol.* 2002;127:133-136.)

256 APPROACH TO THE PATIENT WITH RHEUMATIC DISEASE

VIVIAN P. BYKERK AND MARY K. CROW

Rheumatic diseases are common and an important cause of reduced quality of life, increased comorbidity, and reduced life expectancy. They incur a significant socioeconomic burden and warrant expertise on the part of all physicians who treat patients. This chapter provides a framework to approach the evaluation of patients who present with signs and symptoms suggesting a rheumatic disease. An algorithmic approach is provided that allows the physician to incorporate presenting features, patient characteristics, anatomic structures, along with diagnostic tests, to facilitate a diagnosis and treatment plan.

DEFINITION AND CATEGORIZATION

Rheumatic diseases are disorders of connective tissue in which general or localized inflammation frequently manifests as pain attributable to peripheral joints, the spine, or muscles. Systemic features such as stiffness, fever, or weight loss and a multitude of extramusculoskeletal features, ranging from skin rashes to renal dysfunction, often accompany rheumatic diseases. In most cases, the basic underlying pathology is understood, although this is less true of pain disorders appearing alone or accompanying a rheumatic disease (Chapter 30). For most rheumatic disorders, the underlying molecular mechanisms through which environmental triggers and genetic susceptibility factors collaborate to result in a particular rheumatic disease in an individual remain to be fully elucidated. These diseases can be broadly considered as those that are primarily degenerative, with inflammation occurring secondarily, and those in which inflammation is the primary mediator of the disease. In the latter, the pathogenesis can be mediated through aberrant immune responses or as a result of metabolic abnormalities.

Histopathology

Rheumatic diseases are often also termed *connective tissue diseases,* understandably, because connective tissue is the most abundant tissue in the body supporting and connecting other tissues and organs. Loose and dense connective tissues include cellular components and extracellular matrix. Loose connective tissue fills spaces between muscle sheaths, encases blood and lymphatic vessels, and holds fibroblasts that synthesize collagen fibers. It includes reticular fibers that provide the skeleton of muscle cells, nerves, and capillaries. Dense connective tissue supports the body's soft tissues and includes more collagen fibers and fewer cells. It is found in the dermis, joint capsules, cartilage, bone, and fascia of muscles, and it forms tendons, ligaments, and points of connection where these insert into bone (aponeurosis). Cells included in connective tissue may be wandering, such as mast cells or macrophages, or resident cells, such as fibroblasts, fibrocytes, and reticular cells. Fibroblasts are responsible for synthesizing collagen, elastic reticular fibers, and ground substance of extracellular matrix, including tissue fluids and collagen fibers. Importantly, connective tissue is integrated with cells associated with the body's defense system: lymphocytes, plasma cells, macrophages, dendritic cells, and eosinophils. The close proximity of connective tissue to blood vessels and cells of the immune system provides the setting for a group of disorders that are mediated by impaired immune system regulation and disruptions of the vascular system.

Classification of Rheumatic Diseases

More than 100 types of rheumatic diseases have been described. Although these can be considered to be based primarily on one of two degenerative or inflammatory overarching processes, one can further subdivide rheumatic diseases as follows (and also outlined in Table 256-1): (1) those associated with degeneration of connective tissues attributable to (a) trauma, (b) structural/mechanical imbalances, or (3) inherent early demise of cellular components; (2) those associated with systemic autoimmunity,[1] often linked with measurable autoantibodies that can manifest primarily with (a) synovitis, (b) widespread organ involvement, (c) inflamed blood vessels, or (d) inflammation of muscle; (3) other inflammatory connective tissue diseases involving more dense tissues, not associated with the formation of autoantibodies and hence termed *seronegative rheumatic diseases* or *spondyloarthropathies;* (4) diseases in which inflammation of the vasculature, particularly small, medium, or large arteries, is the predominant feature; (5) autoinflammatory diseases that can be associated with crystal deposition or genetic mutations involving cytokine pathways; and (6) pain syndromes that must often be considered in the context of these diseases, in which some appear to be comorbid and closely linked to the underlying rheumatic disease, such as diffuse pain associated with Sjögren's syndrome, hypermobility of connective tissue, or those regional pain syndromes that are anatomically linked to mechanical disruption. Patients presenting with generalized pain syndromes require investigation to exclude a connective tissue disease. Increasingly, genotypes have been identified that are associated with diseases that fall into each of these categories, and in some cases specific immunologic pathways have allowed grouping of a set of rheumatic diseases previously considered more distinct.

Mimics of rheumatic diseases exist, and clinicians need to be mindful of considering these when evaluating a patient for a rheumatic disease. For instance, arthropathies and syndromes resembling a rheumatic disease can occur in the settings of both infection and malignancy. Autoimmune phenomena are increasingly being recognized in the setting of malignancy.[2] Red flags for each need to be considered in the assessment of a patient for possible rheumatic disease.

No classification of rheumatic disease can completely explain its genesis. However, considering these in a classification schema can aid in the approach to a patient in whom these disorders are being considered (see Table 256-1).

EPIDEMIOLOGY

Although connective tissue diseases can generally be categorized as noted in Table 256-1, in adults there are six prototypical rheumatic diseases most often assessed and managed by rheumatologists: rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), systemic sclerosis (SSc), spondyloarthropathies (SpA) (primarily ankylosing spondylitis [AS]), Sjögren's syndrome (SS), and vasculitis. These diseases are ubiquitous throughout the world (Table 256-2) and for the most part have a similar incidence and prevalence throughout the globe. Each is associated with differing immune aberrations and mechanisms of inflammatory damage, although the cause and reasons for chronicity still remain unknown. Autoimmune rheumatic diseases are also among the leading causes of death and morbidity in the industrial world, in part related to associated comorbid diseases, particularly comorbid cardiovascular disease. They contribute to a significant socioeconomic burden. Increasing evidence points to risks for their genesis relating to environmental factors, socioeconomic factors, and exposure to infectious agents, ultraviolet radiation, and pollutants. Smoking, in particular, has been associated with an increased risk for SLE and RA in genetically susceptible individuals in Western cultures. Effects of migration elucidate some of these risks. For instance, Africans who migrate far away from their native environmental and cultural origins appear to have an increased susceptibility to SLE. Also, reports have linked occupational exposures, such as silica dust, mercury, pesticides, solvents, and metals, to an increased risk for SLE and RA.

In some cases, geographic clusters of rare autoimmune disease argue for specific genetic determinants. For example, with SSc, higher incidence, prevalence, and mortality rates have been reported in African American populations compared with white populations, and the prevalence has been reported as higher in southern Europe, particularly Italy (prevalence of 7 to 33 per 100,000). Additionally, social and demographic factors may contribute to the epidemiology of rheumatic diseases. For example, the prevalence of SLE is reported as very high in Georgia, United States, whereas the prevalence of AS is rare in malaria endemic regions where HLA-B27 genotypes are rare. Inflammatory arthropathies, including RA and AS, have a higher prevalence in North American Native populations.

CLINICAL MANIFESTATIONS

It is important to understand the potential clinical manifestations and natural history of rheumatic diseases. Primary care and hospital-based health care providers are often the first to evaluate a patient with an evolving rheumatic disease, and they need to be attuned to the presenting features to make a timely diagnosis. In many cases, the presentation could signal a life- or organ-threatening condition. Evaluation of constitutional, systemic and joint symptoms should always include rheumatic disease in the differential diagnosis.

TABLE 256-1 COMMON RHEUMATIC DISEASES BROADLY CLASSIFIED ACCORDING TO PATHOGENESIS

DEGENERATIVE DISEASES OF BONES AND JOINTS	SYSTEMIC AUTOIMMUNE DISEASES	SERONEGATIVE SPONDYLOARTHROPATHIES	VASCULAR RHEUMATIC DISEASES	AUTOINFLAMMATORY DISEASES	PAIN DISORDERS
Osteoarthritis	Rheumatoid arthritis	Ankylosing spondylitis	ANCA- associated vasculitis	Adult-onset Still's disease	Regional myofascial pain syndromes
DISH	Systemic lupus erythematosus	Psoriatic arthritis	Temporal artery vasculitis	Crystal diseases	Tendonitis/bursitis
Degenerative disc disease	Sjögren's syndrome	Reactive arthritis	Polymyalgia rheumatica	Pediatric periodic fever syndromes	Adhesive capsulitis
Spinal stenosis	Inflammatory myopathies (polymyositis, dermatomyositis)	Enteropathic arthritis	Behçet's disease		Reflex sympathetic dystrophy
Osteoporosis	Systemic sclerosis				Pain with hypermobility syndromes
					Fibromyalgia*

*The only pain disorder that has not been associated primarily with inflammation.
ANCA = antineutrophil cytoplasmic antibody; DISH = diffuse idiopathic sclerosing hyperostosis (also linked to metabolic factors, including elevated growth hormone).

TABLE 256-2 WORLDWIDE PREVALENCE* AND INCIDENCE OF RHEUMATIC DISEASES ASSOCIATED WITH AUTOIMMUNITY

DISEASE	NORTH AMERICA	CENTRAL AMERICA	SOUTH AMERICA	EUROPE	MIDDLE EAST	ASIA	SUB SAHARAN AFRICA	AUSTRALIA
RA	600-1000 (40)	400-2000	100-500	200-900 (2-7)	200-1500	100-800 (40-90)	Rare - 900	2000
SLE	20-60 (2-7)	50-60 (5)	N/A	20-70 (2-7)	N/A	20-70 (3)	Rare	20-80 (11)
SSc	13-28	N/A	N/A	<10-15 (<2)	N/A	<10	N/A	23 (2)
SpA	50-130 (7)	N/A	N/A	100-850 (2-9)	500	10-240	Rare	N/A
SS	320 (4)	N/A	N/A	200-600 (4-5)	N/A	330-700 (China)	N/A	N/A

*Prevalence (annual incidence) per 100,000 by world regions.
RA = rheumatoid arthritis; SLE = systemic lupus erythematosus; SpA = spondyloarthropathy (primarily ankylosing spondylitis); SS = Sjögren's syndrome; SSc = systemic sclerosis.
Data from Shapira Y, Agmon-Levin N, Shoenfeld Y. Geoepidemiology of autoimmune rheumatic diseases. *Nat Rev Rheumatol.* 2010;6(8):468-476; and Chaaya M, Slim ZN, Habib RR, et al. High burden of rheumatic diseases in Lebanon: a COPCORD study. *Int J Rheum Dis.* 2012;15(2):136-143.

Joint Symptoms as a Common Presenting Feature

Almost all rheumatic diseases can manifest with joint-related symptoms as a significant and frequently presenting feature. This can include symptoms of pain, stiffness, swelling, and erythema, as in the case of autoinflammatory diseases such as gout or pseudogout. The pattern of joint involvement, particularly duration and timing of maximal symptoms, can help the health care provider identify patients who present with spondyloarthropathy or any inflammatory arthritis, regardless of pathogenetic classification. For instance, joint pain that is worse in the morning, is associated with prolonged stiffness, and improves with activity is a classic presentation of inflammatory pain. On the contrary, pain that is worse with activity, better with rest, and associated with a very short period of stiffness signals that the category is degenerative. Location provides a clue to broad classification. Patients describing "pain all over" may have a primary pain syndrome. However pain with an inflammatory pattern localized to the spine or an enthesis (site of ligament insertion) is more likely to indicate a seronegative spondyloarthropathy. A patient noting an inflammatory pattern of symptoms in small joints of the hands and feet suggests the presence of one of the autoimmune rheumatic diseases associated with either a positive antinuclear antibody (ANA) or rheumatoid factor (RF). Thus, joint symptom patterns become central to the evaluation of any rheumatic disease.

Nonspecific Clinical Presentations

All of the rheumatic diseases can be associated with joint involvement. However, joint symptoms are not always present in many of these diseases. Thus, a working knowledge of other patterns of presentation is important. Fever or cutaneous manifestations, including rashes, are common in vasculitis and in the presentation of SLE. Sicca symptoms are pathognomonic of Sjögren's syndrome. Both Sjögren's syndrome and inflammation of blood vessels can occur concurrently in patients with SLE. Systemic features such as myalgias or fatigue are common to almost all rheumatic diseases regardless of their classification, whereas true weakness may be the only presenting complaint of an inflammatory myopathy. Renal involvement is common to seropositive systemic autoimmune diseases and vasculitis and can present with anasarca if proteinuria is severe or prolonged. Consequently, specific and nonspecific features associated with various connective tissue diseases must be identified to correctly develop a differential diagnosis that fits within the classification described in Table 256-1. Features may present sequentially over time; thus, rheumatic diseases from more than one category must often be considered in a patient whose disease has not yet been diagnosed, leaving the patient with a label of a nonspecific or undifferentiated connective tissue disease. Most rheumatic diseases have specific classification criteria. When these are not yet met, features are considered in the context of the broad classifications, and terms such as *undifferentiated inflammatory polyarthritis* or *undifferentiated spondyloarthropathy* may be used in the interim to aid in diagnosis and management. When a patient's disease is not yet diagnosed, investigations and monitoring over time, as indicated in Figure 256-1, can help to ultimately identify an emerging rheumatic disease.

Cutaneous Manifestations

Although cutaneous manifestations are frequent in patients with seropositive autoimmune diseases, particularly SLE, they are important manifestations of all autoimmune diseases. A nonblanching purpuric rash can indicate a vasculitis, and rashes involving specific extensor regions are common to dermatomyositis. In cases of SLE or dermatomyositis, rashes are triggered or worsened by exposure to ultraviolet light and occur in a light-exposed distribution. Rashes of vasculitic origin can indicate either the presence of an autoimmune disease such as SLE or an inflammatory vascular disease such as antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis. These tend to be present for days and are often palpable, and a tissue biopsy of the lesions will be very helpful in diagnosis. Rashes can be transient. In adult-onset Still's disease (an adult form of systemic inflammatory arthritis classified as an autoinflammatory disease), patients present with daily spiking fevers, peaking late in the day, associated with a salmon-colored evanescent blanching rash lasting only 1 to 2 hours. The specific location of a rash aids in diagnosis. A facial rash that spares the nasolabial folds is classic for lupus. A rash that does not spare the nasolabial folds suggests rosacea. Psoriasis is almost always present in psoriatic arthritis (a spondyloarthropathy variant). Although psoriasis is often widespread, involving extensor surfaces, it can be missed if there

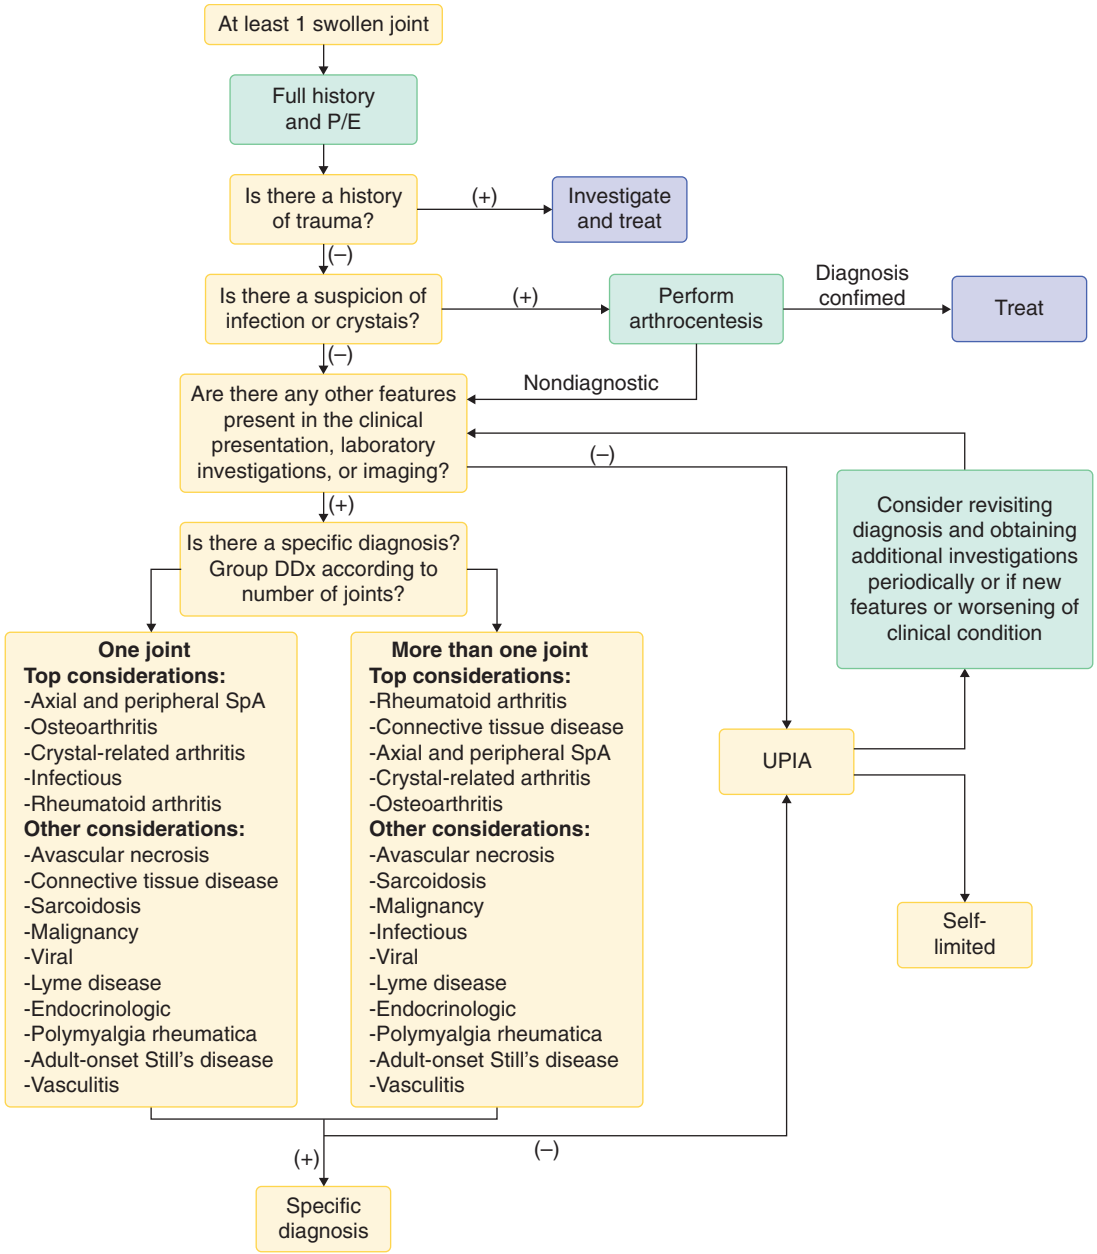

FIGURE 256-1. Algorithm for identification of undifferentiated peripheral inflammatory arthritis. Recommended minimum investigations in all patients: rheumatoid factor and/or anti–citrullinated peptide antibodies, erythrocyte sedimentation rate and/or C-reactive protein, complete blood count, and radiographs of affected joints. DDx = differential diagnosis; P/E = physical examination; SpA = spondyloarthritis; UPIA = undifferentiated peripheral inflammatory arthritis. (From: Hazlewood G, Alethaha D, Carmona L, et al. Algorithm for identification of undifferentiated peripheral inflammatory arthritis: a multinational collaboration through the 3e initiative. *J Rheumatol Suppl.* 2011;87:54-58.)

are very few lesions or if it is located in areas that are not easily seen (intertriginous regions, such as in the ear, umbilicus, buttock creases, or scalp) or if it only involves the nails. The rash of psoriasis can be seen in any of the variants of the spondyloarthropathies. Occasionally RA will manifest with nodules over the extensor surfaces or rashes in the same areas, but this is increasingly rare. However, the presence of nodules over extensor surfaces may also indicate gouty tophi. In SSc, distal tightening of the skin, presence of telangiectasias, and digital ulcers can be seen. These should also be sought in the context of Raynaud's syndrome, characterized by vascular spasm in the hands.

Pattern of Onset of Rheumatic Diseases by Category

Most rheumatic diseases appear spontaneously and often insidiously or with a subacute onset. Not all will manifest with all typical features at the time of presentation, and a diagnosis can take time to make as defining features present themselves. Almost all rheumatic diseases have had classification criteria published that account for the typical and specific features of the disease (these are detailed in other chapters). Although classification criteria are generally published to ensure homogenous recruitment of participants in research studies, they can also aid in diagnosis. However, a diagnosis can be made without meeting all classification criteria because some features of a rheumatic disease are highly specific and are not associated with other diseases. For example, SLE is the only disease that presents with a classic malar rash and a particular autoantibody, anti-Sm, in the serum.

The natural history of each rheumatic disease is related to the severity of presentation, the specific additional organs that become involved, and the development of comorbidities. RA may present with one or two swollen joints or pain in the forefoot. However, when the patient has a high titer of anti–cyclic citrullinated peptide antibody (ACPA), an autoantibody associated with development of erosive joint disease, the diagnosis can be made quickly and treatment initiated early. Autoimmune and vascular rheumatic diseases are associated with high morbidity and mortality when left untreated, and efforts to investigate for all manifestations early on are warranted.

Degenerative Rheumatic Diseases

These refer to rheumatic diseases commonly associated with advancing age. Degenerative joint disease (DJD) is usually thought to include osteoarthritis (OA) and degenerative disc disease (DDD). DJD is heralded by breakdown of articular collagenous structures (cartilage or intervertebral discs) and development of bony hypertrophy. Controversy remains as to which occurs

first. As collagenous structures degrade, associated inflammation commonly occurs. Resultant pain from varying causes contributes to immobility, secondary comorbidities, and disability. DJD represents, by far, the most common of the rheumatic diseases and is described in detail in Chapter 262. In general, these diseases are not associated with rashes or nonspecific constitutional symptoms.

Autoimmune Rheumatic Diseases

These diseases include SLE, RA, SSc, primary Sjögren's syndrome, idiopathic inflammatory myositis, and the systemic vasculitides. They involve multiple organ systems, are heterogeneous in clinical manifestations,[3] and are associated with and partially characterized by autoantibodies that can be measured in the serum (Tables 256-3 and 256-4). Many of these diseases affect females more than males. Most striking is SLE (Chapter 266), which affects 8 to 10 women for every 1 man and typically has its onset in the childbearing years. As noted, cutaneous manifestations, sicca symptoms (of dry eyes or mouth), mucosal ulceration, fevers, alopecia, and Raynaud's syndrome are common and often described by patients. These occur alone or in addition to symptoms affecting the joints and muscles. RA (Chapter 264) has a female-to-male ratio of approximately 3 : 1 and typically has its onset in the later adult decades, with symmetrical arthritis the classic presenting feature. Specific to SSc (Chapter 267), often referred to as scleroderma, are symptoms of skin tightness in the extremities. This is often associated initially with swelling of the digits, followed by tightness of the hands and ultimately tightness of the skin. In addition, skin tightness can involve the face, arms, and in the case of diffuse SSc, trunk, back, and legs. Although these diseases can present classically, facilitating rapid diagnosis, features can overlap. For instance, Sjögren's syndrome (Chapter 268), with prototypical sicca symptoms and autoantibodies, can occur concurrently in SLE and RA. Autoimmune vasculitides and SLE can share similar organ system manifestations, including those involving the lungs, kidneys, skin, and nervous systems. Most can have constitutional disturbance, arthralgia and arthritis, and myalgias. Overlap of symptoms expands the differential diagnosis, and a clear distinction is often not readily apparent, even after serologic testing. Tissue biopsy may help to provide a definitive answer.

Spondyloarthropathies

AS (Chapter 265) is more common in males than females. Localization of symptoms to the back, sacroiliac joints, and large lower extremity joints can be used to differentiate AS from RA. The typical presence of psoriatic skin lesions in patients with psoriatic arthritis can be a distinguishing feature from RA.

Forms of Vasculitis

There are many vasculitis syndromes, and these are generally grouped based on vessel size (Chapter 270). Some are classified as such though not always proved to be of vascular origin. Polymyalgia rheumatica (PMR) (Chapter 271) is a common inflammatory rheumatic disease of the elderly and shares many pathogenetic and epidemiologic features with giant cell arteritis (GCA), a form of older-onset vasculitis.[4] Patients complain of aching around the neck and bilateral involvement of the shoulder and hip girdles, along with significant stiffness that is most problematic in the morning. Symptom onset can be abrupt or insidious over weeks to months. The diagnosis of PMR is primarily clinical, although diagnostic criteria have been suggested, based on the typical clinical presentation and laboratory evidence of acute-phase reactants. Mimics of PMR can include elderly onset RA; thus, tests to exclude this may be indicated. More important, when considering PMR, always consider GCA, often involving inflammation of the temporal arteries, because the consequences of this disease can be damaging and severe, sometimes leading to blindness.

Autoinflammatory Diseases

Rare autoinflammatory diseases that are based on mutations in genes involved in inflammatory pathways are typically diagnosed in children and are covered in detail in Chapter 261. Gout (Chapter 273) is common in middle-aged and older men and may be increasing in prevalence. Exquisitely painful joint erythema and swelling are presenting features. Tophi that might be confused with rheumatoid nodules can be seen.

Pain and Pain Syndromes

Pain (also see Chapter 30) is a common and nonspecific, but very important, symptom central to nearly all rheumatic diseases. Pain is the key presenting feature of joint disease as perceived by the patient. In regional pain syndromes, the distribution of pain is the key clue to the diagnosis. Diffuse pain without evidence of underlying pathology associated with inordinate levels of fatigue, difficulty coping, and intricately detailed descriptions of pain using colorful analogies herald fibromyalgia (Chapter 274). Fibromyalgia is defined as widespread pain involving right and left sides and upper and lower extremities, as well as the neck and back. Most pain syndromes are regional pain syndromes. For instance, a regional pain syndrome relating to a mechanical neck and shoulder syndrome will result in the patient having pain in the involved neck and shoulder but also the trapezius, upper chest, and lower arm and hand. A large proportion of patients presenting with musculoskeletal pain will have regional pain relating to muscular imbalances with or without underlying degenerative arthritis, tendinopathy, or enthesopathy. As an

TABLE 256-3 CLUES TO DIAGNOSIS FOR EACH CATEGORY OF RHEUMATIC DISEASE

DEGENERATIVE DISEASES OF BONES AND JOINTS	SYSTEMIC AUTOIMMUNE DISEASES	SERONEGATIVE SPONDYLOARTHROPATHIES	VASCULAR RHEUMATIC DISEASES	AUTOINFLAMMATORY DISEASES	PAIN DISORDERS
Investigate if persistent symptoms >6 wk or failure of conservative measures (physical therapy, acetaminophen, NSAIDs). If at risk for bone loss and possible fragility fracture, consider osteoporosis.	Frequently associated with inflammatory joint pain and/or swelling with or without constitutional symptoms and other organ involvement. Perform ANA, RF, ESR, CRP.	Consider if psoriasis is present, or if back pain has inflammatory features; consider when known associated nonarticular features are present (e.g., uveitis, inflammatory bowel disease, urethritis, enthesitis, dactylitis).	Consider in all situations in which infarction of tissue has occurred or vasculitic rashes, pulmonary hemorrhage, or acute or subacute renal syndromes are present.	All can present with fever. In children, these are usually genetically determined syndromes mediated through interleukin-1 or TNF-α. In adults, consider crystal diseases.	Consider in situations in which pain is in excess of findings, with history of resolved trauma or repetitive strain, referred pain symptoms, diffuse pain, or colorful descriptions of pain.
INITIAL INVESTIGATIVE APPROACH TO CONFIRM SUSPECTED RHEUMATIC DISEASE IN EACH CATEGORY					
Image specific region giving rise to persistent pain (consider pain may be referred). If osteoporosis is a concern, perform BMD and investigate for metabolic bone diseases.	Investigations should specifically target suspected diseases, e.g., perform CPK if weakness or myalgia; anti-CCP (ACPA) if possible RA; ANA, dsDNA, C3, C4, ENA if possible SLE.	Imaging of sacroiliac (SI) joints (radiographs if long-standing symptoms, MRI if more recent onset). HLAB27 testing if inflammatory back pain or SI pain most predominant, clinical suspicion high for inflammatory back pain, but imaging is negative.	ANCA Anti-PR3 Anti-MPO Acute phase reactants (ESR, CRP) Tissue sampling of involved organs to facilitate pathophysiologic classification.	For suspected crystal disease, perform aspiration of synovial fluid or tophus and examine under polarized light microscopy.	Usually a diagnosis of exclusion. In reflex sympathetic dystrophy, tendonitis or enthesitis, specific physical findings and imaging can facilitate diagnosis.

ACPA = anti–citrullinated peptide antibodies; ANA = antinuclear antibodies; ANCA = antinuclear cytoplasmic antibodies; anti-CCP = anti–cyclic citrullinated peptide; anti-MPO = anti-myeloperoxidase; anti-PR3 = anti-proteinase-3; BMD = bone mineral density scan; CPK = creatinine phosphokinase; CRP = C-reactive protein; dsDNA = anti-double-stranded DNA; ENA = antibodies to extractable nuclear antigens (e.g., Ro, La, Sm, RNP, Scl70, Jo-1); ESR = erythrocyte sedimentation rate; MRI = magnetic resonance imaging; NSAIDs = nonsteroidal anti-inflammatory drugs; RF = rheumatoid factor; SLE = systemic lupus erythematosus; TNF-α = tumor necrosis factor-α.

TABLE 256-4 AUTOANTIBODIES ASSOCIATED WITH SPECIFIC FEATURES OF SEROPOSITIVE SYSTEMIC AUTOIMMUNE DISEASES

	ANTIBODY PREVALENCE	MAIN CLINICAL MANIFESTATIONS AND ASSOCIATIONS
SLE		
Double-stranded DNA	70-80	Kidney disease, skin disease
Nucleosomes	60-90	Kidney disease, skin disease
Smith	10-30	Kidney disease
Small nuclear ribonucleoproteins (spliceosomes, U1-RNP, 70kD, A, C)	15-25	Raynaud's syndrome, puffy fingers, myositis, and hypergammaglobulinemia
N-methyl-D-aspartate receptor	33-50	CNS lupus
Phospholipids (cardiolipin, β2 GP1, prothrombin)	20-30	Thrombosis, pregnancy loss, thickened heart valve disease, and livedo reticularis
α-Actinin	20	Kidney disease
Ribosomes P0, P1, P2	4-12	Hepatic, CNS manifestations (psychosis)
C1q	40-50	Kidney disease, associated with disease activity
SLE AND SJÖGREN'S SYNDROME		
Ro/SSA	30-40	Kidney disease in SLE in the absence of anti-La/SSB, skin disease in SLE and photosensitivity; congenital heart block and neonatal lupus erythematosus, sicca symptoms; subacute cutaneous lupus, hypergammaglobulinemia, leukopenia; interstitial nephritis and increased risk for non-Hodgkin's lymphoma in patients with Sjögren's syndrome
La/SSB	15-20	Congenital heart block and neonatal lupus erythematosus, sicca symptoms; photosensitivity, subacute cutaneous lupus erythematosus, hypergammaglobulinemia, leukopenia; increased risk for increased non-Hodgkin's lymphoma in patients with Sjögren's syndrome
α-Fodrine	46-100 in Sjögren's syndrome and 30 in SLE	Sicca symptoms
IDIOPATHIC INFLAMMATORY MYOSITIS		
Jo-1, Pl-7, Pl-12, OJ, EJ	20-30	Antisynthetase syndrome
Signal recognition particle	2-8	Necrotizing myopathy
Mi-2	8-12 in idiopathic inflammatory myositis, 15-20 dermatomyositis	Dermatomyositis and idiopathic inflammatory myositis
TRIM33	10-30 of dermatomyositis	Dermatomyositis, malignancy
U1-RNP/U2-RNP	8-15	Mixed connective tissue more commonly than system lupus erythematosus, systemic sclerosis, and undifferentiated connective tissue disorder
PM/Scl	12-16	Dermatomyositis and systemic sclerosis overlap, systemic sclerosis, and dermatomyositis
Ku	1-7	Myositis overlap, SLE, idiopathic inflammatory myositis, and systemic sclerosis
CADM-140/anti-MDA-5 antibody (clinically amyopathic dermatomyositis/antimelanoma-differentiation-associated gene 5)	Infrequent	Amyopathic dermatomyositis (53%) with interstitial disease
SYSTEMIC SCLEROSIS		
Centromere	15-40	Limited systemic sclerosis, pulmonary hypertension
Scl-70/topoisomerase	10-40	Diffuse cutaneous systemic sclerosis, pulmonary fibrosis
RNA polymerase III	5-25	Diffuse cutaneous systemic sclerosis, renal crisis, pulmonary hypertension
AUTOANTIBODIES WITHOUT DISEASE SPECIFICITY		
Rheumatoid factor	30-40, 90-95, and 10-20	SLE, Sjögren's syndrome, and myositis
Antibodies against proteasome subunits	40-60, 50-60, and 40	Idiopathic inflammatory myositis, SLE, and Sjögren's syndrome

CNS = central nervous system; SLE = systemic lupus erythematosus.
From Goldblatt F, O'Neill SG. Clinical aspects of autoimmune rheumatic diseases. *Lancet*. 2013;382(9894):797-808.

example, pain syndromes in the trapezial region, referring down the arm to the deltoid and even forearm, can be multifactorial and associated with a combination of muscular spasm, underlying degenerative arthritis in the cervical spine or rotator cuff impingement, not infrequently relating to repetitive activities. Pain in an extremity after trauma or surgery associated with a cold extremity is suggestive of reflex sympathetic dystrophy. The etiology of these will become apparent with a careful history of the pain, along with a medical history, physical examination, and exclusion of "red flags" or factors that indicate an underlying organic pathology. Pain in the setting of a history of malignancy should suggest the possibility of metastases. A tick bite may indicate prior Lyme disease. Most pain syndromes warrant a full medical evaluation before making a definitive diagnosis.

DIFFERENTIAL DIAGNOSIS AND DIAGNOSTIC EVALUATION:

A comprehensive history is needed to complete an evaluation of a patient with a rheumatic disease. In addition to considering age and gender, a patient's personal history, including marital status, occupation, and psychosocial factors, helps to elucidate a patient's diagnosis, prognosis, and treatment options. Clues helpful in making a diagnosis of one of the rheumatic diseases are summarized in Table 256-3.

Assessing clinical signs and symptoms is the cornerstone of diagnosis. Most rheumatic disorders will present with symptoms that involve, or seem to involve, joints. This can be limited to pain involving a specific joint or group of joints or periarticular structures. Querying the patient to determine the pattern of symptoms—whether pain, swelling, or stiffness associated with

joints—is key to narrowing the differential diagnosis of a rheumatic disease. Joint symptoms may have inflammatory features such as prolonged stiffness, pain at rest, or noninflammatory and mechanical features, such as instability or giving way, locking, or increased symptoms with use. Patterns of joint involvement—whether primarily small joints of the hands, wrist, and feet; large joints of the elbows, knees, ankles, or "root" (shoulders or hips); or spinal involvement—will help to narrow down the possible diagnoses. Moreover, questions regarding recent illnesses, exposure to possible infectious pathogens, and presence or absence of systemic features such as fever, fatigue, or weight loss will provide important clues. Appreciation of signs and symptoms indicating extra-articular features, particularly cutaneous, pulmonary, renal, neurologic, or vascular manifestations, will not only help to facilitate a diagnosis but aid in prognosis and an understanding of the needed intensity of therapy.

The presence of one rheumatic disease can be associated with comorbid manifestations unrelated to connective tissue. For example, myocardial infarction is more common in many patients with rheumatic diseases. Immobility or treatment-related factors leading to obesity can increase risks for diabetes and lower joint degeneration.

Factors in the Medical History that Contribute to Diagnosis and Prognosis

Age and Gender

Certain rheumatic diseases typically manifest in childhood. These include genetically based disorders such as hemophilia, associated with arthritis, and a number of autoinflammatory conditions that are by definition childhood diseases. Juvenile idiopathic arthritis refers to forms of arthritis in which the onset occurs before the age of 16 years. Autoimmune rheumatic diseases, and inflammatory rheumatic diseases such as spondyloarthropathies, RA, and SLE, can begin in young adulthood, whereas degenerative conditions such as OA rarely do and more often begin to manifest in the middle and late middle years. The peak onset of RA occurs in the late middle years, although onset can occur at almost any time in life. Elderly people are more prone to OA and PMR, but the latter has a wide differential diagnosis and should be considered at all ages. Autoimmune diseases are more common in women, whereas spondyloarthropathies can be equally common in men and women. Gouty arthritis is more common in men and rarely attacks women before menopause.

Occupation and Recreation

Occupation and recreational activities may give rise to physical and psychological stresses. The demands of a patient's occupation need to be understood, particularly when repetitive activities may contribute to the development of DJD or to regional pain syndromes. Similarly, trauma from sports, including prior injuries, can be significant contributors to DJD.

Family History

It is important to obtain a complete family history because autoimmune diseases, spondyloarthropathies, and gout occur with an increased incidence in families. It is common to see family pedigrees in which different forms of autoimmunity occur throughout a family. This does not mean that any one autoimmune disease has specific heritability. Also, generalized OA that involves the hands and other joints commonly runs in families.

Concomitant Medication Use

Concomitant medications may contribute to the genesis of a rheumatic disease. For example, diuretics can increase hyperuricemia and risk for gouty arthritis. Minocycline can be associated with lupus-like presentations. Antibiotics in the fluoroquinolone class have been associated with enthesopathies. A full medication history needs to be considered in the assessment of patients with rheumatic diseases.

Habits and Social Circumstances

Smoking has increasingly been associated with RA and SLE. Also, poor socioeconomic circumstances and psychosocial or physical stress may contribute to the severity of symptoms and should be considered in planning management strategies. Similarly, patients of different ethnic and cultural origins may have differences in their ability to describe symptoms and in preferences around treatment choices.

Onset and Evolution of Symptoms

Knowledge of the pattern of onset, location, and evolution of symptoms is essential to make an accurate diagnosis of a rheumatic disease. Symptoms that develop over hours to days typically suggest an inflammatory, or possibly an infectious or traumatic, process. When they persist for more than 6 weeks, symptom onset is considered subacute, and the disease chronic. Early in the presentation of some rheumatic diseases, the symptoms can be intermittent or palindromic before becoming constant. Sudden onset of joint pain and swelling, particularly involving one or a few joints, should be considered to be due to an infectious or crystalline etiology during the course of investigation.

Pain and Stiffness

Pain assessment should include a description of its onset, constancy/chronicity, severity, quality, factors that trigger or improve it, and location and radiation of the pain. Stiffness, often described as tightness or linked to difficulty with movement or function, should be determined in terms of location (e.g., is it in a particular joint or more diffuse) and timing and duration (e.g., occurring after a period of rest). Stiffness that resolves in 10 to 15 minutes is more characteristic of OA. In inflammatory disease, stiffness typically lasts longer, often at least 1 hour and even all day.

Joint Involvement

The distribution of joint involvement is key to making a diagnosis of a rheumatic disease. Monoarthritis describes symptoms in a single joint; oligoarthritis (or pauciarthritis) refers to symptoms in two to four joints; and polyarthritis indicates involvement of at least five joints. Peripheral arthritis involves an extremity, whereas spinal involvement is termed *axial disease*. Symmetrical as opposed to asymmetrical peripheral joint disease is more commonly associated with autoimmune rheumatic disorders, whereas asymmetrical arthritis can be associated with spondyloarthropathies or OA. Similarly, predominant small joint involvement is more typical in RA or SLE, whereas large joint involvement is classic for spondyloarthropathies. In addition the presence of associated enthesitis and axial symptoms herald spondyloarthropathy. Joint or spine symptoms associated with inflammatory causes often include predominance of symptoms in the morning, associated with stiffness for more than 60 minutes, worsening with rest, and improvement over the day and with activity. Joint or spine symptoms associated with degenerative joint disease typically worsen with activity, are often worse later in the day, and associated with stiffness, and typically resolve quickly over 15 to 30 minutes. Joint pain is usually felt at the joints (exceptions include shoulder pain, felt over the deltoid, and hip pain, felt in the groin). Joint pain from degenerative or inflammatory causes can vary in severity. Most patients will describe joint pain as aching and rarely rate the pain higher than 8/10 on an ascending severity scale. Pain relating to localized myofascial pain syndromes, including tendinopathies and enthesopathies, may be described as being close to joints, and being worse with specific movements. In people suffering from generalized pain syndromes, pain is often rated very highly (10/10), is poorly localized, involving upper and lower body regions, with descriptions including qualifiers to impress the severity of the pain ("like a truck ran over me").

It is also important to distinguish between arthralgia (subjective joint pain without objective signs) and arthritis, where pain and tenderness are associated with objective signs of joint swelling and warmth (synovitis), deformity, or limitation of movement. Objective findings on physical examination must be identified for a diagnosis of arthritis to be made.

Function

Function is commonly compromised in patients with rheumatic disease. Although this can be related to fatigue or muscular weakness, in the case of rheumatic disorders in which there is no articular involvement, most commonly functional impairment is related to joint involvement. Function should be assessed in terms of a patient's ability to perform activities of daily living, work, and participation. Validated questionnaires of function are available to identify functional limitations.

Physical Examination

Essential Concepts

A complete examination by a physician is required to identify and classify a rheumatic disease. This should include an assessment of temperature, body mass index, affect, pain behaviors, gait, and posture, as well as examination of the scalp, skin, eyes, lymph nodes, cardiovascular system, lungs, abdomen, joints, spine, and skeletal muscles. A systematic joint examination is key to the rheumatic disease examination and should include all regions, with comparisons of right and left sides. The pattern of joint involvement, including symmetry, and axial versus peripheral involvement, should be recorded. Use

of a joint diagram (homunculus) helps to track joint involvement. The joint examination should include documentation of the presence or absence of tenderness, periarticular wasting, erythema, swelling, limitation in range of motion (ROM), sites of prior surgery and trauma, and joint deformity, allowing for comparison over time and between different examiners. Using a four-step systematic approach to joint examination facilitates a thorough examination. This should include (1) inspection (looking for asymmetry, erythema, swelling, and deformity), (2) palpation (feeling for tenderness, specifically joint line tenderness, warmth, synovial thickening and effusion, bony hypertrophy, and crepitus), (3) ROM (both actively and passively for each joint), and (4) special tests specific to each joint or region. A complete examination should also consider relevant possible extra-articular manifestations.

Examples of Musculoskeletal Findings that Help to Classify a Rheumatic Disease

When considering the joint examination, a finding of redness (erythema) can indicate more acute and/or severe inflammation. The presence of erythema is more typically seen in the case of infection or crystalline arthritis. Joint warmth also signifies underlying inflammation. Joint swelling, a definitive sign of joint inflammation or arthritis, may indicate the presence of a joint effusion (excess synovial fluid) representing inflammation of the synovial membrane (synovitis). All rheumatic diseases short of specific pain syndromes can present with synovitis. Palpable bony thickening around a joint indicates swelling related to osteophytes, which is characteristic of OA. Crepitus feels like a grinding sensation under the examiner's hand during active or passive joint motion. Fine or velvety crepitus may indicate chronic proliferative synovitis, whereas coarse crepitus may indicate either roughening of the cartilage surface or complete loss of hyaline cartilage. Joint damage may manifest as loss of cartilage or bony hypertrophy. In some diseases such as RA, psoriatic arthritis, or Jaccoud's arthropathy (a form of SLE-related deforming arthropathy) deformity occurs as a result of joint subluxation or contracture related to nature's forces on joints and tendons and where chronic synovitis has caused joint capsule distension, ligamentous laxity, tendon rupture, or contracture.

Assessing Range of Motion

Both active and passive ROM should be assessed to appreciate joint function. Generally, active ROM is assessed first by asking patients to demonstrate full ROM of a joint; active ROM requires intact strength, innervation, muscle and tendon function, and joint mobility. Passive ROM is assessed by the examiner and for the most part assesses joint mobility or in some cases ligament or tendon impingement. First, assessing active ROM enables the examiner to appreciate potential areas of pain and where to examine carefully. If mobility is full on passive ROM, other causes can be considered for loss of mobility.

Establishing a Diagnosis

The findings from a thorough history and physical examination can be used to guide an appropriate set of investigations. Table 256-3 and Figure 256-1 provide clinical clues that are helpful in establishing a diagnosis based on the broad classifications in Table 256-1. By using the algorithm and Table 256-3, clinicians can develop a more parsimonious differential diagnosis and use investigations that will help to confirm the suspected diagnosis.

Laboratory and Imaging in Rheumatic Diseases

Identifying the presence of specific laboratory or imaging features can support a diagnosis and aid in specific classification of a rheumatic disease.[5] For example, in vasculitis, testing ANCAs or imaging the vascular tree of an involved area is key to establishing a diagnosis. Similarly, in seronegative spondyloarthropathies, imaging of the sacroiliac joint using radiographs when symptoms are sustained, or MRI if the disease is of more recent onset, is key. Radiographs and MRIs of specific joint areas in DJD not only help establish diagnosis but also aid in staging the disease. In the case of RA, testing of rheumatoid factor and ACPA is critical. When considering other prototypical seropositive systemic rheumatic diseases, the list of potential autoantibodies is much longer, and depending on the degree of difficulty in making the diagnosis, or appreciating the extent of disease and associated organ involvement, many of these can be considered for testing. These are listed in Table 256-4. It should be noted that no test alone should be used to diagnose a rheumatic disease, but rather that the tests should support the diagnosis.

TREATMENT

Rx

The treatment approaches to each rheumatic disease are highlighted in detail in the following chapters. Therapeutic approaches to degenerative rheumatic diseases continue to involve control of symptoms with either nonsteroidal anti-inflammatory drugs or analgesics. Additionally, physical modalities and injections of glucocorticoids (GCs) or other agents are employed to manage symptoms. When these conservative approaches fail, orthopedic surgery is often indicated. However, the approach to systemic and inflammatory rheumatic diseases usually requires more intense or immune-modulatory therapies. GCs are a major component of treatment regimens, particularly when organs are at risk for damage, when other agents take time to become fully effective, and in situations in which there are no alternative options for therapy. However, GCs are not without risk, and these should be discussed with each patient. Depending on the disease, GC-sparing therapies are usually initiated, the potency of which is tailored to the severity and risk for the illness itself. For example, SLE patients presenting with only a rash or synovitis may receive hydroxychloroquine, whereas patients with renal disease may receive mycophenolate mofetil, cyclophosphamide, or other therapies to most effectively treat that disease manifestation. Similarly in RA, patients presenting with high-titer ACPA levels, a high swollen joint count, and erosions on baseline radiographs of the hands and feet may receive rapidly escalating doses of methotrexate with or without other disease-modifying antirheumatic drugs and earlier use of tumor necrosis factor inhibitors. Specific approaches and GC-sparing therapies will be outlined in chapters addressing each rheumatic disease. In almost all rheumatic diseases, GCs are used as transitional therapy with a view to tapering these and using them again only for disease exacerbations.

SUMMARY

A broad-based set of rheumatic disease classifications can provide an overall construct for consideration of a multitude of possible rheumatic diseases. When the classifications are based on pathogenic mechanisms as well as clinical features, this facilitates identification of specific symptoms and signs and guides a further line of investigation. Although all rheumatic diseases will not fit within this classification, a systematic and directed analysis will accelerate achieving the correct diagnosis of the patient.

REVIEW QUESTIONS

1. On physical examination, which of the following categories of rheumatic diseases, when active, is *not* typically associated with inflammatory signs of synovitis?

A. Systemic autoimmune diseases
B. Degenerative diseases of bones and joints
C. Pain syndromes
D. Seronegative spondyloarthropathies
E. By definition, they are all associated with synovitis.

Answer: C Signs of synovial inflammation (synovitis), including erythema, warmth, and swelling, are typically not found in the pain disorders like fibromyalgia, reflex sympathetic dystrophy, adhesive capsulitis, and regional myofascial pain syndromes. It is important to distinguish between *arthralgia,* which is subjective joint pain without objective signs, and *arthritis*, in which pain is associated with objective signs of tenderness, swelling, and warmth (synovitis); the latter is sometimes also associated with deformity or limitation of movement.

2. A 65-year-old woman presents with complaints of increasing pain in her fingers and hands. She states that she has morning stiffness in those regions that tends to resolve within 10 to 15 minutes after start of activity. There are no other rheumatic or systemic symptoms and physical examination of the hands is completely normal. Which of the following is the most likely clinical diagnosis?

A. Osteoarthritis
B. Rheumatoid arthritis
C. Fibromyalgia
D. Scleroderma/systemic sclerosis
E. Systemic lupus erythematosus (SLE)

Answer: A Morning stiffness that resolves in 10 to 15 minutes is most characteristic of osteoarthritis. The morning stiffness of rheumatoid arthritis and other inflammatory rheumatic diseases typically lasts longer: at least 1 hour and even for much of the day. Hand involvement with scleroderma/SSc is characteristically associated with initial swelling of the digits, then progressing to skin tightness, which was not observed in this patient. Fibromyalgia involves widespread body pain of both sides, including upper and lower extremities, back and neck. This would be an unusual age for presentation with SLE, which typically begins in women in the age range of 15 to 45 years.

3. Which of the following would *not* be considered an important epidemiologic factor in the differential diagnosis of a patient with rheumatic disease?

A. Occupation and recreational activities
B. Age and gender
C. Concomitant medication use
D. Family history
E. Global geographic origin

Answer: E Connective tissue diseases are ubiquitous around the world and for the most part have a similar incidence and prevalence throughout the globe (see Table 256-1). In contrast, the clinical onset of various rheumatic diseases is often characteristic of certain age groups (e.g., ranging from autoinflammatory diseases typically presenting in childhood to polymyalgia rheumatica or osteoarthritis presenting in older age groups) and gender (with increased prevalence of autoimmune diseases in women and gout in men). A variety of medications taken chronically can be linked to specific rheumatic syndromes. Positive family histories are not uncommon in patients with autoimmune and other rheumatic disorders.

LABORATORY TESTING IN THE RHEUMATIC DISEASES

DAVID S. PISETSKY

The rheumatic diseases are a heterogeneous group of conditions that result from diverse pathophysiologic mechanisms and involve the musculoskeletal system as well as other organs. These conditions range from mild, diffuse joint and muscle pain to severe life-threatening kidney failure and stroke. Although the rheumatic diseases have many origins, immune disturbances resulting in local and systemic inflammation are frequently the underlying basis for disease manifestations. The approach to diagnosis therefore entails a wide array of laboratory tests to assess functional disturbances of individual organs and their relationship to inflammation and autoimmunity.

Laboratory testing in patients with rheumatic disease involves determination of biomarkers of the following kinds: antecedent (risk for disease); screening (subclinical disease); diagnostic (overt disease); staging (disease severity or activity); and prognostic (disease course, response to therapy, monitoring therapy). Some tests are useful in all contexts, although others have more specific uses related to their performance characteristics, specificity, and pattern of expression during disease. In view of the increasing efficacy

of treatment for diseases such as rheumatoid arthritis (RA) and the availability of more specific serologic assays for early diagnosis, laboratory screening may be important to improve outcomes further by identifying individuals who have symptoms (e.g., arthralgias) that could represent the first manifestations of disease (preclinical autoimmunity); serologic screening could also be useful in identifying individuals at risk for disease (e.g., siblings or first-degree relatives). In general, the assessment of damage relies on specific tests of end-organ function or structure rather than process markers. Distinguishing activity from damage is important in patient management, especially with respect to the use of therapies associated with toxicity. In many diseases, prognosis can reflect ongoing disease activity as well as damage from past disease activity and effects of treatment, with laboratory testing needed to assess these various processes.

MARKERS OF INFLAMMATION

For many patients, the initial goal of evaluation is to determine the presence of inflammation. Inflammation is the body's response to injury and is characterized by a cascade of cellular and molecular events that arise irrespective of stimulus or locale (Chapter 48). The immediate response to inflammatory stimuli is termed the *acute phase response* and includes a set of proteins produced primarily in the liver in response to cytokines such as interleukin-6 (IL-6), tumor necrosis factor-α (TNF-α), and IL-1. These cytokines are produced by macrophages and dendritic cells after stimulation of pattern recognition receptors (PRRs) that include both toll-like receptors (TLRs) and other non-TLR sensing systems that trigger a system called the *inflammasome*; PRRs recognize intracellular as well as extracellular bacterial and viral products as well as large and small (e.g., adenosine triphosphate, uric acid) molecules released from damaged cells. The result is stimulation of innate immunity (Chapters 46 and 48). Many proteins in the acute phase response show large increases in serum levels, although some show a reduction. Because the levels of these proteins can increase dramatically in magnitude, they provide a sensitive and powerful set of markers for inflammation, whether induced by infection, trauma, or autoimmunity.

Of the proteins stimulated during the acute phase response, C-reactive protein (CRP) has received the most attention as a marker of inflammation in both rheumatic and nonrheumatic diseases. CRP is a member of the pentraxin family; although its function is not fully known, its ability to bind to phosphocholine suggests a scavenger function to eliminate bacterial products or damaged cells and to attenuate the consequences of infection or tissue injury.[1] Other molecules, such as serum amyloid protein (SAP), fibrinogen, and complement, also show marked elevations in levels during the acute phase response, signifying a broad-based effort at host defense.

The CRP level provides a very useful measure of inflammation and can convey information for categorization of a clinical process (e.g., inflammatory versus noninflammatory arthritis) as well as assessment of disease activity or prognosis (e.g., activity of RA or likelihood of joint erosion). The advantage of measuring CRP in the blood, rather than cytokines, is that the protein levels are much higher. Furthermore, CRP levels remain elevated for a longer period (days) than do cytokines; the latter may appear only transiently in the blood and thereby evade detection. The levels of CRP are in part determined by genetic factors, with baseline values important in determining the significance of any increases that can be associated with disease activity. Although CRP testing is commonly performed to assess the risk for atherosclerosis, a frequent complication of systemic rheumatic disease, the application of this screening in a patient with an inflammatory condition must take into account the various determinants of this marker, especially during active disease.

Another simple laboratory test reflecting the acute phase response is the erythrocyte sedimentation rate (ESR). In this test, commonly called the *sed rate*, anticoagulated blood is drawn into a long, thin tube and allowed to settle under the influence of gravity for 1 hour. The distance the blood falls depends on a number of factors, including the concentration of serum proteins such as immunoglobulins and fibrinogen, an acute phase reactant. The sedimentation rate is nonspecific with respect to disease association and also depends on the age and gender of the person. The upper limits of normal vary between women and men. Other simple laboratory tests point to an acute phase response. For example, patients with inflammation frequently exhibit a leukocytosis or thrombocytosis, most likely reflecting the action of cytokines and other mediators, including glucocorticoids, during this process. With chronic inflammation, anemia of chronic disease can also occur, with the hematocrit, in conjunction with the white blood cell and platelet counts, pointing to the presence of an inflammatory process. In this regard, in systemic lupus erythematosus (SLE), lymphopenia, thrombocytopenia, and low CRP values often characterize active disease, with the discordance between laboratory and clinical findings a clue to diagnosis.

LABORATORY EVALUATION OF MUSCULOSKELETAL DISEASE

The most common presentation of musculoskeletal disease is pain in and around the joints in association with functional impairment. Collectively, diseases causing joint symptoms are called arthritis, implying inflammation. The extent of inflammation in these diseases varies markedly, however, with some forms such as osteoarthritis (Chapter 262) showing only limited evidence of inflammation either locally or systemically.

Arthritis results from many different diseases and occurs in various patterns defined by the number and size of joints affected, symmetry, and involvement of the axial as well as peripheral joints. For each pattern (e.g., chronic polyarthritis), a key issue in diagnosis concerns its place in the spectrum of inflammatory versus noninflammatory arthritis. Furthermore, although many diseases can cause arthritis, their prevalence varies enormously, with osteoarthritis or degenerative joint disease being the most common form of noninflammatory arthritis and RA the most common form of inflammatory arthritis.

The differential diagnosis of arthritis is based on a comprehensive history and physical examination to assess symptoms suggesting inflammation (e.g., morning stiffness and fatigue), the presence of synovitis, and results of laboratory tests indicative of inflammation. Of these tests, the ESR and CRP are nonspecific indicators of inflammation. Depending on the stage of disease and prior therapy of the patient, however, both the CRP and ESR may not be elevated at the time of an initial evaluation because many treatments, especially those directed against cytokines, can effectively reduce the acute phase response; multiplex assays of various other mediators may allow assessment of disease activity in this circumstance. Two autoantibody tests, rheumatoid factor (RF) and antibodies to citrullinated proteins, provide more specific diagnostic information. Given the demographics of inflammatory arthritis, testing for antinuclear antibodies is often part of this evaluation as well.

Rheumatoid Factor

RF comprises a family of specificities that bind to the immunoglobulin G (IgG) molecule. These RFs target primarily the constant region or Fc portion of IgG, reacting with antigenic determinants that are most likely conformational in origin. IgM RFs are the most abundant of these antibodies and have been easiest to measure, using agglutination assays with red blood cells or latex beads coated with IgG. More recently, enzyme-linked immunosorbent assay (ELISA) and nephelometry have been used to detect RFs.

RFs occur in approximately 80% of patients with RA (Chapter 264) and represent one criterion for the classification or diagnosis of this disease. Furthermore, high levels of RFs are often associated with a worse prognosis, the occurrence of joint erosion as measured by radiographs, and deformity. Despite these associations, RFs occur in the sera of patients with a wide range of autoimmune and inflammatory diseases as well as in normal individuals, especially with age (Table 257-1). The frequent occurrence of RFs may reflect their etiology and role in innate immune responses to promote the binding of IgG to antigen by Fc cross-linking. Although RFs may occur in many settings other than RA, depending on the pretest probability, the test nevertheless remains useful in the evaluation of patients with inflammatory arthritis.

Antibodies to Citrullinated Proteins

Antibodies to citrullinated proteins are other autoantibody specificities important in the diagnosis of RA (Chapter 264). Citrulline is a post-translational modification of the amino acid arginine that results from deimidation. This chemical reaction is catalyzed by the enzyme peptidylarginine deiminase (PAD) and may occur in the setting of inflammation; the function of this modification is unknown. Citrullination can affect many different proteins, creating antigenic sites on proteins that include vimentin, enolase, and filaggrin.[2]

Although antibodies are directed to citrullinated residues on intact proteins, they can be conveniently measured using synthetic peptides containing citrulline. Among these synthetic antigens, a citrulline-containing protein with a cyclic structure provides sensitive and specific assays in an ELISA format. Antibodies directed to this type of antigen are known as anti-CCP (cyclic citrullinated peptide) and can be formally distinguished from antibodies to the citrullinated proteins themselves (ACPA, or anti–citrullinated protein antibodies); The term *anti-CCP* is commonly used for these

TABLE 257-1 RHEUMATIC DISEASES AND NONRHEUMATIC CONDITIONS ASSOCIATED WITH A POSITIVE RHEUMATOID FACTOR

DISEASES	FREQUENCY
Rheumatoid arthritis	50-90%
Systemic lupus erythematosus	15-35%
Sjögren's syndrome	75-95%
Systemic sclerosis	20-30%
Polymyositis/dermatomyositis	5-10%
Cryoglobulinemia	40-100%
Mixed connective tissue disease	50-60%
Aging (>70 yr)	10-25%
Infection	
Bacterial endocarditis	25-50%
Liver disease	15-40%
Tuberculosis	8%
Syphilis	Up to 13%
Parasitic diseases	20-90%
Leprosy	5-58%
Viral infection	15-65%
Pulmonary disease	
Sarcoidosis	3-33%
Interstitial pulmonary fibrosis	10-50%
Silicosis	30-50%
Asbestosis	30%
Miscellaneous diseases	
Primary biliary cirrhosis	45-70%
Malignancy	5-25%

Modified from Shmerling RH, Delbanco TL. The rheumatoid factor: an analysis of clinical utility. *Am J Med.* 1991;91:530.

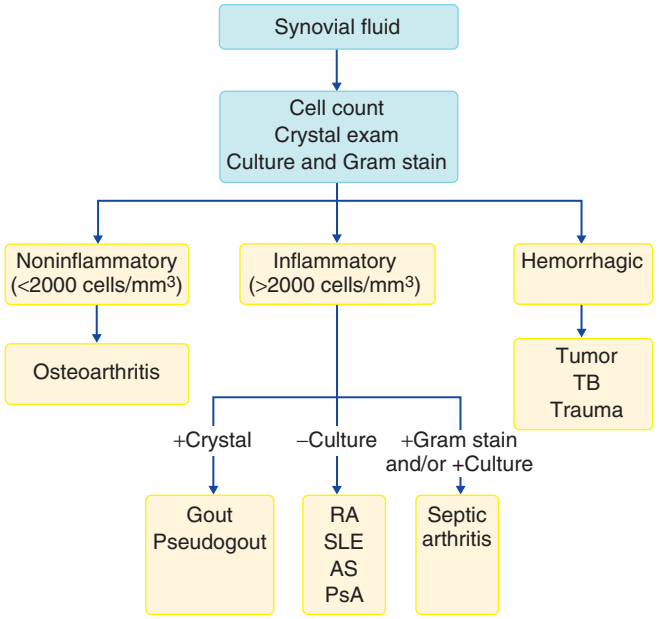

FIGURE 257-1. Algorithm for analysis of joint fluid. Examples of inflammatory arthritis are indicated, although many conditions can produce these findings. AS = ankylosing spondylitis; PsA = psoriatic arthritis; RA = rheumatoid arthritis; SLE = systemic lupus erythematosus; TB = tuberculosis.

specificities, although it is not formally synonymous with ACPA. ACPA can be assessed by a variety of analytic techniques using as antigens both modified proteins as well as arrays of peptides. For detection of anti-CCP antibodies, the formulation of peptides has changed over the years as designated by assay generation. Furthermore, among commercially available assays, results of assays can vary, making it important to know the performance characteristics of assays in interpreting the results of testing.

Anti-CCP antibodies are highly associated with RA and represent a criterion in the classification of patients with this disease.[3] Depending on the assay, these antibodies occur in 60 to 70% of patients with RA and uncommonly in those with other forms of inflammatory arthritis, making their presence important in diagnosis. Significantly, anti-CCP antibodies can occur before the onset of other signs and symptoms of RA, suggesting utility for screening of at-risk patients. In addition, in patients with arthalgias without clinical evidence of synovitis by examination, the presence of anti-CCP may predict the development of subsequent arthritis. Thus, because of the specificity of anti-CCP for RA, the presence of these antibodies in patients with early signs and symptoms of disease may indicate the diagnosis of RA and allow more prompt initiation of therapy before disease is fully manifest. In this regard, although RA can occur in the absence of anti-CCP antibodies, the presence of these antibodies may define disease subsets that differ in etiology, clinical course, and response to therapy.

Joint Fluid Analysis

Analysis of joint fluid can provide decisive data in the evaluation of arthritis and, in some instances, a definitive diagnosis. This analysis is essential in the setting of acute monoarthritis to investigate the possibility of infection; for chronic forms of arthritis, joint fluid should be analyzed if there is uncertainty about the diagnosis and involvement of one joint out of proportion to others. Joint aspiration is a sterile procedure performed with a local anesthetic. Although fluid can be analyzed by tests to assess viscosity and mucin content, the cell count, examination of crystals, and stains and cultures to evaluate infection are the most informative.

On the basis of cell counts, joint fluids can be categorized into four main types: noninflammatory, inflammatory, septic, and hemorrhagic. A noninflammatory fluid has fewer than 2000 cells/mm^3 with mononuclear cell predominance. An inflammatory fluid has more than 2000 cells/mm^3, with 50,000 cells/mm^3 frequently used as the upper limit for this type of fluid. In an inflammatory fluid, polymorphonuclear cells predominate. A septic fluid is an inflammatory fluid in which culture or staining for microorganisms demonstrates infection. Suspicion of infection is especially high for fluids with cell counts greater than 50,000/mm^3. However, crystal-induced arthritis can produce cell counts of this magnitude, and an infected fluid can have counts below this level. Hemorrhagic fluids have red cell predominance that can approximate that of blood.

In the setting of an acute monoarthritis, crystal-induced disease is much more common than infection, with the presence of crystals demonstrated by polarization microscopy. With this technique, monosodium urate crystals in gout appear needle shaped and are negatively birefringent. In contrast, calcium pyrophosphate dihydrate crystals in pseudogout are rhomboidal in shape and are weakly positively birefringent. Infection can coexist with crystal-induced disease, necessitating microbiologic evaluation even when crystals are found. Hemorrhagic fluids can also result from infection, although their presence suggests malignancy or trauma. Figure 257-1 provides an algorithm for the analysis of joint fluid.

Depending on the clinical findings and the results of initial laboratory testing, other studies may be performed to investigate less common diagnostic possibilities such as metabolic disease or malignancy. The laboratory evaluation of inflammatory arthritis may also include serologic tests for infections such as Lyme disease, HIV infection, or hepatitis.

LABORATORY EVALUATION OF SYSTEMIC INFLAMMATORY DISEASE

Among rheumatic diseases, some are characterized by severe systemic inflammation that can cause organ-threatening and life-threatening manifestations. These diseases can have arthritis as a component and presenting complaint, although the prominence of extra-articular manifestations, especially as they develop over time and involve organs such as the kidney, points to their systemic nature. These diseases can be categorized on the basis of clinical, serologic, and pathologic findings, with the presence of vasculitis, irrespective of blood vessel size, providing a unifying feature in disease classification.

The terms *connective tissue disease* (CTD) and *collagen vascular disease* are both used to denote a group of diseases that includes RA, SLE, Sjögren syndrome, polymyositis, dermatomyositis, and progressive systemic sclerosis. Diseases in this group can share common or overlapping clinical features, especially early in their course, when their presentations may be similar. In this stage of disease, the condition may be called *undifferentiated CTD*, with serologic markers sometimes predictive of the eventual diagnosis.

Antinuclear Antibodies

The expression of antibodies to components of the cell nucleus (antinuclear antibodies, or ANAs) is characteristic of CTD and is essentially invariable in patients with SLE (Chapter 266). These antibodies target a host of nuclear macromolecules, including DNA, RNA, and proteins as well as complexes of proteins with nucleic acid. These antigens are ubiquitously expressed in cells and subserve critical processes related to chromosomal structure, cell division, transcription, and translation. The basis for the antigenicity of these molecules is unknown, although DNA and RNA both have intrinsic immunologic activities and can stimulate cytokine production through action on both TLR and non-TLR PRRs, especially when in the form of immune complexes. Furthermore, these antigens may undergo post-translation modification as well as enzymatic cleavage reactions during cell death, perhaps increasing their immunogenicity.

ANAs are commonly measured by immunofluorescence (IF) assays in which sera are incubated with tissue culture cells (e.g., Hep2 cells) fixed to a glass slide. Antibody binding is revealed by fluorescence microscopy after incubation of the slide with a fluoresceinated anti-immunoglobulin reagent. Results are reported in terms of the pattern of fluorescence as well as the end-point titer of sera at which fluorescence can be observed. The patterns of binding differ depending on the location of the particular macromolecular target, although a few patterns predominate. These patterns include homogeneous, rim, nucleolar, and speckled; in addition, ANA tests can detect antibodies to cytoplasmic antigens. Despite some disease associations, these patterns do not have diagnostic significance. Table 257-2 presents a list of major ANAs with their pattern and disease associations.

A major limitation in the assays of ANAs concerns the frequency of positive reactivity in the sera of otherwise normal individuals who lack evidence of a CTD. Depending on the titer for screening, the sera of as many as 20% of normal individuals express reactivity in the IF ANA test.[4] The basis of this reactivity, which occurs more commonly in women than men, is not well understood, although it may reflect a predisposition to autoimmunity that is manifest in ANA production in the absence of other immunopathologic disturbances for the complete development of a CTD. Because ANA testing is often performed to evaluate nonspecific complaints such as arthralgias, fatigue, and fever, a positive test must be interpreted with caution and not used as proof of a CTD in the absence of correlative clinical or laboratory findings.

Because of detailed biochemical studies, the molecular identity of many ANAs is now known, allowing for the development of specific immunochemical assays using technologies that can eliminate the need for visual inspection of a slide stained for fluorescence. These tests (e.g., ELISA) can be performed individually, although multiplex assays provide simultaneous assessment of multiple specificities. With multiplex assays, a version of the ANA test can be generated by measuring antibodies to a select set of more commonly targeted autoantigens, with positive binding to any one antigen considered indicative of a positive value for an ANA. Because sera of patients with SLE and other systemic inflammatory diseases contain numerous ANAs, focus on a limited set of specificities may fail to detect some positive sera. In addition, because immunochemical assays may detect low levels of antibody binding, the significance of this reactivity is not certain. Thus, although multiplex assays are operationally easier than conventional ANA testing by immunofluorescent staining, in clinical situations, the IF assay remains an important laboratory test for patient evaluation.

Among many ANA specificities now identified, only a few are performed routinely because of their value for diagnosis and prognosis. For certain CTDs, diagnosis can be readily determined from clinical findings or other laboratory tests. In these instances, the ANA determination provides confirmatory information as well as clues to the occurrence of certain clinical manifestations.

Antibodies to DNA

Antibodies to DNA (anti-DNA) are serologic markers of SLE and represent a criterion in the classification of patients with this disease (Chapter 266). These antibodies bind sites on both single-stranded (ss) and double-stranded (ds) DNA, although anti-dsDNA antibodies are more specific for SLE and therefore routinely measured. Although these antibodies can bind free DNA, DNA in the cell occurs in association with histones to form a structure called the *nucleosome*, with DNA wrapped around a histone core. Anti-DNA may therefore be considered a subset of antibodies to nucleosomes, with nucleosomes probably serving as the driving antigen for this response.[5]

In clinical practice, the measurement of anti-DNA antibodies is an important element in the evaluation of patients with a broad array of clinical complaints, given the heterogeneity and multisystemic nature of SLE. Anti-DNA determinations, in addition to their value in diagnosis, also convey prognostic information and serve as an index of disease activity. The association with disease activity appears strongest with glomerulonephritis, most likely because of the role of DNA–anti-DNA immune complexes in immunopathogenesis. The association of anti-DNA antibodies with other disease manifestations is less certain, limiting the use of this marker as a measure of overall disease activity. The presence of anti-DNA may nevertheless be important in assessing likelihood of response to therapies such as belimumab (anti-BLyS or anti-BAFF), an agent indicated for treatment of patients with active disease as evidenced by the presence of either anti-DNA antibodies or a positive test for ANA.

Several immunochemical approaches can be used to detect anti-DNA antibodies, although solid-phase ELISA assays are convenient and sensitive and eliminate the need for radioactivity. The assays vary in regard to the spectrum of anti-DNA antibodies detected, and results between assays may not

TABLE 257-2 SELECTED ANTINUCLEAR ANTIBODIES AND RHEUMATIC DISEASES

DISEASE PATTERN	ANTIBODY	ANTIGEN	ASSOCIATION
Homogeneous	Antihistone	Histones H1, H2A, H2B, H3, H4	Drug-induced lupus (>95%)
Rim	Anti-double-stranded DNA	Double-stranded DNA	SLE (50%)
Speckled	Anti-Sm	snRNP proteins	SLE (30%)
	Anti-U1-RNP	U1 snRNP proteins	SLE (30%); MCTD (>95%)
	Anti-Ro (SS-A)	Two proteins complexed to small RNAs Y1-Y5	SLE (30%); Sjögren syndrome (70-80%)
	Anti-La (SS-B)	Single protein plus RNA polymerase III transcript	SLE (15%); Sjögren syndrome (50-70%)
	Anti-Ku	DNA binding protein	SLE (10%)
	Anti-SCL-70	DNA topoisomerase I	PSS (40-70%); CREST (10-20%)
Nucleolar	Anti-PM-Scl	Nucleolar protein complex	PSS (3%); PM (8%)
	Anti-Mi-2	Nuclear protein complex	DM (15-20%)
	Anti-RNA polymerase	Subunits of RNA polymerase I	PSS (4%)
Dividing cell	Anticentromere	Centromere/kinetochore protein	CREST (80%); PSS (30%)
	Antiproliferating cell nuclear antigen	Auxiliary protein of DNA polymerase δ	SLE (3%)
Cytoplasmic	Anti-Jo-1	Histidyl tRNA synthetase	ILD in PM/DM (18-25%)
	Anti-PL-7	Threonyl tRNA synthetase	PM/DM (3%)
	Anti-PL-12	Alanyl tRNA synthetase	PM (4%)
	Anti-SRP	Signal recognition particle	SLE (10%)
	Anti-ribosomal P	Large ribosomal subunit	PM/DM (3%)

CREST = calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia; DM = dermatomyositis; ILD = interstitial lung disease; MCTD = mixed connective tissue disease; PM = polymyositis; PSS = progressive systemic sclerosis (diffuse scleroderma); SLE = systemic lupus erythematosus; snRNP = small nuclear ribonucleoprotein; tRNA = transfer RNA.

correlate.[6] Nevertheless, for each assay, the dynamic range for testing is large. With treatment and disease quiescence, anti-DNA antibodies may essentially disappear; with flare, levels may increase dramatically. This property distinguishes anti-DNA antibodies from other ANAs in SLE, levels of which tend to be more consistent over time.

As is the case for other ANAs, the appearance of anti-DNA antibodies in the serum may precede other manifestations of SLE, suggesting vigilance if these antibodies are present in patients who have symptoms that suggest a CTD but lack other evidence to establish a firm diagnosis.

Other Antinuclear Antibodies

Anti-Sm and anti-RNP antibodies are related specificities that commonly occur together in the sera of patients with SLE, a phenomenon called *linkage*. These antibodies bind proteins on subcellular particles called *snRNPs* (small nuclear ribonucleoproteins) that are composed of a set of proteins and uridine-rich RNAs. Anti-Sm and anti-RNP antibodies differ in protein specificity and in the ability to cause immunoprecipitation of the bound RNA molecules. Anti-Sm antibodies occur only in patients with SLE and represent a serologic marker in disease classification. In contrast, anti-RNP antibodies can appear in the sera of patients with other clinical presentations and, in the absence of anti-Sm, may characterize patients with overlapping CTD features, so-called mixed CTD or MCTD. In SLE, the frequencies of anti-Sm and anti-RNP antibodies vary among racial and ethnic groups, although a clear association with particular clinical manifestations has not been established.

Anti-Ro and anti-La antibodies (or anti-SS-A and anti-SS-B), another set of linked ANAs, are directed to protein-RNA complexes that are involved in cellular metabolism of RNA. These antibodies are expressed more widely in patients with CTD and appear in the sera of patients with SLE, RA, and Sjögren's syndrome, among others. Assessment of these antibodies is important because of their association with the neonatal lupus syndrome, which results from the transplacental passage of antibodies and causes congenital heart block as well as rash in the neonate. Although both Sm/RNP and Ro/La are complexes of proteins and RNA, these antibodies appear to be expressed by different patient subsets, suggesting distinct mechanisms of induction and clinical associations.[7]

Although ANAs are directed to ubiquitous antigens, they nevertheless are expressed in disease-specific patterns and may show association with particular organ-specific manifestations. These associations include anti–ribosomal P antibodies with central nervous systemic involvement in SLE, antibodies to DNA topoisomerase 1 (anti-SCL-70) with progressive systemic sclerosis (diffuse scleroderma), antibodies to centromeres with CREST syndrome (calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia), and antibodies to histidyl transfer RNA synthetase (anti-Jo-1) with interstitial lung disease in scleroderma (Chapter 267). In inflammatory myopathies, the presence of certain autoantibodies may be associated with particular patterns of disease, with antibodies to the enzyme 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase present in a syndrome of necrotizing myositis; the syndrome can occur in patients treated with statins, which can inhibit the enzyme.[8]

In addition to their association with specific disease manifestations, antibodies to both DNA- and RNA-binding proteins such as Sm and RNP may contribute to overall immune dysregulation in patients with autoimmune disease because of their formation of immune complexes containing DNA or RNA. These complexes can stimulate the production of type 1 interferon by triggering both TLR and non-TLR nucleic acid sensors as well as other cellular receptors (e.g., Fc receptors). Because immunoassays of interferon with patient sera are limited, the presence of interferon is observed more clearly in the pattern of gene expression known as the interferon signature in peripheral blood cells. This signature can be assessed by both microarray assays and measurement of more limited sets of messenger RNA molecules that are induced by interferon. Because antibodies to RNA-binding proteins in particular may promote this pattern, the serologic assay of these ANAs may allow assessment of the likelihood of both nonspecific and specific immunologic disturbances.[9]

Antibodies to Phospholipids

Originally defined by their effects on in vitro clotting tests, antibodies to phospholipids (APLs) are associated with in vivo thrombosis and have been termed *lupus anticoagulants* (LACs). Patients with these antibodies display a clinical condition, termed the *antiphospholipid antibody syndrome*, which is characterized by arterial or venous thrombosis, thrombocytopenia, and first-trimester spontaneous abortions (Chapter 176). This syndrome may occur by itself or in the context of SLE, where it may contribute to the acceleration of atherosclerosis, premature stroke, and myocardial infarction. The laboratory evaluation of this condition involves specific assays of antibodies to phospholipids and related proteins as well as functional assays of clotting. Because expression of these antibodies may vary over time, testing must be performed on more than one occasion at least 6 weeks apart. Furthermore, the results of immunochemical and functional assays may not be congruent because they are likely related to the heterogeneity of antibodies.

The serology of APLs is complicated because it is related to the nature of the antigenic targets as well as heterogeneity among patients.[10,11] These antigens include phospholipids such as cardiolipin. Cardiolipin, however, can bind to the protein β_2-glycoprotein 1, which is also a target for antibodies in this condition. Serologic evaluation thus involves assays with a complex of cardiolipin and β2-glycoprotein 1 as well as β2-glcycoprotein in an ELISA format using reagents to measure IgG and IgM. The association of antibodies with thrombosis appears strongest with IgG antibodies; determination of the IgA isotype may also be informative depending on the results of IgG and IgM assays. ELISAs for these antibodies are not yet standardized, making it important to specify assay features related to quantitation such as cutoff values used to define positivity and values that are considered significant.

Functional assays for LACs involve tests directed at inhibition of in vitro clotting (e.g., activated partial thromboplastin time, dilute Russell viper venom time), recognizing the discordance between in vivo thrombosis and in vitro anticoagulation. Functional assays to detect lupus anticoagulants involve a mixing step in which patient plasma is mixed with normal plasma to determine the presence of an inhibitor (i.e., an antibody) as opposed to a deficiency state. The mechanisms by which antibodies to phospholipids and related proteins may cause thrombosis in vivo are unknown, although these antibodies may interact with the surface of cells (e.g., endothelium) to promote a prothrombotic state. Assessing the likelihood of the syndrome is best accomplished by considering results of both the immunoassays and functional assays in the context of the individual patient because both factors may promote thrombotic events.

Complement

Assessment of the complement system can provide valuable information on the activity of diseases in which immune complex deposition may promote inflammation and tissue injury (Chapter 50). This system involves a large number of proteins that function in enzyme cascades to generate degradation products that amplify immunologic reactions and promote the destruction or removal of foreign organisms as well as damaged cells. In the setting of SLE and in certain forms of vasculitis and glomerulonephritis, immune complexes activate complement to promote local inflammation. This activation can be measured in terms of the total complement level in the blood by functional assays of hemolytic activity; by measurement of individual complement components such as C3 and C4, whose levels are reduced by cleavage during activation; by measurement of split products of cleaved complement components; and by measurement of complement fragments bound to red blood cells during complement activation. Proteins of the complement system are acute phase reactants and can increase with inflammation, including active disease. Correspondingly, low levels may reflect inherited complement deficiency rather than consumption; genetic deficiency of C1q, for example, is highly associated with SLE.

Antineutrophil Cytoplasmic Antibodies

Antineutrophil cytoplasmic antibodies (ANCAs) are autoantibodies that react to determinants in the neutrophil and occur prominently in patients with certain forms of necrotizing vasculitis or rapidly progressive glomerulonephritis. Reflecting the serology, conditions have been called ANCA-associated vasculitis (AAV). Two main forms of ANCA have been distinguished on the basis of the target antigens and pattern of immunofluorescence staining of fixed neutrophils: PR3-ANCA (C-ANCA), which reacts with proteinase-3 (PR3), and MPO-ANCA (P-ANCA), which reacts with myeloperoxidase (MPO). By immunofluorescence, PR3-ANCA shows staining in the cytoplasm; staining by MPO-ANCA localizes in the perinuclear area. ANCAs to other proteins have also been identified, but these may also occur in conditions other than vasculitis.

In the evaluation of severe, multisystem inflammatory disease, ANCA testing is important to evaluate diagnostic possibilities.[12] ANCAs occur in association with varying clinical manifestations in patients with AAV and help define patterns of clinical involvement in terms of organ system involvement as well as histopathology (e.g., presence of granulomatous inflammation). PR3-ANCA occurs commonly in patients with granulomatosis with polyangiitis (GPA, formerly called Wegener granulomatosis) as well

eosinophilic granulomatosis with polyangiitis (EGPA, formerly called Churg-Strauss disease); MPO-ANCA marks the course of vasculitis caused by microscopic polyangiitis.[13] Although there is overlap between serology and clinical features, PR3-ANCA occurs commonly in patients with upper airway disease, whereas MPO-ANA occurs commonly patients with patients with rapidly progressive renal disease (Chapter 270).

In patients with ANCA-associated glomerulonephritis, the kidney lacks evidence of immune deposits, as indicated by the lack of staining for immunoglobulins or complement. Kidney disease of this kind is termed *pauci-immune glomerulonephritis*. Although ANCA testing is useful in initial diagnosis, its role for assessing disease activity is less certain. Occasionally, in patients who are desperately ill and cannot tolerate a lung or kidney biopsy, the presence of an ANCA can be used as preliminary evidence for diagnosis to allow the initiation of immunosuppressive therapy. ANCA testing is also useful for assessing the likelihood for relapse because patients who express PR3-ANCA appear at risk for recurrent disease.

Cryoglobulins

Cryoglobulins are serum immunoglobulins that precipitate in the cold and promote the pathogenesis of systemic inflammatory disease through tissue deposition. The presence of a cryoglobulin is detected by allowing blood, collected warm, to remain cool at 2° to 4° C for 1 or more days. After centrifugation, the amount of cryoprecipitate is measured and expressed as a cryocrit. In the preanalytical phase, it is important that the blood remain at a temperature of 37° C during all steps from drawing the blood from the patient to separation of the serum fraction after coagulation. Thermos flasks with preheated sand or water and other special devices are available to keep the blood tubes at 37° C during transport. If these steps are not taken, cryoprecipitation at even room temperature may already occur before separation of the serum from the blood cells, possibly resulting in false-negative results.[14]

Subsequent analysis of the cryoprecipitate by immunochemical assays allows determination of its components. Cryoglobulins can be classified into three main types on the basis of their composition: (1) single, or type I; (2) mixed, type II; and (3) mixed, type III. A type I cryoglobulin consists of only a monoclonal immunoglobulin that precipitates in the cold. A mixed-type cryoglobulin contains RFs bound to polyclonal IgG to form an immune complex. In type II cryoglobulins, the IgM RF is monoclonal, and in type III, the IgM RF is polyclonal.

Type I cryoglobulins occur in patients with lymphoproliferative disorders such as Waldenström macroglobulinemia, multiple myeloma, or chronic lymphocytic lymphoma (Chapters 184 and 187). In contrast, patients with mixed cryoglobulins can present with a wide range of signs and symptoms resulting from vasculitis. These manifestations include purpura (a sign of leukocytoclastic vasculitis), weakness, arthritis, and neuropathy, representing a syndrome known as *essential mixed cryoglobulinemia*. Most patients with this condition have infection with hepatitis C virus, with viral components present in the complexes. These patients have serologic evidence of this infection as well as manifestations attributable to the underlying liver disease. As in the case of other CTDs and systemic inflammatory diseases, the evaluation of patients with essential mixed cryoglobulinemia demands attention to the entire patient and the impact of disease on multiple organs.

IMAGING STUDIES IN THE RHEUMATIC DISEASES

RONALD S. ADLER

Historically, rheumatic disorders have been well characterized by conventional imaging. In as much as these disorders often manifest in characteristic distributions and present with specific alterations in the appendicular or axial skeleton and adjacent soft tissues, radiographic evaluation has been sufficient to both characterize the abnormalities as well as provide a relatively small number of differential possibilities as to the specific disease. The most well-studied example is rheumatoid arthritis (RA) in which symmetric involvement of the metacarpophalangeal joints, uniform joint space narrowing, periarticular osteopenia, and juxta-articular erosions along the "bare areas" are pathognomonic.

The development of new therapeutic alternatives for the inflammatory arthritides, so-called disease-modifying antirheumatic drugs (DMARDs), and chondroprotective strategies in the case of osteoarthrosis, require methods to diagnose these diseases at an earlier stage, characterize the degree of inflammation, and provide a useful metric to assess therapeutic response.[1] Indeed, it has become necessary to assess for possible joint and soft tissue abnormalities before irreversible tissue damage, the latter often being the case when the radiographic findings are abnormal. Fortunately, the requirement to achieve earlier diagnosis has paralleled advances in imaging. Ultrasonography and magnetic resonance imaging (MRI) have largely supplanted conventional radiographic evaluation in the imaging work-up of patients with suspected rheumatologic disorders and negative radiographs.[2,3] The term *molecular imaging* has been applied, particularly in the case of MRI and positron emission tomography (PET), in as much as these modalities reflect local tissue environment or metabolic activity.

RADIOGRAPHIC EVALUATION

Radiographic evaluation is among the first studies ordered in patients with a suspected rheumatologic disorder. In the current digital era, conventional analog-based radiographs have been largely replaced by computed radiography. Images are usually displayed on workstations with high-resolution monitors within the context of a picture archiving system (PACS). Digital radiographs are of high spatial resolution but relatively poor soft tissue contrast. These images are amenable to a variety of image processing schemes, resulting in enhanced definition of the cortical surfaces and cancellous bone, which may be of value in displaying subtle erosions.

It is important to recognize that radiographs are projection images. To detect an abnormality, it may be necessary to view a joint or other structure at a specific angle. For instance, subtle erosions may only be apparent when viewed tangentially as opposed to en face. It is therefore necessary to have specific image protocols in order to optimally display the joint, cortical surface, or soft tissue structure. Most radiographic evaluations contain at least two orthogonal projections. The addition of an oblique view or other specialized projection may be necessary to address a specific clinical question.

The nature and distribution of joint space narrowing, presence of osteopenia, new bone formation, soft tissue swelling, soft tissue calcification, chondrocalcinosis, presence and nature of erosions, and assessment for joint malalignment may allow a specific diagnosis and help determine the severity of disease (Fig. 258-1). For instance, the presence of a juxta-articular erosion extending over an adjacent area of slightly hyperdense soft tissue swelling in the setting of normal bone mineralization with maintenance of the adjacent joint space is diagnostic of gout, in contrast to RA noted earlier. The seronegative arthritides, such as psoriatic arthritis, have a characteristic appearance in the small joints of the hand and feet, including a predilection for distal joints, asymmetry, and appositional new bone formation.

Table 258-1 summarizes some of the features of several of the more common diseases that may be encountered in clinical practice.

Finally, radiographs provide a direct means for needle localization during percutaneous procedures, predominantly joint injections, aspirations, and some biopsies. These are generally performed while imaging in real time (fluoroscopy) using short bursts of low-intensity x-rays enhanced through an image intensifier. Injection of joints under fluoroscopic guidance provides a convenient means to ensure intra-articular deposition of therapeutic agent or for diagnostic aspiration. Intra-articular location is verified by injection of a small amount of a standard iodinated contrast material. Arthrography using fluoroscopic guidance can be used as a primary diagnostic tool, but this application has largely been replaced by intra-articular injection of contrast followed by computed tomography (CT) or MRI.

For some procedures, CT may be preferable, depending on the location of the abnormality. The principal disadvantages of fluoroscopy relate to the use of ionizing radiation and poor soft tissue contrast. The latter becomes important with needle placements near neurovascular structures that may be potentially compromised by poor position. CT allows greater control over needle placement at the cost of greater levels of radiation exposure. Ultrasonography has replaced fluoroscopy and CT for a large number of percutaneous procedures. MRI provides another method to perform a variety of procedures without the necessity of ionizing radiation. These options will be discussed in greater detail below.

FIGURE 258-1. Three hands with different diagnoses. A, Gout. Radiograph of the left hand showing multiple dense soft tissue nodules (n) with multiple small erosions affecting the ulnar styloid, triquetrum and fifth ray. A large erosion (arrow) at the fifth distal interphalangeal (DIP) joint demonstrates bone formation extending circumferentially about the adjacent tophaceous deposit typical of an overhanging edge. Bone mineralization and joint spaces are preserved. **B, Rheumatoid arthritis.** There is ulnar deviation of the second through fifth metacarpophalangeal (MCP) joints with uniform joint space loss involving the MCP joints and the carpus. The DIP joints are spared. Periarticular demineralization is present with small erosions along the radiovolar aspect of the second (*arrow*) MCP joint. **C, Osteoarthrosis.** Soft tissue swelling affecting the third digit with joint space narrowing and bone production affecting the DIP joints, third and fifth proximal interphalangeal (PIP) joints, basal joint of the thumb, and scaphotrapeziotrapezoid joint. There are subchondral cystic changes at the third PIP joint having an erosive character (*arrow*). Mineralization is preserved, as are the radiocarpal and MCP joint spaces.

TABLE 258-1 DISTINGUISHING RADIOGRAPHIC FEATURES OF SEVERAL COMMON RHEUMATIC DISEASES

CONDITION	COMMON SITES	DISTRIBUTION	RADIOGRAPHIC FEATURES
Rheumatoid arthritis	Hands: MCP, PIP; wrists: intercarpal, DRUJ, ulnar styloid; feet: fifth MTP, cervical spine (atlantoaxial, apophyseal)	Bilateral, symmetric, polyarticular	Periarticular osteopenia, periarticular swelling, subluxations (e.g., ulnar, volar), uniform joint space loss, erosions (bare areas)
Osteoarthritis (primary)	Hands (DIP), wrists (basal joint, STT),feet (first MTP), hips (superolateral), knees (medial), spine (discs, facet, apophyseal, uncovertebral)	Symmetric, weight-bearing joints	Normal or increased density, nonuniform joint space loss, subchondral sclerosis, cysts, bone formation (osteophytes) Spine–disc space narrowing, end plate sclerosis and bone formation
Psoriatic arthritis	Hands (DIP, terminal tufts), feet (IP joints), entheses (calcaneus: plantar, posterior), spine, sacroiliac joints	Asymmetric (single ray), polyarticular, segmental (intervertebral, apophyseal)	Normal or increased density, periosteal bone formation, soft tissue swelling, ankylosis (SI joints), thick hyperostosis spine (nonmarginal syndesmophytes), juxta- and periarticular erosions
Ankylosing spondylitis	Spine, SI joints, fibrous joints (pubic symphysis), entheses (adductor origin), rhizomelic joints (hips, shoulders)	Symmetric, continuous (may affect entire spine-bamboo spine)	Normal or increased density, erosions (spine squaring, shining corner) with superimposed bone formation (ankylosis: SI), thin (marginal) syndesmophytes)
Gout	Feet (first MTP), other damaged joints, elbow, knee, hindfoot	Asymmetric, extensor surfaces (elbow), abnormal joints (e.g., osteoarthritic joints)	Normal joint space, normal or increased density, dense soft tissue nodules (tophi), para-articular and subchondral erosions with bone formation along tophi (overhanging edge)
Calcium pyrophosphate dihydrate crystal deposition disease	Hands (second, third MCP), wrists (radiocarpal), TFC, knees (lateral compartment and patella-femoral, menisci)	Symmetric, fibrocartilaginous joints	Normal or increased density, hypertrophic bone formation, subchondral or periarticular cysts, chondrocalcinosis (hyaline, fibrocartilage), periarticular, peritendinous, periligamentous calcification
Infection	Any joint, pyogenic, TB	Monoarticular (mostly), any joint	Pyogenic (osteopenia; 8-10 days), joint space widened (early), joint space loss (rapid development), soft tissue swelling, erosions (both sides of joint), sequestra, periostitis, TB (joint space and mineralization may be preserved), juxta-articular erosions, spine–disc space loss and end plate erosion

DIP = distal interphalangeal; DRUJ = distal radial ulnar joint; IP = interphalangeal; MCP = metacarpophalangeal; MTP = metatarsophalangeal; PIP = proximal interphalangeal; SI = sacroiliac; STT = scaphotrapezotraphezoid; TB = tuberculosis; TFC = triangular fibrocartilage.

COMPUTED TOMOGRAPHY

Computed tomography provides a two-dimensional map of tissue attenuation obtained from external x-ray source(s) located on a rotating gantry, whose radiation is detected by a series of detectors opposite the source. The current generation of CT scanners uses multiple detectors (16, 32, 64, and so on), allowing rapid image acquisition that can be displayed in a single plane in real time (CT-fluoroscopy) or as extremely thin section contiguous or overlapping acquisitions in the axial plane. The acquired images can be reconstructed in multiple planes with equivalent (isotropic) resolution elements (voxels) or as a three-dimensional rendering. Some scanners use dual energy sources, taking advantage of differences in the attenuation characteristics of various tissues at different energies. This has received greatest attention in the setting of gout, enabling a definitive diagnosis as well as depicting tophaceous deposits in anatomic locations not conducive to radiographs or ultrasound.[4]

Computed tomography allows the best assessment of trabecular and cortical bone, providing an excellent means to assess fractures and erosions, the presence of new bone formation (e.g., fracture callus), and degenerative or inflammatory arthritis. Soft tissue mineralization can likewise be well characterized, providing important information as to its etiology. Joints that are difficult to assess on radiographs, including the sacroiliac, temporomandibular, wrist, and sternoclavicular joints, are well seen on CT (Fig. 258-2).

Computed tomography generally has poor soft tissue contrast. Nevertheless, it is still very useful in performing a number of guided procedures because of its tomographic nature and rapid image acquisition capability. Improved soft tissue contrast can be obtained with use of iodinated contrast material. A number of soft tissue tumors, inflammatory synovitis, and infectious processes display pathologic enhancement after contrast administration. CT can likewise be used to produce angiographic displays (CTA) when used in combination with contrast, providing exquisite detail of central and peripheral vascular disease, including in patients with suspected vasculitis. These agents are typically administered intravenously following well-defined enhancement characteristics. CTA has become the method of choice in evaluating patients with suspected pulmonary embolism. Likewise, contrast agents may be used to improve intra-articular contrast (CT arthrography), currently the method of choice in assessing internal derangement in the postoperative shoulder, knee, and so on and in patients who are unable to undergo MRI (e.g., those with claustrophobia, aneurysm clips, or cardiac pacemakers). Imaging of cartilage and soft tissue abnormalities usually depends on pathologic imbibition of contrast material, indicative of degeneration or tearing. A limitation of this approach resides in the fact that some abnormalities may remain occult. An example is the inability to detect a bursal-sided rotator cuff tear after shoulder CT arthrography.

The radiation dose from CT can be high, especially when using the newer scanners. This is most significant when one is looking to minimize exposure, such as in children, requiring protocols specifically designed for the pediatric population. Intravenous (IV) use of iodinated contrast agents are contraindicated in patients with impaired renal function or history of allergic reaction. Nonionic agents can diminish the associated risks but still should be used with caution.

ULTRASONOGRAPHY

Ultrasound imaging takes advantage of the near uniform speed of sound and predictable attenuation characteristics of sound propagation in soft tissue. In general, anatomic images derive from specular surfaces whose dimensions exceed the ultrasound wavelength; inherent noise (speckle) within the image derives from small scatterers, smaller than the resolution element of the transducer. Modern ultrasound equipment contains various methods to reduce speckle in the image, resulting in a more anatomic rendition of the soft tissues. Rapid image acquisition and processing enables ultrasonography to be performed in real time (≈30 frames per second). Ultrasonography is also conducive to evaluation of blood flow from which estimates of flow velocity can be obtained through the Doppler equation. Doppler information is typically reported by either continuously estimating velocity at a specific depth (spectral Doppler) or through a color encoded two-dimensional map (color or power Doppler).

There is great appeal for using ultrasonography in patients with rheumatic disorders. There is no ionizing radiation, and it is real time, inexpensive, relatively portable, and well tolerated. Historically, however, ultrasonography has played only a limited role in the diagnostic assessment and treatment of patients with suspected musculoskeletal abnormalities, being used to differentiate fluid-filled from solid masses. The detection of a Baker cyst in the knee or the presence of a joint effusion constituted two major applications. There has also been limited application of ultrasonography to perform image-guided aspirations and biopsies. Within the United States, in particular, the development of MRI further limited the musculoskeletal applications of ultrasonography.

With the development of linear high-frequency small parts transducers; new imaging capabilities of ultrasound scanners; and the evolution of a new class of compact, portable (laptop) ultrasound units that have excellent image quality, the role of ultrasonography has dramatically changed in recent years.[5,6] These new applications have paralleled the development of new classes of DMARDs for which diagnosis of inflammatory synovitis prior to joint destruction is optimal.

The current generation of ultrasound scanners enables examination of the small joints of the hands and feet, allowing early detection of synovitis (Fig. 258-3). Typically, a 10-MHz or higher frequency linear transducer is used. The displacement of the joint capsule by hypoechoic (dark) soft tissue that displays vascularity on Doppler imaging or is incompressible with direct pressure by the transducer is characteristic, allowing differentiation of synovitis from an effusion. In addition to the detection of synovitis, ultrasonography has been shown to be more sensitive than conventional radiographs in the detection of erosions. Erosions appear as discrete irregular discontinuities

FIGURE 258-2. Infectious sacroiliitis in a 12-year-old boy with a 2-week history of back and left hip pain. A, Axial computed tomography (CT) image of the pelvis at the level of the sacroiliac joints (SIs) photographed using window settings optimized for bone detail. There is clear asymmetry in the two SI joints, with the left appearing more irregular. The cortical margins of the left sacral ala are less distinct and there is an isolated bone fragment (*arrow*) surrounded by soft tissue suspicious for a sequestrum. **B,** CT-guided aspiration of the left SI joint confirmed an infectious origin.

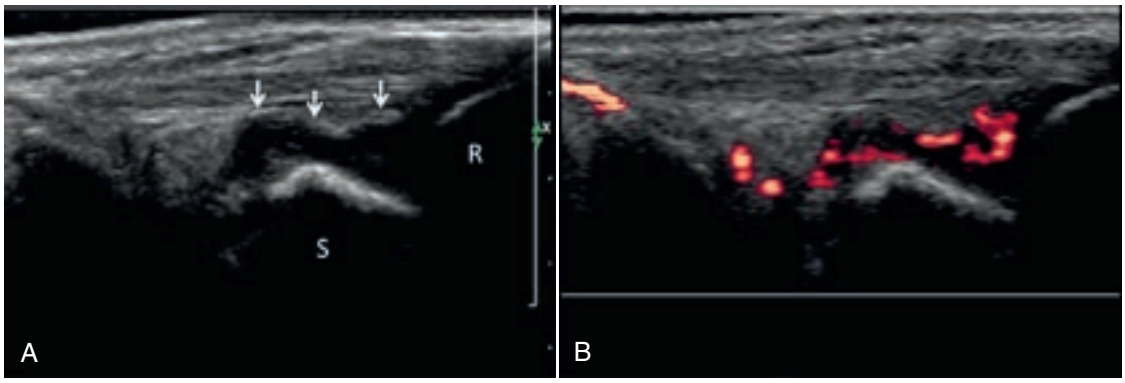

FIGURE 258-3. Synovitis on ultrasonography in a female patient with normal hand radiographs. A, Gray-scale ultrasound image obtained along the dorsal aspect of the radioscaphoid joint shows hypoechoic soft tissue (*arrows*) distending the dorsal recess. The cortical margins of the scaphoid (S) and radius (R) appear as bright reflectors on ultrasonography. **B,** Power Doppler image depicts the marked vascularity (*red color hues*) of the soft tissue illustrating the level of disease activity.

in the normally smooth hyperechoic (bright), reflecting cortical surfaces, often seen in continuity with adjacent inflammatory soft tissue. There is some variation in the appearance of synovitis among various arthritides. The distribution, presence, or lack of symmetry and other concomitant findings may be necessary to obtain a specific diagnosis.

The level of vascularity on color-flow imaging can reflect active inflammation, correlating with clinical and biochemical parameters. A parametric image encoding either mean Doppler shift (color Doppler) or amplitude (power Doppler) is typically used as a standard Doppler map. Both maps can be used to detect abnormal levels of vascularity. Whereas power Doppler provides an indirect measure of the number of moving scatterers within the region being scanned, color Doppler provides a velocity map, and therefore is more subject to artifact (angle dependence and sampling errors). When combined with color-flow imaging, the activity of the synovitis can be estimated. Ultrasound contrast agents can depict capillary flow, resulting in significantly improved detection sensitivity of synovial inflammation, and are used extensively in Europe. They constitute microbubble agents encased in a lipid or polysaccharide shell that can be instilled as either bolus or constant infusion, with the shell being metabolized in the liver and the gas exhaled in the lungs. These agents have biological half-lives on the order of minutes and are best suited to examining target joints. Contrast agents have received Food and Drug Administration approval for cardiovascular applications and therefore can only be used off label for the assessment of synovitis.

Articular and fibrocartilage have characteristic appearances on ultrasonography. Whereas the former appears as a thin hypoechoic band paralleling the articular surface, fibrocartilage appears hyperechoic. Chondrocalcinosis appears as discrete hyperechoic foci with the substance of the cartilage, in which case its presence is suggestive of calcium pyrophosphate deposition disease. Calcification along the margin of the articular cartilage gives rise to the double-line sign seen in gout.

Tendons and muscles have characteristic appearances on ultrasonography. The presence of tendinosis, tendon tears, muscle edema or inflammation, atrophy, and tears can be diagnosed. Ultrasonography is very sensitive, although not specific, for the detection of small amounts of calcification or ossification. It is an excellent method to assess for calcific peritendinitis and to provide guidance for treatment. Abnormal fluid distention of synovial lined structures can be assessed and treated under ultrasound guidance. Ultrasonography is an excellent modality to provide image guidance for therapeutic aspiration and injection of small and large joints, tendon sheaths, and cysts (e.g., bursae, ganglion, paralabral cysts, hematomas, abscesses,) (Fig. 258-4). The real-time capability of ultrasonography is useful to demonstrate the presence of subluxations or painful snapping, to document the distribution of injected material, and to assess adhesions. Ultrasonography is considered the method of choice to detect foreign bodies.

Nerves also have a characteristic appearance on ultrasonography. In cross-section, a nerve often has a "cluster of grapes" appearance, with nerve fascicles appearing hypoechoic and surrounded by hyperechoic endo- and epineural fat. In long axis, nerves display a characteristic tram-track appearance. Ultrasonography has been shown to be useful in the diagnosis and treatment of carpal tunnel syndrome and cubital tunnel syndrome. It is an excellent modality to assess for the presence of posttraumatic or postsurgical and interdigital neuromas and to provide image guidance for treatment, including therapeutic injections and ablative therapy.

Although ultrasonography is well suited to the evaluation of superficial structures, it is less well suited to deep structures. Frequency and penetration are reciprocally related: the higher the frequency, the better the axial resolution but poorer the degree of penetration. A 15-MHz linear transducer would work well in the hand but not in the hip. Examination of a hip might require a 5-MHz transducer and curved transducer geometry with reduced image quality. Excessive abdominal fat can further limit acoustic penetration and distort the ultrasound beam, limiting image quality. Diagnostic ultrasonography does not penetrate bone, resulting in limited acoustic access to joint structures. In some instances, soft tissue contrast can be poor. An inexperienced scanner may find ligaments and tendinous insertions difficult to differentiate from adjacent fibrofatty structures.

MAGNETIC RESONANCE IMAGING

The natural abundance of hydrogen in biological systems and an inherent property of hydrogen, called *spin,* form the basis of conventional MRI. When placed in a strong magnetic field, protons tend to align themselves along the direction of the field. Magnetic field strengths are specified as Tesla and can be variable between clinical scanners. The majority of scanners in clinical usage vary between 1 and 3 Tesla. Application of a radiofrequency (RF) pulse to the system of protons induces the spins to rotate away from the direction of the field, during which time they precess about the direction of the magnetic field at a characteristic frequency, called the Larmor frequency. When the RF pulse is turned off, the spins relax toward their initial state determined by two tissue-dependent relaxation times, T1 and T2, which vary with field strength. T1 (also known as the spin-lattice relaxation) and T2 (or the transverse relaxation time) along with proton density are the principal determinants of signal intensity. The image can emphasize either the T1 or T2 characteristics of the tissue, impacting tissue contrast. Different tissues have varying appearance often based of levels of fat and water content, reflected by their inherent T1 and T2 relaxation times. Tissue morphology is often characterized by their appearance on T1-weighted or proton density images: tendon, muscle, fat, marrow, cortical bone, articular, and fibrocartilage have characteristic appearances. Many pathologic states, alternatively, are characterized by increased mobile water or effective T2 lengthening. Examples include soft tissue edema, inflammatory infiltrates, and neoplasm (Fig. 258-5). Images that emphasize T2 contrast are therefore helpful to display most pathologic states. Selective maps of T2 have been used to characterize the state of articular cartilage in early degenerative disease.[7] Other cartilage specific properties that relate to water content, glycosaminoglycan (GAG) content, and integrity of collagen architecture can be assessed using T2 and other parametric maps that can be derived from the MR data (Fig. 258-6).

The widely used contrast for MRI studies is a neutral, hydrophilic salt of the gadolinium chelate, gadolinium diethylenetriamine-penta-acetic acid (Gd-DTPA). Gadolinium can be injected intravenously or directly into the joint. IV injection (indirect magnetic resonance arthrography) carries the contrast in the vascular system to areas of hyperemia and inflammation (Fig. 258-7). It can be used for assessment of synovial activity in inflammatory joint diseases.[8] Gadolinium is taken up in inflamed synovium and is able to demonstrate thickened pannus. The slope of the early time-signal intensity curve provides a measure of tissue perfusion and can quantify inflammatory activity. Contrast material excreted into the synovial fluid provides excellent depiction of intra-articular structures and can be used in lieu of arthrographic

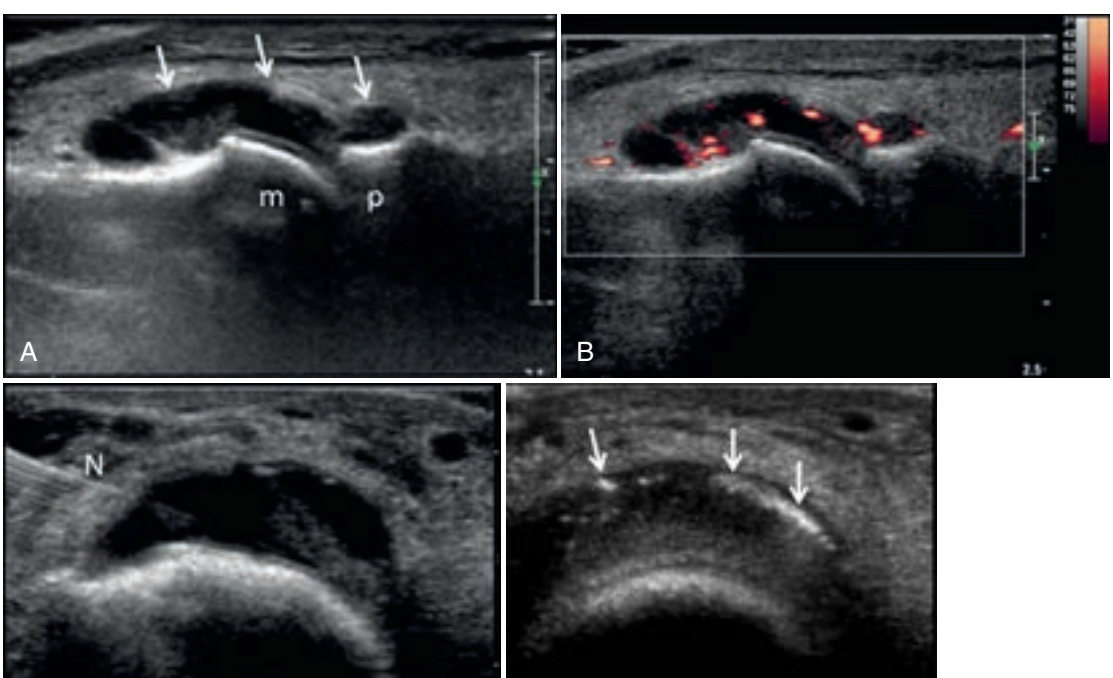

FIGURE 258-4. Ultrasound-guided therapy in the first metatarsophalangeal (MTP) joint of a patient with pain and swelling. A, Longitudinal gray scale image of the dorsal recess of the first MTP joint. Fluid and soft tissue distend the joint capsule (*arrows*). The metatarsal (m) and proximal phalanx (p) are labeled. Note that a thin hypoechoic (dark) band parallels the surface of the metatarsal head, corresponding to the overlying articular cartilage. **B,** Increased vascularity (*red color hues*) demonstrated on power Doppler imaging within the dorsal recess reflects the level of disease activity. **C,** Transverse gray scale ultrasound image shows a needle (N) within the distended dorsal recess from which several drops of synovial fluid were aspirated followed by therapeutic injection. **D,** Postinjection transverse ultrasonography depicts low level echoes (small echogenic foci within dorsal recess) and microbubbles (*arrows*) within the distended joint capsule from injected material. Whereas microbubbles aggregate along the nondependent portion of the distended joint capsule, injected material tends to settle to the deep portion of the recess.

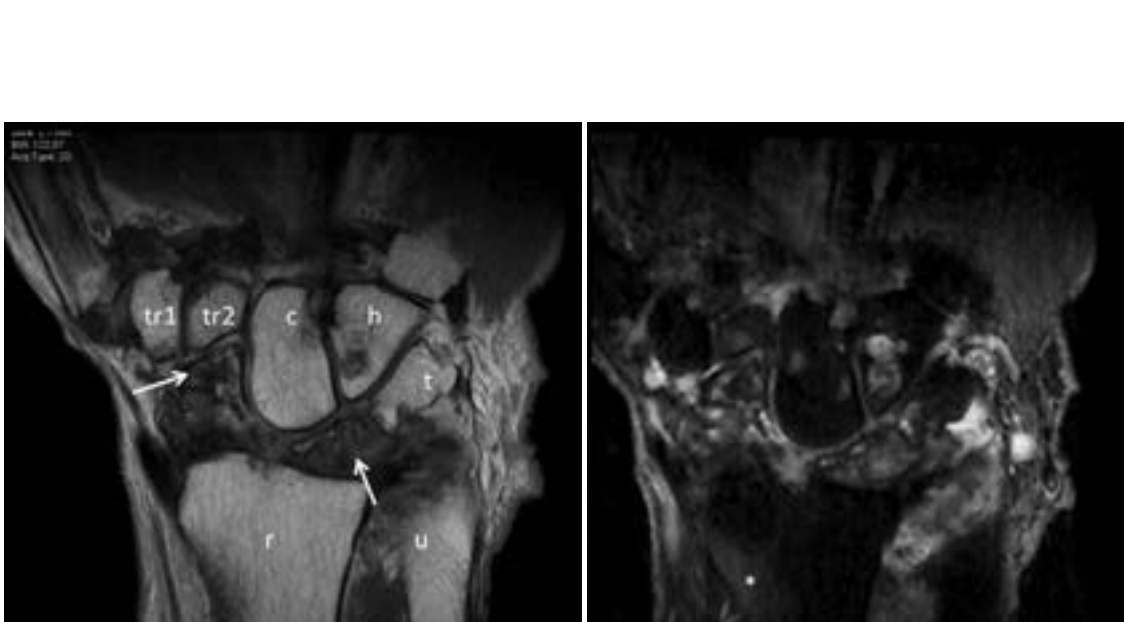

FIGURE 258-5. Magnetic resonance image of the right wrist in a female patient with advanced rheumatoid arthritis. A, Proton density coronal image shows loss of normally bright marrow signal within the scaphoid and lunate bones (*arrows*). The proximal scaphoid is eroded, and the lunate appears deformed and translocated and volarly tilted (not shown), giving rise to its triangular appearance. The distal ulna (u) is poorly visualized because of a large erosion. Intermediate-intensity material (appears dark gray) within the carpus and distal radioulnar joint is difficult to separate from the distal ulna, lunate, and scaphoid. The triquetrum (t), hamate (h), trapezium (tr1) and trapezoid (tr2), capitate (c), and radius (r) are labeled. **B,** Fluid-sensitive coronal image emphasizing T2 relaxation demonstrates increased signal intensity (bright) within the inflammatory pannus, compatible with increase in mobile water associated with inflammation. Increased signal intensity is evident within the lunate, scaphoid, and distal ulna, including focal areas within the distal row of carpal bones, corresponding to small erosions. Diffuse increased signal within the distal radius likely reflects reactive marrow edema (*asterisk*).

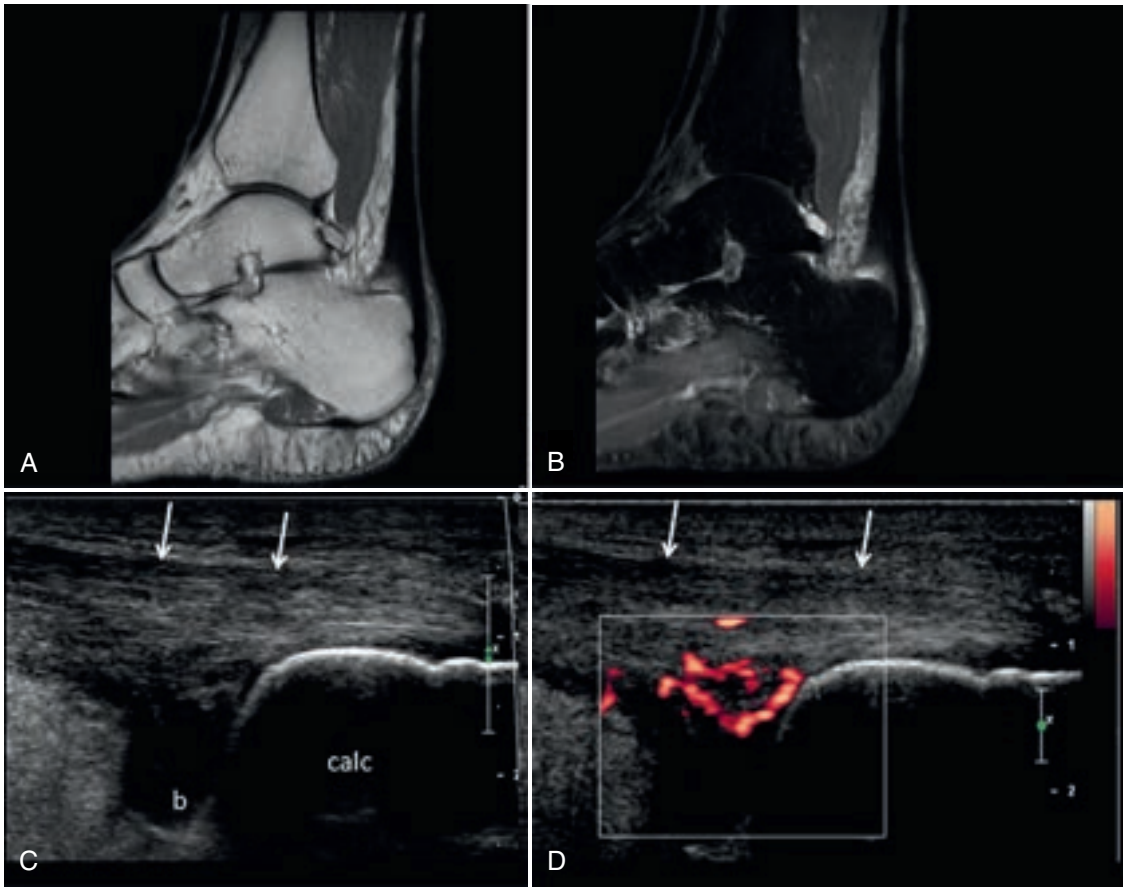

FIGURE 258-6. **Imaging of the soft tissues in a patient with retrocalcaneal pain demonstrating complementary nature of magnetic resonance imaging and ultrasonography. Whereas the proton-density sagittal image (A) emphasizes anatomic detail, the fluid-sensitive image (B) depicts thickening and increased signal intensity within the distal Achilles tendon, reflecting tendinosis, retrocalcaneal bursitis, or a tear of the deep surface of the tendon. Surrounding increased signal intensity (bright areas) within the adjacent soft tissue reflects adjacent soft tissue edema. Long-axis gray scale (C) and power Doppler (D) images of the same patient obtained when the patient presented for ultrasound-guided therapeutic injection. The tendon (*arrows*) is inhomogeneous. A prominent hypoechoic collection deep to the tendon is compatible with retrocalcaneal bursitis (b). There is prominent increased vascularity on power Doppler imaging at the margin of the bursa and tendon. The calcaneus (calc) is labeled.**

direct techniques. In glycosaminoglycan (GAG) -depleted cartilage, there can be delayed uptake of contrast into the cartilage, which would normally be inhibited by the negatively charged GAG molecules.

Patients with renal disease who receive IV injection of gadolinium can develop nephrogenic systemic fibrosis (NSF). (Also see the section Nephrogenic Systemic Fibrosis in Chapter 267.) When the kidney cannot sufficiently clear out the gadolinium, it produces fibrosis of many tissues, including the skin, muscle, heart, nerves, and pleura. To date, NSF has been seen only in patients who have been given IV gadolinium with acute or chronic renal insufficiency. The changes in the skin with NSF are usually bilateral and symmetrical, primarily involving the extremities and the trunk. These changes can mimic systemic sclerosis but, unlike that disease, the face is usually spared. If renal function improves, the skin lesions may stabilize or get better, although in some patients, the process progresses, affecting mobility and causing severe pain.

Injection of dilute gadolinium into the joint (direct magnetic resonance arthrography) is helpful for outlining structures to determine whether there is morphologic damage. Injection is usually performed either under fluoroscopic or ultrasound guidance. This technique is particularly effective for visualization of small structures such as the labrum of the hip or shoulder if there is no joint effusion. It is also helpful for demonstrating breakdown of soft tissue structures that normally prevent communication between joint compartments such as the rotator cuff, triangular fibrocartilage of the wrist, and ligaments in the various joints. Newer techniques that enable image acquisition in near real time as well as the development of MR-compatible needles now permit a variety of percutaneous procedures to be performed directly under MR guidance.

SCINTIGRAPHY

Scintigraphy by its nature represents physiologic imaging because it derives from labeling physiologically occurring substances with a gamma-emitting radionuclide and uses detectors in the form of gamma cameras arranged in a planar or circumferential configuration to determine the distribution of radionuclide within the tissue. Scintigraphy can provide a global assessment of abnormal tracer update or can be performed using a targeted approach (Fig. 258-8). Images often provide high tissue contrast but are of relatively poor spatial resolution. Commonly used agents vary from tagged red blood cells to assess blood flow; agents that reflect bone metabolism (technetium-99m methylene diphosphate [Tc-MDP]); agents that reflect glucose metabolism (18-fluorine deoxy-glucose [18-FDG]), in the case of PET ; and agents that concentrate at sites of inflammation, such as autologous white blood cells labeled with ^{111}In (Indium) and ^{67}Ga-citrate (gallium). Clinical applications include detection of a variety of malignancies, osteomyelitis, vascular graft infection, multifocal infectious disease, inflammatory diseases such as RA, vasculitis, inflammatory bowel disease, sarcoidosis, fever of unknown origin, and infection of joint prostheses.

Traditional nuclear medicine involves use of single gamma photon emissions as a product of nuclear decay. The information can be displayed using planar imaging through a single (or multiple) pinhole camera or displayed tomographically in a manner similar to CT (single-photon emission computed tomography [SPECT]). Bone scintigraphy uses Tc-MDP as the radioactive tracer. The isotope goes to areas of high bone turnover and vascular flow as well as areas of calcium or bone deposition. Three-phase bone scans are obtained at different intervals after injection, reflecting the early vascular phase, the intermediate blood pool phase, and the late phase. Each phase allows for further characterization of the disease process. Abnormal tracer uptake is seen in areas of inflammation, infection, neoplasm, osteonecrosis, and fracture. The scan is most useful to identify the location of lesions within the skeleton but is nonspecific.

Positron emission tomography scans use the appearance of two simultaneously produced 511-KEV gamma rays after annihilation of a positron and electron pair to localize the distribution of radionuclide. The

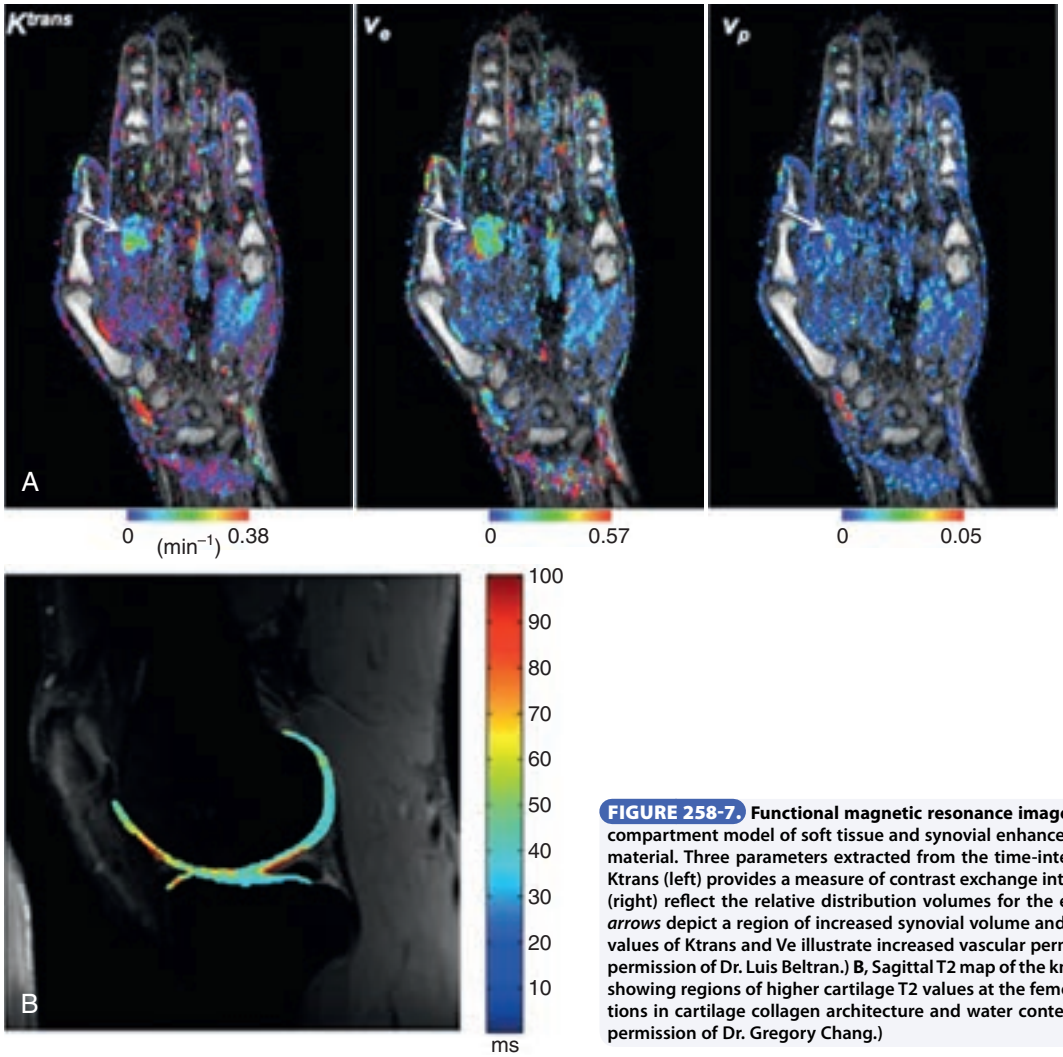

FIGURE 258-7. Functional magnetic resonance image. A, Parametric image derived from fitting a two-compartment model of soft tissue and synovial enhancement after intravenous administration of contrast material. Three parameters extracted from the time-intensity curves are displayed as parametric images: Ktrans (left) provides a measure of contrast exchange into the extravascular soft tissues; Ve (center) and Vp (right) reflect the relative distribution volumes for the extravascular space and plasma, respectively. The *arrows* depict a region of increased synovial volume and enhancement at the second MCP joint. Increased values of Ktrans and Ve illustrate increased vascular permeability at the site of inflammation. (Printed with permission of Dr. Luis Beltran.) **B,** Sagittal T2 map of the knee in which relative T2 relaxation is color encoded, showing regions of higher cartilage T2 values at the femoral condyle and tibial plateau. This reflects alterations in cartilage collagen architecture and water content and possibly early osteoarthritis. (Printed with permission of Dr. Gregory Chang.)

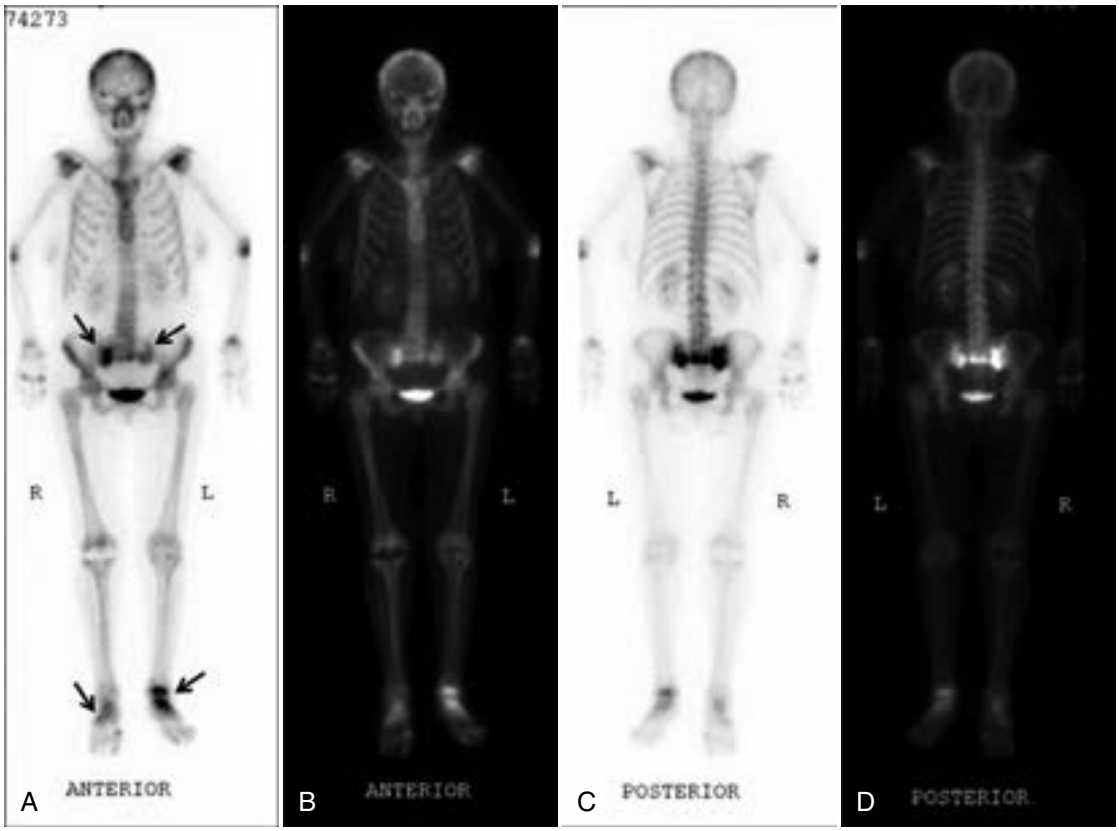

FIGURE 258-8. Rectilinear bone scan in a patient with back pain. Anterior (**A**) and posterior (**B**) delayed images of the axial and appendicular skeleton demonstrate increased tracer uptake in the region of the sacral ala, left ankle, and right midfoot (*arrows*). Follow-up radiographs confirmed the presence of bilateral sacral ala fractures. Note that the central pooling of tracer in the expected location of the urinary bladder is normal. Bone scans provide a sensitive but nonspecific method to evaluate the appendicular and axial skeletal. Increased uptake in the feet in this patient was attributed to degenerative change.

near-simultaneous detection of the photons (coincidence counting) provides an estimate of source tracer concentration. Newer PET scanners are often used in combination with either CT or MRI to achieve improved spatial registration, allow accurate estimates of soft tissue attenuation, provide high-quality anatomic images, and quantify metabolic activity.[9] Combined PET-CT or PET-MRI provides high-resolution images of abnormal metabolic activity and may ultimately provide the most definitive maps of inflammatory activity in patients with rheumatic disease.[10] Early results to date have been promising and are expected to provide sensitive evaluation of the response to DMARDs in patients with inflammatory arthritis.

REVIEW QUESTIONS

1. With regard to imaging of gout, the following statement(s) is (are) true:

A. The presence of periarticular articular erosions and soft tissue nodules are pathognomonic.
B. Osteopenia is a hallmark of the disease.
C. Dual-energy computed tomography can be of value to assess disease extent.
D. It has a characteristic appearance on ultrasound in these patients.
E. C and D are correct.

Answer: E Dual-energy CT is well suited to assess the distribution of tophaceous deposits in patients with gout because of differences of the absorption characteristics of sodium urate crystals compared with other types of deposition diseases. On ultrasonography, calcification along the superficial margin of the cartilage is characteristic of gout, giving rise to a double-line sign.

2. A patient presents with radial-sided wrist pain that extends proximally into the forearm. What imaging test(s) would assess possible etiologies?

A. Radiographs alone should be adequate
B. MRI
C. Ultrasonography
D. B and C are correct
E. A and B are correct

Answer: D The clinical history suggests DeQuervain's tenosynovitis. Radiographs would allow assessment of the osseus structures but not the adjacent tendons. Although MRI would provide the most complete examination of the radial-sided structures, ultrasonography is well suited to evaluating the soft tissues, including the first dorsal compartment tendons. One also could perform ultrasound-guided therapy at the time of diagnosis.

3. A patient is suspected of having sacroiliitis. What imaging study would be appropriate to initially evaluate the patient?

A. Radiographs of the SI joints
B. Computed tomography
C. Nuclear scintigraphy (bone scan)
D. MRI
E. Ultrasonography

Answer: A Dedicated radiographic views of the sacroiliac joints should be the first study ordered to assess for possible erosions and may be sufficient to establish the diagnosis. Computed tomography would provide a more sensitive evaluation for subtle erosions as well as the adjacent soft tissues, particularly with the addition of intravenous contrast. Computed tomography provides an ideal method to perform guided therapy or aspiration. A bone scan would provide a sensitive evaluation of the SI joints but findings would be likewise abnormal for trauma, inflammatory, or degenerative etiologies. A bone scan would allow a global assessment of the axial and appendicular skeleton to determine whether other sites are potentially affected. MRI allows the best assessment of the bone, adjacent marrow space, and soft tissues.

4. A patient has shoulder pain and gives a history of prior dislocation. There is an equivocal abnormality on the humeral head on radiographic evaluation. Which additional study should be considered?

A. Ultrasonography to rule out a rotator cuff tear
B. Noncontrast computed tomography
C. Additional specialized radiographs to evaluate the scapula
D. Direct MR arthrography
E. Nuclear scintigraphy

Answer: D Although ultrasonography could evaluate the rotator cuff, it does not provide adequate assessment of the capsular labral complex. Cross-sectional imaging with intra-articular contrast would best accomplish this. MR arthrography would be optimal. Direct arthrography has been the method of choice in assessing the glenoid labrum, surrounding ligaments, and capsule. CT arthrography is of value, particularly in the postoperative shoulder, and provides indirect imaging of internal structures by coating them with contrast material. Noncontrast CT would be very limited in assessing the labroligamentous complex, even in the presence of a joint effusion caused by poor soft tissue contrast.

5. A patient with early rheumatoid arthritis is being considered for placement on a DMARD. All of the imaging studies below could assess the level of disease activity and response to therapy *except*

A. ^{18}FDG scan.
B. radiographs of the hands and wrists.
C. gray-scale ultrasonography with power Doppler.
D. MRI with gadolinium.
E. parametric MR imaging of distribution volumes of contrast in the extravascular space.

Answer: B Radiographic findings in rheumatoid arthritis usually occur when there has already been irreversible joint damage. Ideally, therapy would be instituted on a radiographically negative patient. The remaining examinations can provide sensitive evaluation of disease activity before the development of either bone or cartilage erosion.

CONNECTIVE TISSUE STRUCTURE AND FUNCTION

SUNEEL S. APTE

Connective tissues are those having a primary mechanical or structural role. They are typically skeletal or osteoarticular tissues such as bone, cartilage, tendon, ligament, fascia, intervertebral disc, and joint-associated structures such as synovium and fibrocartilaginous menisci, although adipose tissue is also included (Table 259-1). However, all viscera, glands, and vascular and nervous tissue contain varying amounts of connective tissue elements that maintain proper spatial relationships between their cells, organize them into functional units, and provide an internal fibrous skeleton or external protective capsule. These connective tissue elements primarily comprise extracellular matrix (ECM), which is organized as a basement membrane or an interstitial matrix. Examples include elastic fibers in the aorta and lung that mediate stretch and recoil, glomerular basement membrane that participates in filtration, and the fibrous endoskeleton that connects the heart valves and transmits myocardial contraction. Indeed, heart valves and chordae tendinae have regional structural similarities to cartilage and tendons.

In addition to their structural role, connective tissues are involved in storage and activation of growth factors, cytokines, and morphogens. Some connective tissue molecules mediate inflammation when released as intact molecules, or may acquire new properties as proteolytically derived fragments (matrikines).[1] Connective tissues such as bone, cartilage, and tendon harbor mesenchymal stem-like cells (MSC) that undergo expansion and differentiation during growth, repair, and regeneration and are therapeutically valuable. Bone contributes to calcium and phosphate homeostasis. A broad perspective on connective tissue is thus crucial for understanding the complex clinical presentation of inherited connective tissue disorders, pathways of tissue repair and regeneration, and pathogenesis of degenerative and autoimmune conditions.

CONNECTIVE TISSUE CELLS, THEIR EXTRACELLULAR MATRIX AND TISSUE-SPECIFIC BIOMECHANICS

Connective tissues comprise cells, typically derived from mesoderm, or in the craniofacial region, derived from the neural crest, and the ECM they secrete and assemble around them. Unique morphologic and biosynthetic properties of the differentiated cells specify osteoblasts, osteoclasts, and osteocytes (in bone); chondrocytes (in cartilage); and tenocytes (in tendons), as well as mixed phenotypes such as cells of fibrocartilage (in the intervertebral disc, some tendon and ligament insertions, and joint menisci). Chondrocytes alter their biosynthetic profile as they terminally differentiate into hypertrophic chondrocytes in growth plate cartilage, downregulating aggrecan and collagen II expression and synthesizing collagen X as a specialized product.[2] As the growth plate transitions into bone, the hypertrophic cells die, blood vessels invade the cartilage, and the cartilage matrix is gradually replaced by bone. Fibroblasts, which secrete collagens as a major product, are the dominant cells in tendons, fascia, ligaments, and dermis. The abundant ECM of connective tissues is their major defining characteristic, but in other tissues and organs, fibroblasts are relatively quiescent, and the interstitial ECM is less organized and not as abundant. However, under appropriate stimuli, fibroblasts transition to highly contractile, biosynthetically active myofibroblasts, which are associated with hypertrophic scars and fibrosis.

During embryonic development, undifferentiated connective tissue cells (mesenchymal cells) produce a hydrated, loose, provisional ECM optimal for migration, branching, and folding of individual cells and cell collectives, such as epithelial sheets. As embryogenesis progresses, provisional ECM is remodeled by matrix-degrading proteinases and replaced by specialized connective tissues whose mechanical properties[3] are better suited to weight bearing, locomotion, and increased circulatory stress. This requirement for increased mechanical strength is not met in the severest forms of inherited connective

TABLE 259-1 DIVERSITY OF CONNECTIVE TISSUES

STRUCTURE	FUNCTION	CELLS	KEY MATRIX COMPONENTS
Adipose tissue	Energy metabolism Physical protection	Adipocytes, fibroblasts, endothelial cells	Collagen I, collagen III, microfibrils, collagen IV, laminin
Basement membranes	Epithelial support Cell polarity Filtration barrier Cell barrier Transparency (lens)	Epithelial and endothelial cells, myotubes, adipocytes, lens fibers	Collagen IV, laminin, nidogens, perlecan
Bone	Structural support Hematopoiesis Mineral storage	Osteoblasts, osteoclasts, osteocytes	Collagen I, osteocalcin, bone sialoprotein, hydroxyapatite
Cartilage	Bone growth Joint motion Load transmission	Chondrocytes	Collagen II, aggrecan
Dermis	Elasticity and resiliency	Fibroblasts	Collagen I, elastin
Ligament	Connects bone to bone	Fibroblasts	Collagen I, SLRPs
Tendon	Connects muscle to bone	Fibroblasts	Collagen I, SLRPs, fibrillins
Visceral stroma	Internal scaffold and capsule	Fibroblasts	Collagen I, collagen III, versican, fibronectin
Synovium	Produces synovial fluid	Fibroblasts, macrophages	Collagen I, collagen III

tissue disorders affecting the vasculature, bone, or cartilage, with neonatal, juvenile, or early adult mortality resulting.

Connective tissues continually sense and adapt to their mechanical environment. The anabolic response of many connective tissues to optimal levels of mechanical stress is now recognized as a crucial, remediable determinant of health. This concept is embodied in Wolff's law of bone remodeling, which states that bone remodels in response to the mechanical loads imposed on it. The composition of specific connective tissues reflects adaptations in response to their mechanical environment or requirements for other specialized functions. For example, articular cartilage and other hyaline cartilages comprise proteoglycan aggregates that exert a swelling pressure and a network of collagen II fibrils that restrain them, contributing to compressive strength and shock absorption.[4] The superficial zone of articular cartilage, in contrast, in enriched in collagenous fibrils that are arranged parallel to the surface to resist shear forces. A mucinous glycoprotein, lubricin, present on the joint surfaces, ensures the low coefficient of friction of synovial joints. In tendons, the major ECM component is collagen I, which has high tensile strength, but in bone, a composite of collagen I and calcium hydroxyapatite provides tensile and compressive strength. The contractile apparatus of skeletal muscle is connected by the dystrophin–glycoprotein complex to the muscle basement membrane and via hierarchical assemblies of interstitial matrix (endomysium, perimysium, and epimysium) to tendons and ultimately to bone, thus efficiently transmitting muscle contraction forces.[5] In the intervertebral disc, the nucleus pulposus is rich in aggrecan, which exerts a swelling pressure that is constrained by the surrounding concentric lamellae of fibrillar collagen in the annulus fibrosus. This composite structure absorbs vertical loads on the spine while limiting deformation of the nucleus pulposus. The interfaces between different connective tissues show structured transitions, highlighted by fibrocartilage present at tendon insertion sites and by Sharpey fibers, which seamlessly integrate perimysial collagen of muscle fibers with collagen in bone. In knee menisci, the cells and ECM of the inner third are cartilaginous, with abundant proteoglycans. Whereas the cells of the outer third, which is vascular and connected to ligaments, are fibroblastic, with corresponding predominance of fibrillar collagens, the cells and ECM in the middle third have an intermediate fibrochondrocyte phenotype.

MAJOR EXTRACELLULAR MATRIX COMPONENTS

Extracellular matrix comprises collagens; the glycosaminoglycan (GAG) hyaluronan (HA); proteoglycans; a variety of glycoproteins; phosphoproteins (especially in bones and teeth); and matricellular proteins such as thrombospondin, tenascin, and periostin, which regulate cellular functions via ECM but do not have a structural role. The distribution of ECM molecules and macromolecules is tightly regulated to achieve specific microenvironments that control proliferation, differentiation, polarity, and migration of cells and provide niches for postnatal stem cells. Collagens, the most abundant proteins of the body, comprise several distinct molecules, each containing at least one triple-helical domain composed of αchains having a repeating Gly-X-Y sequence. Twenty-eight different collagen types are formed from the products of more than 40 genes encoding collagen α chains. The presence of glycine, the smallest amino acid, at every third position, permits triple-helix formation; the amino acid proline, which is frequently modified to form hydroxyproline at the Y position, ensures stability of the triple helix. Fibrillar collagens (e.g., types I-III, V, XI) have long triple-helical (collagenous) regions, so they form rodlike structures. Whereas collagen I, the most widely distributed and abundant, is a heterotrimer comprising two α1(I) chains and an α2(I) chain, collagen II and III are homotrimers of α1(II) and α1(III) chains, respectively. Mutations of either collagen I chain cause the majority of cases of osteogenesis imperfect (Chapter 260) and infrequently can also cause rare subtypes of Ehlers-Danlos syndrome (EDS) (Chapter 260). The triple helices of nonfibrillar collagens are shorter and interspersed with interruptions of the Gly-X-Y sequence or noncollagenous domains that introduce flexible regions. Collagen XIII, XVII, XXIII, and XXV are transmembrane proteins. Fibrillar collagens are synthesized as procollagens having bulky terminal propeptides. The folding of the triple helix occurs intracellularly and is propagated from the C- to the N-terminus to form homo- or heterotrimeric triple helices. The propeptides are subsequently excised by specific proteinases, resulting in rodlike tropocollagen that can be assembled into tightly packed, quarter-staggered fibrils. Failure to remove the N-propeptide of collagen I impairs fibril assembly and leads to a specific type of EDS with severe skin fragility (type VIIc or dermatosparactic type). Whereas collagen I is the major component of bone, dermis, tendons, ligaments, and the sclera of the eye, collagen III is abundant in the skin, lung, and vasculature, explaining the association of genes encoding these collagens with osteogenesis imperfecta and vascular EDS (also known as type IV). Collagen II, together with minor amounts of collagen IX and collagen XI, predominates in cartilage, ocular vitreous and the nucleus pulposus of the intervertebral disc, and mutations of either of these collagen genes can cause the Stickler syndrome (triad of cartilage, eye, and hearing anomalies). Collagen fibrils can consist of more than one collagen type; for instance, collagen V is found in heterotypic fibrils with collagen I and is required for nucleation of fibrillogenesis to form large collagen I fibrils.

Basement membranes are formed from collagen IV, with significant content of laminins, nidogens, and the heparin sulfate proteoglycan perlecan, which is also an important constituent of cartilage. Basement membranes have crucial roles in regulating molecular transport, such as in glomerular filtration, and in establishment and maintenance of epithelial polarity. Collagen VI is widely distributed as beaded microfibrils that form pericellular matrices in fibroblasts and, alongside collagen VII anchoring fibrils, connect basement membranes to interstitial ECM. Hyaluronan, a polymer with repeating disaccharide units, can achieve a molecular weight in the millions of Daltons. It is a key component of cartilage matrix, pericellular matrix of many cell types, and a mediator of inflammation. Proteoglycans are characterized by covalent attachment of glycosaminoglycans, such as chondroitin, heparan, and keratan sulfate, to a core protein. Aggrecan and versican are large chondroitin sulfate proteoglycans that form giant aggregates with hyaluronan in chondrocytes or nucleus pulposus cells and fibroblasts, respectively. On the other hand, some small leucine repeat-rich proteins (SLRPs) such as decorin, biglycan, and lumican are proteoglycans that may have only one or two glycosaminoglycan chains. This class of molecules, which also includes fibromodulin, interacts with collagen fibrils to cross-link them and regulate fibril diameter. They have been shown to bind transforming growth factor β (TGF-β) and, when released from connective tissue, to provide danger signals to the immune system. During connective tissue healing, fibrin and fibronectin provide a transitional ECM permissive for cell migration, differentiation, and other aspects of the repair process.

Elastic fibers are formed by coacervation of a soluble precursor named tropoelastin. Elastic fiber assembly is guided by tissue microfibrils that are formed from three large glycoproteins named fibrillins.[6] Fibrillin-1 is abundant in the aorta, ocular zonule, and perichondrium of bone and is mutated in Marfan syndrome (Chapter 260), resulting in aneurysms, ectopia lentis, and skeletal overgrowth. Fibrillin-2 mutations cause Beals syndrome, with skeletal overgrowth and limb contractures as major features but typically, not severe cardiac or eye problems. The elastic fiber-microfibril network additionally contains versican, microfibril-associated glycoproteins, latent TGF-β–binding proteins, and fibulins. Cutis laxa, which primarily affects the skin but can also involve vasculature and internal organs, can be caused by mutations affecting elastin and fibulin-5.

Most ECM molecules undergo one or more posttranslational modifications. These include enzymatic formation of intra- and interchain disulfide bonds, phosphorylation, and several kinds of glycosylation, including addition of N- and O-linked sugars or glycosaminoglycans such as chondroitin, keratan, or heparan sulfates. Whereas N-linked sugars on some proteins are essential for protein folding and secretion, glycosaminoglycan (GAG) chains provide crucial biophysical properties (such as of aggrecan) and mediate intermolecular interactions. During its biosynthesis, collagen undergoes lysyl and prolyl hydroxylation. Some lysyl and hydroxylysl residues are modified extracellularly by lysyl oxidase and form stable cross-links between adjacent collagen molecules, which strengthens bone, tendons, and skin.[7] Gene defects affecting collagen-modifying enzymes or subunits of the molecular complexes they operate in lead to various recessive forms of osteogenesis imperfecta or EDS. L-Ascorbic acid is a cofactor for lysyl hydroxylase and prolyl hydroxylase and stimulates procollagen synthesis. Its nutritional deficiency leads to scurvy by reducing collagen synthesis, triple-helical stability, and tropocollagen cross-linking. Lathyrism (a now rarely seen neurotoxic disease) is caused by excess ingestion of β-aminopropionitrile, which inhibits lysyl oxidase–mediated formation of lysine aldehydes, which are the precursors of the major collagen and elastin cross-links, and leads to connective tissue fragility. Copper is a required cofactor for lysyl oxidase, and its deficiency can also lead to lathyrism.

CELL-MATRIX INTERACTIONS IN CONNECTIVE TISSUE REGULATION

Cellular ECM receptors mediate cell-matrix interactions that ensure force transmission from cells to ECM[8]; the dynamic reciprocity between cells and

ECM is crucial for environmental sensing and adaptive responses. Receptors provide feedback to the cells regarding the quality, content, or mechanical properties of the matrix (outside-in signaling) to generate appropriate responses, including cell proliferation or migration, or lead to altered ECM synthesis or degradation. Alternatively, cytoplasmic signals may alter cell-matrix interactions (inside-out signaling). Integrins are a large group of heterodimeric receptors with distinct binding preferences that comprise α and β subunits having short cytoplasmic domains. Integrins are crucial for fibronectin assembly, which in turn substantially influences assembly of collagen, fibrillins, and TGF-β activation. Intracellular signals activate integrins to promote high-affinity binding to ECM proteins, and binding of ECM proteins via specific integrin-binding motifs such as Arg-Gly-Asp initiates clustering of cell adhesion complexes and intracellular signaling that, among diverse effects, may elicit the production of inflammatory cytokines. Integrin αvβ6 transmits cellular traction to matrix-bound latent TGF-β, exposing the active growth factor. Because osteoclast attachment to and spreading on bone surfaces is dependent on $\alpha_v\beta_3$, it is being targeted for treatment of osteoporosis (Chapter 243) using chemical antagonists or blocking antibodies. Syndecans are transmembrane heparan sulfate proteoglycans that work as coreceptors alongside high-affinity ECM receptors such as integrins. Discoidin domain receptors are receptor tyrosine kinases activated by binding to native triple-helical collagen.[9] DDR1 and DDR2 bind to fibrillar collagens I-III and collagen V. Collagen IV activates DDR1 but not DDR2, whereas collagen X activates DDR2. With their extended structure, extensive post-translational modification, and exposure of numerous binding sites, ECM molecules such as collagens, fibrillins, and the classical cell-binding protein fibronectin bind to multiple receptor types. Among several hyaluronan-binding molecules on the cell surface, including hyaluronan synthases, CD44 is a major hyaluronan receptor with a role in assembling the pericellular matrix and in inflammation.

EXTRACELLULAR MATRIX NETWORKS AND CONNECTIVE TISSUE DISORDERS

Extracellular matrix molecules and macromolecules are assembled to form higher order (supramolecular) complexes and networks whose varied composition and geometry further diversify connective tissues. These are exemplified by parallel arrays of extensively cross-linked collagen fibrils conferring high tensile strength to tendons, ligaments, and bone, by the multidirectional or "basket-weave" arrangement of collagen in dermis, both permitting and constraining multiaxial mobility, and by the concentric elastic lamellae and crimped collagen in the aorta that regulate hemodynamics. In the eye, orthogonally oriented collagen fibrils in corneal stroma and the lattice-like structure of collagen VIII in the Descemet membrane allow transparency and are crucial for normal vision.

Cartilage and nucleus pulposus ECM comprises large aggregates of hyaluronan and aggrecan, with hundreds of aggrecan molecules attached to each hyaluronan polymer via their N-terminal domain, leaving the C-terminal domain free for interactions with fibrillins, fibulins, and other ECM networks. Each aggrecan molecule has approximately 100 chondroitin sulfate chains and several keratan sulfate chains. Their high fixed-charge density creates an osmotic environment that favors water retention and restricts water flux in cartilage. Through the attachment of hyaluronan to cell-surface receptors, the aggrecan–hyaluronan network is retained by the chondrocyte as a conspicuous pericellular matrix (or glycocalyx). In connective tissue cells other than chondrocytes, pericellular matrices use versican or heparin sulfate proteoglycans instead of aggrecan. The pericellular matrix occupies the crucial interface between cells and their environment and influences cell behavior. It is a provisional ECM in microcosm because it is metabolically more active than further removed matrix, which is more stable. Some interstitial collagen and elastin can be stable for decades.

Connective tissue disorders arise from inborn defects affecting cells or ECM, as well as cellular dysfunction caused by repetitive injury, inflammation, or metabolic or aging processes. Because ECM is such a crucial component of connective tissues, most inherited and acquired connective tissue disorders result from mutant ECM molecules, insufficient but essentially normal matrix (e.g., osteoporosis), or excess or inappropriately deposited matrix (e.g., adhesions, fibrosis, and scleroderma). Osteoarthritis (OA) involves all structures that form the joint, including the synovium and subchondral bone, and appears to result from a combination of genetic and nongenetic factors (Chapter 262). OA of the hip and hands has a stronger genetic component than OA of the knee. Because the function of cartilage is to absorb impact and distribute it to bone without aberrant loading of joint structures, variations in genes that affect joint congruity and alignment or cartilage or meniscal integrity could predispose to OA. For instance, variations in genes encoding cartilage ECM components mutated in chondrodysplasias (Chapter 205), such as collagen II, IX, cartilage oligomeric protein, or matrilins, have been associated with early-onset OA, suggesting a genetic link and a spectrum extending from OA predisposition at the milder end to severe chondrodysplasia. Another genetic link is with the mechanisms that influence the formation of joints, correlating with the association between joint malalignment and OA. Variations in genes associated with the TGF-β superfamily pathway, including *GDF5* (encoding a morphogen required for joint development), *ASPN* (encoding an ECM protein that binds TGFβ), and SMAD3 (encoding a cytoplasm-nucleus signaling intermediary), are associated with OA.[10] Factors that affect load distribution across joints, such as ligament and meniscal tears or hip dysplasia, predispose to OA. Cartilage breakdown in arthritis is not caused by wear and tear but by altered cell-matrix interactions that lead to enzymatic digestion. Loss of aggrecan, followed by loss of SLRPs and other molecules from the surface of collagen fibrils, are initial changes that render collagen fibrils susceptible to destruction by collagenases. The loss of articular cartilage collagen II is thought to constitute an irreversible change in joint disease. Whatever the original insult, the response of chondrocytes or synovium can lead to a vicious cycle of joint destruction because the cells may respond by producing excess ECM and ECM-degrading proteases, with release of both intact and fragmented molecules that may further potentiate inflammation. Rodent immune arthritis models have revealed a role for the alternative complement pathway in arthritis, and cartilage proteins and their fragments released by proteolytic breakdown can have complex effects on the complement pathways that lead to both activation and suppression.

Cell-matrix interactions are profoundly affected in muscular dystrophies (Chapter 421), revealing a continuum that is essential for force transmission from the cytoskeleton to interstitial matrix. Mutations affecting components of the dystrophin–glycoprotein complex including dystroglycan, a receptor that connects muscle cytoskeleton to laminin in the muscle basement membrane, muscle basement membrane (laminin and collagen IV), and collagen VI filaments in ECM, cause a variety of muscular dystrophies. Specific adhesion complexes such as hemidesmosomes in the epidermis mediate anchorage to basement membranes and underlying interstitial ECM. Autoantibodies against collagen XVII and VII, or laminin 5 mutations, affect major components of these complexes and lead to blistering skin diseases (Chapter 439).

PROTEASES AND CONNECTIVE TISSUE TURNOVER

Reflecting continuous adaptation to their environment, connective tissues have intrinsic mechanisms that ensure ECM renewal (i.e., through coupled synthesis and degradation). ECM molecules are substrates for several proteinase classes, chiefly matrix metalloproteinases (MMPs), astacin MMPs such as BMP1 and tolloids, cathepsins, and A disintegrin-like and metalloproteinase domain with thrombospondin type 1 repeats (ADAMTS).[11] Although these proteases are typically considered to be catabolic, some are also essential for the maturation of precursor proteins, such as ADAMTS2, which excises the amino-propeptide of procollagen I, II, and III and is defective in EDS, dermatosparactic type. BMP1, which excises the C-propeptides of procollagen I, II, and III and cleaves lysyl oxidase and several other proteins, is deficient in a type of recessive osteogenesis imperfecta. Although most MMPs are secreted, a class of membrane-type MMPs is cell-surface bound. Most MMPs require proteolytic activation by other MMPs or serine proteinases such as plasmin and furin, and are inhibited by tissue inhibitors of MMPs (TIMPs) and α_2-macroglobulin. Whereas MT1-MMP is crucial for collagen I proteolysis in bone, MMP-13 has been implicated as a major collagen II degrading enzyme in arthritis. Cell surface MMPs such as MT1-MMP and A disintegrin-like and MMPs (ADAM) are responsible for ectodomain shedding of ECM receptors, cell-surface cytokines and cytokine receptors, together regulating a variety of inflammatory and oncogenic situations. ADAMTS4 and ADAMTS5, also known as aggrecanase-1 and -2, respectively, are principal aggrecan-degrading proteases implicated in OA and, together with MMP-13, are potential drug targets in this disorder. However, MMPs, ADAMs, and ADAMTSs have structurally similar catalytic domains and zinc and calcium-dependent proteolytic mechanisms, which renders selective inhibition of any single proteinase from these classes challenging. Indeed, a major side effect of MMP inhibitors used in clinical trials for cancer was connective tissue stiffness and inflammation, presumably resulting from reduced physiological turnover of collagen and other

ECM proteins. Among other proteinases, cathepsin K produced by osteoclasts is active at acidic pH, unlike MMPs, and therefore efficiently digests bone collagen in the acidic osteoclast–bone interface. Neutrophil elastase (a serine proteinase), MMP-9, and MMP-12 (metalloelastase) can degrade elastin. Proteolysis of ECM proteins can release bioactive fragments (matrikines) such as endostatin (from collagen XVIII) or endorepellin (from perlecan), which are antiangiogenic; some fibronectin fragments released in OA are proinflammatory. Hydroxyproline antibodies that recognize ECM-fragments with specific cleaved ends (neoepitope antibodies), as well as cross-linked collagen fragments released by proteolytic activity, are useful biomarkers of bone and cartilage turnover.

AGING OF CONNECTIVE TISSUE

Some visible hallmarks of aging result not only from cellular senescence but also reduced ECM synthesis and increased catabolism, as well as greater connective tissue fragility. This leads, for example, to reduced bone mass or osteoporosis; thinning and loss of elastic properties of dermal ECM, which are visible as wrinkles and sagging skin; reduced volume of intervertebral discs; and increased capillary fragility. Loss of HA and GAGs reduces tissue hydration and of collagen and elastin reduces tensile strength and elasticity, respectively. Products of ECM proteolysis stimulate cells to release free radicals and cytokines that further accelerate ECM breakdown or lead to cell death. Extrinsic factors such as sunburn and ultraviolet irradiation induce cytokines that accelerate this process. In addition, aging collagen can be cross-linked by the Maillard reaction, especially when glucose levels are high, resulting in its modification by advanced glycation end products (AGE), which renders it inflexible, alters the rate of turnover, and affects binding to matrix receptors.[12] AGE binding to a cellular receptor has been shown to lead to cellular dysfunction, oxidative stress, and inflammation.

In summary, connective tissue provides the framework of the musculoskeletal system and a structural scaffold for internal organs while serving as a reservoir for growth factors, cytokines, and stem-like precursor cells. Inherited connective tissue disorders have the potential to disturb these functions in specific ways. Acquired disorders such as OA and fibrosis reflect perturbation of diverse physiological networks and pathways, with altered cell-matrix interactions at the center.

INHERITED DISEASES OF CONNECTIVE TISSUE

REED E. PYERITZ

MUCOPOLYSACCHARIDOSES

DEFINITION

Proteoglycans are ubiquitous components of the extracellular matrix (ECM) and the surfaces of cells, and they are among the largest and most complex of human molecules. Proteoglycans consist of a protein core to which are covalently bound glycosaminoglycans (GAGs; formerly called mucopolysaccharides) of several types: dermatan sulfate, heparan sulfate, keratan sulfate, and chondroitin sulfate. These four polymeric molecules are cleaved from their protein core in lysosomes; then they, plus hyaluronan (a GAG lacking a protein core), are catabolized further in lysosomes in a stepwise fashion by more than a dozen enzymes. Genetic defects in any one of these enzymes lead to the accumulation of GAG metabolites in lysosomes, with profound disruption of cellular physiology. The phenotypes resulting from deficiencies of these catabolic enzymes are termed *mucopolysaccharidoses* (MPSs) and are classified into seven types (Table 260-1). Several additional storage disorders, termed *mucolipidoses* (MLs), are caused by a genetic defect in posttranslational modification of lysosomal enzymes and share features with the MPSs.

EPIDEMIOLOGY

All MPS disorders are rare, each with an incidence of one or fewer cases per 100,000 births, and are without ethnic predilection.

PATHOBIOLOGY

With the exception of MPS II (Hunter syndrome), which is X-linked, each of these disorders is autosomal recessive. All MPSs are caused by deficiency of a single lysosomal enzyme responsible for a specific step in GAG metabolism. Catabolism of GAG proceeds normally until the step requiring the defective enzyme, when further normal metabolism halts. Although a minor degree of nonspecific breakdown occurs, resulting in urinary excretion of cleaved GAG that can be useful diagnostically, the accumulation of GAG within lysosomes of cells of mesenchymal origin; endothelium; and, in most cases, neurons causes widespread, progressive cellular dysfunction and clinical effects. Lysosomal enzymes are targeted to lysosomes by posttranslational addition of mannose 6-phosphate. Deficiency of the phosphotransferase that catalyzes the first step in this reaction results in an inability to catabolize any GAG molecules. The catabolic enzymes, which normally would be transported into lysosomes, instead are secreted from the cell and are found in unusually high concentrations in plasma, providing one diagnostic test for MLs.[1]

Pathology

All pathologic manifestations of MPS and ML disorders worsen with age, and some are present from early developmental stages. Gross anatomic hallmarks are hepatosplenomegaly, marked skeletal alterations (termed *dysostosis multiplex*)[2] that result in short stature and thoracic cage deformity, thickening and narrowing of airways and arteries, and coarsening of facial features. Although mental retardation is a prominent feature of some of these conditions, the brain may show only ventriculomegaly secondary to communicating hydrocephalus. On microscopy, mesenchymal cells show a cytoplasm full of apparently empty vacuoles; these are lysosomes from which GAG has been removed by fixation. Cells cultured from patients show greatly enlarged lysosomes filled with granular material. In the severe form of ML, dense inclusions are present, which gave rise to the common name, *I-cell disease.*

CLINICAL MANIFESTATIONS

Each of the disorders in Table 260-1 shows a wide spectrum of clinical severity. This wide spectrum has led to a classification that gives the impression of separate disorders within some of the MPS and ML types, but these represent the apparent ends of the continuum. Some of the disorders result in death by adolescence (Hurler syndrome, severe Hunter syndrome, ML II), but others are commonly compatible with survival to adulthood. The latter group of disorders is emphasized here.

The milder end of the MPS I spectrum, Scheie syndrome, may not be diagnosed until adulthood; patients present with stiffened joints, corneal clouding and glaucoma, carpal tunnel syndrome, and aortic valvular disease. Stature and intelligence are not affected. The main health risks are valvular involvement, thickening of meninges that can produce a myelopathy, and thickening of the upper airways that can produce obstructive symptoms and sleep apnea.

The milder form of MPS II, Hunter syndrome, is distinctive because it is X-linked (affecting males almost exclusively), and the cornea shows little overt clouding. Cervical myelopathy, obstructive airway disease, and cor pulmonale are important concerns. A combined conductive and neurosensory hearing loss is common.

Neither MPS IV (Morquio syndrome) nor MPS VI (Maroteaux-Lamy syndrome) affects intelligence. Both syndromes often are associated with severe skeletal changes, which are distinct radiographically but produce similar problems of kyphoscoliosis, pectus carinatum, restrictive lung disease, severe short stature, and joint degeneration. Cervical myelopathy resulting from a thickened dura is common to both disorders and is accentuated by odontoid hypoplasia in MPS IV. Thickening of the aortic and mitral valves may produce severe dysfunction necessitating their replacement. General anesthesia is especially hazardous because of the narrow upper and middle airways and cervical instability.

Patients with ML III (pseudo-Hurler polydystrophy) resemble patients with MPS VI but often have mild to moderate mental retardation. Aortic regurgitation is common.

TABLE 260-1 MUCOPOLYSACCHARIDOSES AND MUCOLIPIDOSES

TYPE	EPONYM OR COMMON NAME	CLINICAL FEATURES	INHERITANCE	OMIM*	ENZYMATIC DEFECT
MPS IH	Hurler syndrome	DM and short stature; MR; corneal clouding; HS; heart disease; death in childhood	AR	252800	α-L-iduronidase
MPS IS	Scheie syndrome	Coarse facies; stiff joints, corneal clouding; aortic valve disease; normal intelligence and lifespan	AR	252800	α-L-iduronidase
MPS II	Hunter syndrome	Severe form: coarse facies, DM and short stature, HS; MR; no corneal clouding; death by late adolescence Mild form: coarse facies, short stature; normal intelligence; survival to adulthood	XL	309900	Iduronate sulfatase
MPS IIIA	Sanfilippo A	Severe MR and hyperactivity; mild somatic changes	AR	252900	Heparan *N*-sulfatase
MPS IIIB	Sanfilippo B	Same as MPS IIIA	AR	252920	α-*N*-acetylglucosaminidase
MPS IIIC	Sanfilippo C	Same as MPS IIIA	AR	252930	Acetyl-coenzyme A: α-glucosaminide acetyltransferase
MPS IIID	Sanfilippo D	Same as MPS IIIA	AR	252940	*N*-acetylglucosamine 6-sulfatase
MPS IVA	Morquio A	Short stature and distinct skeletal dysplasia with odontoid hypoplasia and myelopathy; corneal clouding; normal intelligence; valvular heart disease	AR	253000	Galactose 6-sulfatase
MPS IVB	Morquio B	Same as MPS IVA	AR	253010	β-Galactosidase
MPS VI	Maroteaux-Lamy	DM and short stature; corneal clouding; normal intelligence; aortic stenosis; leukocyte inclusions; hydrocephalus in severe form	AR	253200	*N*-acetylgalactosamine
MPS VII	Sly syndrome	DM; HS; widely variable, including MR	AR	253220	β-Glucuronidase
MPS IX	—	Short stature; periarticular soft tissue masses	AR	601492	Hyaluronidase
ML II	I-cell disease	Similar to but more severe than MPS IH but with cellular inclusions; no mucopolysaccharidurria	AR	252500	UDP-*N*-acetylglucosamine: lysosomal enzyme *N*-acetylglucosaminyl-1- phosphotransferase
ML III	Pseudo-Hurler polydystrophy	Short stature and mild DM; stiff joints, mild MR; survival to adulthood	AR	252500	Same as ML II arthropathy, coarse facies; variable but milder

*Entries in Online Mendelian Inheritance in Man, OMIM. McKusick-Nathans Institute of Genetic Medicine. Baltimore: Johns Hopkins University. http://omim.org.
AR = autosomal recessive; DM = dysostosis multiplex; HS = hepatosplenomegaly; MR= mental retardation; XL = X-linked.

DIAGNOSIS

Differential Diagnosis

Diagnosis of these conditions is difficult in young children, before most of the clinical features have progressed, but should be considered in any person with hepatosplenomegaly and coarsening of the facial features. Evaluation requires a pedigree analysis, ophthalmologic examination, skeletal radiographic survey, echocardiography, and analysis of the urine for excretion of GAGs. Often the specific MPS is evident from radiographs, the presence or absence of corneal clouding, and the pattern of mucopolysaccharidurria. Enzymatic analysis of leukocytes confirms the diagnosis. Patients with MLs do not show mucopolysaccharidurria but have marked elevation of all the GAG catabolic lysosomal enzymes in plasma.

TREATMENT Rx

Ventriculoperitoneal shunting is necessary if intracranial pressure is elevated. Close attention to hearing and visual problems is essential throughout life. Many adults with MPS or ML require surgery for carpal tunnel syndrome. Cardiovascular surgery for valvular or coronary disease may be necessary. All use of anesthesia is high risk because of the narrow airways and, in the case of MPS IV, atlantoaxial instability. For patients who remain ambulatory, selective joint replacement can be beneficial. Because of the morbidity associated with thoracic cage deformity, consideration should be given to stabilizing the spinal deformity before it becomes severe.

Replacement of the deficient enzyme via intravenous infusion is being studied for most of the MPS disorders. Laronidase (Aldurazyme) has been approved in the United States for treatment of MPS I. An infusion every 2 weeks for 1 year in adolescent and adult patients resulted in substantial reduction in hepatosplenomegaly and modest improvement in pulmonary function, sleep apnea, and joint mobility. Whether early institution of therapy in young children modulates mental retardation in the Hurler variant of MPS I is uncertain. Galsulfase (Naglazyme) has been approved for the treatment of MPS VI, in which somatic rather than neurologic problems predominate. Bone marrow transplantation has been attempted in many of the MPS disorders, with mixed success. The earlier transplantation occurs, the better the outcome in terms of somatic problems, but prevention of mental retardation has not occurred. Current recommendations based on consensus in Europe calls for hematopoietic stem cell transplantation for patients with Hurler syndrome before the age of 2.5 years. Enzyme replacement should be started in all patients when diagnosed.[3]

MARFAN SYNDROME

DEFINITION

Marfan syndrome is an autosomal dominant, pleiotropic disorder caused by defects in the principal component of the extracellular microfibril, the large glycoprotein fibrillin-1. The disease manifestations occur in multiple systems, especially the eye, skeleton, heart, aorta, lung, and integument. Notable features include dislocation of the ocular lens, tall stature with particularly long limbs and digits, deformity of the thoracic cage from pectus carinatum or excavatum with abnormal curvature of the spine, mitral and tricuspid valve prolapse, dilation of the sinuses of Valsalva and predisposition to aortic dissection, spontaneous pneumothorax, abnormal skin stretch marks, hernias, and dural ectasia. If untreated, patients often die before 30 or 40 years of age from aortic dissection or congestive heart failure.

EPIDEMIOLOGY

Marfan syndrome is a common Mendelian disorder, with an estimated incidence of about one per 5000 births. Marfan syndrome is found throughout the world, without ethnic or geographic predilection.

PATHOBIOLOGY

Pathogenesis

Mutations in *FBN1,* which maps to human chromosome 15q21.1 and encodes fibrillin-1, cause Marfan syndrome and related connective tissue disorders. More than 1000 distinct mutations have been found, and few occur in more than one family. Patients are heterozygous for mutations in *FBN1,* leading to autosomal dominant inheritance. Extracellular microfibrils are

polymers of many fibrillin-1 molecules and are ubiquitous in the ECM of most tissues. Latent transforming growth factor β (TGF-β) binding protein, which keeps the cytokine inactive, bears striking homology to regions of fibrillin. Abnormalities of either the quality or the quantity of microfibrils disrupt normal signaling by TGF-β, especially during embryonic development and postnatal growth. Studies in mice engineered to harbor human mutations in *FBN1* showed that excessive TGF-β signaling causes abnormal lung septation (the precursor to pneumothorax), mitral valve prolapse, muscular hypoplasia, and aortic dilatation. This fundamental shift in understanding of the pathogenesis of Marfan syndrome has suggested novel therapies, such as with small molecules that affect the activity of TGF-β or its downstream signaling.

The features of Marfan syndrome are highly variable, even among relatives who share the same mutation in *FBN1*. This variability persists after accounting for the effects of age. Men tend to be affected more severely, for unclear reasons.

Pathology

The features of Marfan syndrome are age dependent. Some severely affected infants have flagrant features and often die of mitral regurgitation and heart failure despite aggressive management. At the other end of the clinical spectrum, Marfan syndrome merges with several related disorders, and patients may not come to medical attention, let alone receive a definitive diagnosis, until adulthood.

None of the gross or microscopic pathologic changes is specific for Marfan syndrome. The medial degeneration of the aortic wall, characterized by disarray and fragmentation of the elastic fibers and increased proteoglycan (often inappropriately termed *cystic medial necrosis*) also can be seen in other disorders and in older people with hypertension. Aortic dissection (Chapter 78) usually begins just superior to the aortic valve (type A) and often progresses to the bifurcation. Death usually results from retrograde dissection and hemopericardium. About 10% of dissections begin in the descending thoracic aorta (type B).

CLINICAL MANIFESTATIONS

The lens tends to be displaced superiorly, and usually the zonules remain intact. The retina is at increased risk of detachment, especially in patients who are highly myopic. Tubular bones overgrow, accounting for the disproportionate tall stature (dolichostenomelia), long digits (arachnodactyly), and sternal deformity. Ligaments may be lax, causing scoliosis and joint hypermobility. Alternatively, congenital contractures are common, especially of the elbows. The palate typically is highly arched, and the dentition can be crowded and malocclused. Mitral valve prolapse occurs in about 80% of cases, and the valve leaflets become progressively thickened (myxomatous on histopathology) (Chapter 75). The mitral annulus may dilate and calcify. Aortic root dilation begins in the sinuses of Valsalva and progresses with age, albeit at highly variable rates (Chapter 78).[4] Most males with Marfan syndrome have an aortic root dimension above the upper limit of normal for their body surface area by adolescence. Some females show a slower progression and may have a root diameter near the upper limit of normal well into adulthood. The dilation usually does not involve the distal ascending aorta. Spontaneous pneumothorax, resulting from rupture of apical blebs, occurs in about 5% of patients. Stretch marks (striae atrophicae) occur over areas of flexural stress, such as the shoulders, breasts, and lower back. The neural canal in the lumbosacral region is enlarged in most people with Marfan syndrome; this may be visible on plain radiographs, especially if the neuroforamina are widened. Imaging by computed tomography or magnetic resonance imaging is diagnostic and should be used in patients with back pain and radicular symptoms. Dural ectasia progresses with age; large anterior meningoceles in the pelvis are a severe manifestation.[5] Simple cysts in the liver and kidneys are common, increase with age, and seldom cause clinical problems. Sleep apnea is of increased frequency in adults.[6]

DIAGNOSIS

Differential Diagnosis

The conditions that overlap clinically and genetically with Marfan syndrome include familial aortic aneurysm, familial ectopia lentis, mitral valve prolapse, mild aortic dilation, striae, skeleton (MASS) phenotype (which includes many families with mitral valve prolapse syndrome), and Loeys-Dietz syndrome. Most of these conditions are diagnosed clinically, so differentiating among them is arbitrary. A careful family history is essential to this process. Molecular genetic testing has a limited role. However, if the mutation in *FBN1* is known in a family, analysis of DNA can be used effectively for presymptomatic or prenatal diagnosis. Loeys-Dietz syndrome, which is associated with generalized arterial tortuosity and susceptibility to dissection, is caused by mutation in either of two receptors for TGF-β, *TGFBR1* and *TGFBR2*, and molecular analysis is clinically available.

A question of Marfan syndrome arises most commonly in tall, lanky adolescents who have several minor skeletal features, nearsightedness, and athletic desires. A detailed ophthalmologic examination with full pupillary dilation and a transthoracic echocardiogram are essential components in the evaluation. If these test results are negative and no one in the family has a history of Marfan syndrome or aortic dissection, the patient probably can be reassured.[7]

TREATMENT

Rx

Life expectancy for those with Marfan syndrome has improved markedly, to the point that many patients can expect survival to advanced years. All patients should be seen at least annually by a physician who manages the overall care. Most patients require annual ophthalmologic and cardiologic consultation and orthopedic consultation as required by specific problems. Lens subluxation often requires surgical correction.[8] A number of studies, but only one randomized clinical trial, support the prophylactic use of β-adrenergic blockade from an early age to slow the rate of aortic root dilation and protect against aortic dissection. Based on studies of the Marfan mouse, therapies that interfere with excess signaling through pathways mediated by TGF-β are being studied in human clinical trials. One large European trial suggested a benefit of the angiotensin receptor blocker losartan on aortic root dilatation rate,[9] but a large international trial found no benefit of losartan compared with atenolol.[10] Prophylactic surgical repair of the aortic root has had the greatest beneficial impact. The composite graft, involving a prosthetic valve in a Dacron tube and implantation of the coronary ostia into the graft, was the first approach to produce markedly improved survival in these patients. More recently, replacement of the aneurysm and preservation of the native aortic valve have shown promise and should be considered first.[9,10] For adults, aortic root surgery should be strongly considered when the maximal aortic diameter reaches 45 mm, and a family history of aortic dissection should prompt earlier repair (Chapter 78).

EHLERS-DANLOS SYNDROMES

DEFINITION

The Ehlers-Danlos syndromes (EDSs) are clinically variable and genetically heterogeneous. Diagnoses still are based largely on the bedside examination. The unifying themes among these disorders are fragility of tissues, joint hypermobility, and skin hyperextensibility.[11]

EPIDEMIOLOGY

No accurate data exist, but an incidence of about one in 5000 births is a reasonable estimate of how many individuals qualify for one of the EDS diagnoses. Each type represents something of a clinical spectrum, with the mild end merging with what might be considered normal variation. Just as the diagnostic criteria are arbitrary, so would be any determination of prevalence based on phenotypic criteria. The extent to which normal variation in joint hypermobility, skin elasticity, and tissue fragility represents genetic variation at loci that encode collagen or other ECM genes requires considerable research.

PATHOBIOLOGY

Pathogenesis

Defects in collagen and other proteins in the ECM of various tissues underlie all forms of EDS that have been elucidated so far. The specific mutations occur in a variety of genes, with the effect of altering the structure, synthesis, posttranslational modifications, or stability of the collagens involved. The known molecular defects are listed in Table 260-2.

Pathology

Few findings in the routine pathologic evaluation distinguish among the various types of EDS or even distinguish individual types from normal. Thickness of the dermis is decreased in some forms, especially the vascular type, and the walls of arteries are reduced in thickness in this type. By electron microscopy, the classic, hypermobile, and kyphoscoliotic types have abnormal collagen fibers, especially when viewed in cross section (variable and often increased fiber diameter with an irregular outline). In the vascular type,

TABLE 260-2 EHLERS-DANLOS SYNDROMES

TYPE	FORMER NAME	CLINICAL FEATURES*	INHERITANCE	OMIM†	MOLECULAR DEFECT
Classic	EDS I and II	Joint hypermobility; skin hyperextensibility; atrophic scars; smooth, velvety skin; subcutaneous spheroids	AD	130000 130010	Structure of type V collagen caused by mutations in *COL5A1* or *COL5A2*
Hypermobility	EDS III	Joint hypermobility; some skin hyperextensibility, with or without a smooth, velvety texture	AD AR	130020 225320	? Tenascin-X *(TNX)*
Vascular	EDS IV	Thin skin; easy bruising; pinched nose; acrogeria; rupture of large- and medium-caliber arteries, uterus, and large bowel	AD	130050 (225350) (225360)	Deficient type III collagen *(COL3A1)*
Kyphoscoliotic	EDS VI	Joint hypermobility; congenital, progressive rupture; scoliosis; scleral fragility with globe rupture; tissue fragility, aortic dilation, MVP	AR	225400	Deficiency of lysyl hydroxylase
Arthrochalasis	EDS VII A	Joint hypermobility, severe, with subluxations, congenital hip dislocation; and skin hyperextensibility; tissue fragility	AD	130060	No cleavage of amino terminus of type I procollagen caused by mutations in *COL1A1* or *COL1A2*
Dermatosparaxis	EDS VII C	Severe skin fragility; decreased skin elasticity, easy bruising; hernias; premature rupture of fetal membranes	AR	225410	No cleavage of amino terminus of type I procollagen caused by deficiency of peptidase
Unclassified types	EDS V	Classic features	XL	305200	?
	EDS VIII	Classic features and periodontal disease	AD	130080	?
	EDS X	Mild classic features, MVP	?	225310	?
	EDS XI	Joint instability	AD	147900	?
	EDS IX	Classic features; occipital horns	XL	309400	Allelic to Menkes syndrome
	EDS, progeroid form	Classic features and premature aging	AR	130700	Deficiency of galactosyltransferase I

*Listed in order of diagnostic importance.
†Entries in Online Mendelian Inheritance in Man, OMIM. McKusick-Nathans Institute of Genetic Medicine. Baltimore: Johns Hopkins University. http://omim.org.
AD = autosomal dominant; AR = autosomal recessive; EDS = Ehlers-Danlos syndrome; MVP = mitral valve prolapse; XL = X-linked.

some patients have dilated endoplasmic reticulum consistent with aberrant secretion of type III collagen molecules.

CLINICAL MANIFESTATIONS

The major and minor features of each EDS are detailed in Table 260-2. Infants with classic EDS often are born prematurely by 4 to 8 weeks because of rupture of fetal membranes. Diagnosis of the vascular and kyphoscoliotic types is important because of their cardiovascular features. The vascular type, previously termed *EDS IV,* is characterized by spontaneous rupture of large arteries and hollow organs, especially the colon and uterus, and pneumothorax. Because these events carry considerable morbidity, life expectancy is reduced, on average, by more than half. During pregnancy, women with this form of EDS are especially vulnerable to rupture of major arteries and the uterus. In the kyphoscoliotic type, aortic root dilation and aortic regurgitation can develop. Patients with most forms of EDS are prone to develop mitral valve prolapse, and progression to mitral regurgitation (Chapter 75) occurs more often than in the common form of mitral valve prolapse.

DIAGNOSIS

Differential Diagnosis

By carefully adherence to the clinical features shown in Table 260-2 and judicious use of laboratory tests, the various defined types of EDS can be differentiated. Many specific non-EDS syndromes need to be excluded. The kyphoscoliotic type of EDS in infants shares some features with severe Marfan syndrome. Patients with Larsen syndrome may resemble patients with the arthrochalasis type of EDS. The skin redundancy and loss of elasticity of the dermatosparaxis type of EDS is reminiscent of autosomal dominant cutis laxa, which is not associated with easy bruising or tissue fragility.

The most difficult decision is whether any diagnosis of EDS is warranted. Patients who have only joint hypermobility without skin changes should not be labeled with EDS; a diagnosis of familial joint hypermobility might be more appropriate. Familial joint instability involves a predisposition to dislocations of major joints that is rare in most types of EDS except for arthrochalasis.

TREATMENT

Rx

Management of most skin and joint problems should be conservative and preventive. Sutures need to be placed with careful attention to approximating the margins and avoiding tension; removable sutures should be left in place for twice the usual time. Most instances of joint hypermobility and pain in EDS do not require surgical treatment. Benefit often is derived from physical therapy designed to strengthen the muscles that provide support for the loose ligaments. All patients should receive genetic counseling about the mode of inheritance and their risk of having children affected with EDS. The possibility of prenatal diagnosis exists for all of the EDS types with defined molecular or biochemical defects.

The vascular type of EDS requires particular surgical care; the ruptured arteries are difficult to repair because of the pronounced vascular fragility. Experienced vascular surgeons are having some success with prophylactic repair of vessels deemed to be at risk of dissection or rupture.[12] One clinical trial suggested improved outcomes with prophylactic β-adrenergic blockade. Rupture of the bowel is a surgical emergency. Because the risk of uterine and vascular rupture is especially high during pregnancy in women with the vascular form, affected women should be advised that there is a substantial risk of death related to pregnancy and delivery. Patients should be advised to avoid contact sports and to treat blood pressure elevations aggressively. Arteriography and arterial lines should be avoided if possible. Biochemical and genetic screening holds the potential for reassuring relatives at risk that they do not have a defect in type III collagen.

The kyphoscoliotic type of EDS may improve with large doses of vitamin C (1-4 g/day) because ascorbate is a cofactor for the enzyme that is deficient. No other metabolic or genetic therapy is effective in other forms of EDS.

OSTEOGENESIS IMPERFECTA SYNDROMES

DEFINITION

The heterogeneous group of disorders called *osteogenesis imperfecta* (OI) includes, at one end of the severity spectrum, a type that is lethal prenatally or in the neonatal period and, at the other, such mild features that distinguishing affected individuals from the general population is difficult. The unifying feature is hereditary osteopenia (insufficient bone), with primary defects in the protein matrix in bone and other tissues. The clinical syndromes all involve osteoporosis with liability to fracture (Chapter 243).

EPIDEMIOLOGY

No careful epidemiologic study has been performed, and the milder forms of type I OI merge with the phenotypes of familial osteoporosis, fracture

TABLE 260-3 OSTEOGENESIS IMPERFECTA

TYPE	CLINICAL FEATURES	INHERITANCE	OMIM*	BASIC DEFECTS
I	Fractures variable in number; little deformity; stature normal or nearly so; blue sclerae; hearing loss common but not always present; DI uncommon	AD	166200	Typically, one nonfunctional *COL1A1* allele
II	Lethal in utero or shortly after birth; many fractures at birth typically involving ribs (may appear "beaded") and other long bones; little calvaria; pulmonary hypertension	AD	166210	*COL1A1* or *COL1A2:* substitution of glycyl residues; occasionally deletions of a portion of the triple-helical domain
		AR	259400	Deletion in *COL1A2* plus a nonfunctional allele
III	Fractures common, but long bones progressively deform starting in utero; stature markedly reduced; sclerae often blue but become lighter with age; DI and hearing loss common	AD	259420	One single amino acid substitution
		AR (rare)	259440	Two mutations in *COL1A1* and/or *COL1A2* (rarely)
IV	Fractures common; stature usually reduced; bone deformity common but rarely severe; scleral hue normal to grayish; hearing loss variable; DI common	AD	166220	Point mutations in *COL1A1* or *COL1A2*
			166240	Exon skipping mutations in *COL1A2*
V	Similar to type IV without DI or blue sclerae; fractures develop hyperplastic callus; calcification of the interosseous membrane between the radius and ulna	AD	610967	?
VI	Similar to type IV without DI, blue sclerae or Wormian bones; excess osteoid present in bone	?	610968	?
VII	Similar to types II or III with fractures at birth, blue sclerae, no DI; presence of rhizomelic limb shortening and coxa vara	AR	610682	Mutations in *CRTAP*
VIII	Similar to types II or III with fractures at birth	AR	610915	Mutations in *LEPRE1*
IX	Similar to types II or III with fractures at birth	AR	259440	Mutations in *PPIB*

*Entries in Online Mendelian Inheritance in Man, OMIM. McKusick-Nathans Institute of Genetic Medicine. Baltimore: Johns Hopkins University. http://omim.org.
AD = autosomal dominant; AR = autosomal recessive; DI = dentinogenesis imperfecta.

susceptibility, and joint hypermobility found in the general population. A crude estimate of the overall prevalence of OI is one to two per 20,000 births. The neonatal lethal form (type II), which is almost always caused by a new mutation in a parental gamete, has an incidence of about one in 50,000 births.

PATHOBIOLOGY

Pathogenesis

Most patients in whom mutations have been found usually have defects in the two genes that encode the procollagen chains of type I collagen, *COL1A1* and *COL1A2*. Type I collagen is composed of two α1(I) and one α2(I) procollagen chains; the mature fiber requires considerable posttranslational modification, which occurs appropriately only if the three procollagen chains have intertwined to form a triple helix that is perfect and completed at the right speed. A mutation that affects formation of the triple helix, such as substitution of one of the mandatory glycine residues that occurs at every third position, also has adverse effects on the modifications that render the molecule capable of forming effective mature fibers. As a result, a single nucleotide change resulting in a missense mutation can have profound effects on the ECM and produce a severe condition.[13] Alternatively, and at first glance paradoxically, a mutation that eliminates an entire allele, or at least production of any product capable of intertwining with normal procollagen chains, has a much milder effect on the ECM and on the severity of OI. Examples of the most common classes of mutations are shown in Table 260-3. Hundreds of mutations have been described. Patients with mutations in *COL1A1* or *COL1A2* are heterozygous, and thus the most common forms of OI are inherited as autosomal dominant traits. Several autosomal recessive forms of OI occur because of mutations in genes that encode enzymes that process type I collagen into mature fibrils.[14]

Pathology

Other than the gross pathology associated with the clinical manifestations, the most characteristic pathology is a primary reduction in bone matrix with secondary undermineralization.

CLINICAL MANIFESTATIONS

The major phenotypic features of OI are shown in Table 260-3. Among the most common forms, the most severe type is type II, followed in decreasing order by types III, IV, and I. In type II, infants either are stillborn or die soon after birth of pulmonary failure secondary to the small thorax, which usually is compromised further by myriad rib fractures. A few infants have survived for at least a few years but require enormous attention to their medical needs.

Type III OI may be confused with type II at birth, but survival alone helps make the distinction. Bony deformity is pronounced and not necessarily caused by fractures. Mobility is impaired, and most patients require a wheelchair at an early age. Stature may be severely compromised. Because of progressive vertebral column deformity and rib fractures, restrictive lung disease is a common problem as patients age; many die of pulmonary complications. Basilar impression causing compression of the brain stem and the craniocervical junction can produce central sleep apnea, headache, and upper motor neuron signs.

Patients with type IV OI generally have reduced stature, some bony deformity, and abnormal teeth that are opalescent and wear easily (dentinogenesis imperfecta). As in type I OI, the tendency to fracture is highest in childhood and lessens with adolescence. A distinguishing characteristic of type IV OI is a normal scleral hue.

Type I OI is probably the most common form and is associated with a bluish or blue-gray scleral hue. People with type I OI who also have dentinogenesis imperfecta tend to have more severe skeletal problems. The risk of fracture diminishes during adulthood but reemerges as a major concern for women after menopause. Hearing impairment in all forms of OI is common and age related, being rare before adolescence. The deficits are of either a mixed or a predominantly conductive form.

The recessive forms of OI (types VI-IX) range in severity from type IV to type II and may have distinctive radiologic or histopathologic findings.

DIAGNOSIS

Differential Diagnosis

The range of diagnostic possibilities in a person with multiple fractures largely depends on age. In infancy, the genetic conditions hypophosphatasia, severe osteochondrodysplasias (e.g., achondrogenesis and forms of spondyloepiphyseal dysplasia), and Menkes syndrome need to be excluded when a diagnosis of type II or type III OI is considered. The radiographic features eventually become entirely diagnostic, but often the neonatologist has to arrive at a definitive answer in short order. Analysis of serum alkaline phosphatase and copper can be helpful. In childhood, the most common situation leading to consideration of a mild form of OI is child abuse. In this situation, the pattern of fracture is usually distinct, and bone mineralization should be normal if the child is the object of nonaccidental or repeated accidental trauma. Abnormal scleral hue, dentinogenesis imperfecta, and wormian bones (microfractures along the cranial sutures) all support the diagnosis of

OI. The legal and child-protective systems often request exclusion of OI by analysis of collagen production from cultured skin fibroblasts or analysis of DNA for a mutation.

In older children, the disorder idiopathic juvenile osteoporosis should be considered in any patient seen initially with repeated fractures. Many osteochondrodysplasias are associated with short stature, skeletal deformity, and a tendency to fracture. Pyknodysostosis and osteopetrosis are associated with sclerotic bones rather than osteoporotic ones. In adulthood, early-onset osteoporosis may be confused with OI (Chapter 243). Mutations in type I collagen also cause familial osteoporosis, and the skeletal phenotypes merge; patients with true OI may have scleral, hearing, or dental abnormalities and a positive family history.

Analysis of the specific enzymes defective in the recessive forms of OI is useful for establishing the diagnosis and enabling reproductive counseling and prenatal diagnosis if desired.

TREATMENT

Rx

Management of the skeletal complications largely depends on orthopedic, physical, and occupational therapy approaches. Risedronate (2.5 or 5 mg daily) increases bone mineral density and reduces both first and recurrent fractures in children with OI.[A1] The long-term goals are for the patient to maintain function and independence as an individual. These goals can be advanced in some patients by judicious use of intramedullary rods in the long bones of the legs; if mobility and especially ambulation can be maintained, the demineralization associated with inactivity can be avoided.

Unaffected parents of a child with OI and all affected individuals should have genetic counseling. For the parents of a child with type II OI, the possibility of germinal mosaicism (which has been well documented in this condition) should not be overlooked. If one parent has a "new" mutation in one of the type I procollagen genes and multiple gonadal cells carry this mutation, the risk of recurrence in future children is not negligible. If the mutation in the affected child can be defined, the risk of recurrence can be quantified (through molecular analysis of sperm) if the mutation arose in the father.

PSEUDOXANTHOMA ELASTICUM

DEFINITION

Pseudoxanthoma elasticum (PXE) is a heritable disorder of connective tissue with pleiotropic manifestations wherever elastic fibers are found but primarily in the skin, eye, and vasculature.[15] Life expectancy is reduced, on average, because of a predisposition to myocardial infarction and gastrointestinal hemorrhage.

EPIDEMIOLOGY

The exact frequency of PXE is unknown, but it is probably underdiagnosed. Rough approximations suggest a prevalence of one in 25,000 to 100,000 births. Males and females are equally affected, although women are more likely to seek medical attention out of concern for the skin changes.

PATHOBIOLOGY

Pathogenesis

In most families, PXE occurs as an autosomal recessive trait, which means, given relatively small sibships, that many patients will have no affected relatives. Apparent autosomal dominant inheritance may reflect expression in occasional heterozygotes. The gene for PXE maps to human chromosome 16 and encodes one of the adenosine triphosphate (ATP)-binding cassette transporters *(ABCC6)*. Because of the prominent histopathologic feature of calcification of elastic tissue, this gene may be important in calcium homeostasis. It is unclear, however, whether calcification is a primary or a secondary phenomenon in PXE.

Pathology

The hallmark of PXE, and an important diagnostic clue, is the histopathologic finding of hyperproliferated elastic fibers in the mid-dermis; these fibers become fragmented, clumped, and calcified. An arteriolar sclerosis develops in the media of muscular arteries and arterioles; the lumen may become progressively and concentrically narrowed. Alternatively, microaneurysms can form. Thickening of the endocardium, especially in the atria, develops in some patients. In the eye, Bruch membrane becomes calcified and fragmented.

CLINICAL MANIFESTATIONS

Because of the pleiotropic nature of PXE, the diagnosis initially may be suspected by any of a variety of clinicians, especially dermatologists, ophthalmologists, cardiologists, and gastroenterologists. The condition gains its name from the dermatologic feature of yellowish papules that appear at areas of flexural stress, especially the neck, groin, and popliteal and cubital fossae; in periumbilical regions; and on the buccal mucosa. The appearance of affected skin has been likened to that of a "plucked chicken." Over time, affected areas coalesce and become thickened.

Changes in the eye begin as a generalized, subtle, mottled pattern in the retina (peau d'orange) and progress to the characteristic angioid streaks. The latter changes are not specific for PXE and can be seen in diabetes mellitus, sickle cell disease, and a variety of other conditions. Streaks represent breaks in Bruch's membrane, an elastic lamina that lies between the retinal vasculature and the choroid. Spontaneous hemorrhages, especially those involving the macula, lead to progressive visual loss.[16]

Involvement of arteries of various calibers produces problems because of occlusion and hemorrhage.[17] The lifetime risk of serious gastrointestinal hemorrhage from any site, but especially the stomach, is about 10%. Hypertension is relatively common, in part because of involvement of the renal vasculature. Progressive occlusion of peripheral arteries leads to absence of pulses; acral ischemia is rare because of the development of collaterals. The risk for stroke, myocardial infarction, abdominal angina, and intermittent claudication is increased independent of other risk factors. Impaired left ventricular function is common in adults.

DIAGNOSIS

Differential Diagnosis

Whole exome sequencing is an efficient and sensitive way to make the diagnosis.[18] An acquired form of PXE has been reported and is also of unclear etiology. This form is difficult to differentiate from a sporadic case in a family because of heterozygosity in the parents, but it tends to affect only the skin. As suggested by the name, the cutaneous features of PXE need to be differentiated from those of true xanthoma, which results from a disorder of lipid metabolism (Chapter 206). The dermatologic manifestations need to be differentiated from those of Miescher elastoma, elastic tissue nevi (Buschke-Ollendorff syndrome), and solar elastosis.

TREATMENT

Rx

No cure for or means of preventing PXE is known. In many instances, careful attention to the ocular features by a retinal specialist experienced in PXE can delay but not prevent loss of vision. The risk of gastrointestinal hemorrhage suggests that patients should avoid gastric irritants such as aspirin, nonsteroidal anti-inflammatory drugs, and excessive alcohol. Stool should be checked regularly for occult blood, and angiography may be necessary to detect the source of bleeding. All standard risk factors for atherosclerosis should be managed aggressively. Complaints of chest pain should prompt a rigorous investigation for coronary artery disease. Angioplasty has not been reported to be effective, and the coronary lesions tend to be diffuse. Coronary artery bypass graft surgery has been performed, but long-term results have not been reported. It may be theoretically advantageous to use vein grafts rather than the internal mammary artery for bypass. The excessive wrinkling and pseudoxanthoma in exposed areas can be ameliorated by plastic surgery.

FUTURE DIRECTIONS

Each of these disorders poses special considerations in clinical diagnosis, utility of molecular testing, genetic counseling, and management. For the storage disorders, the clinical utility of enzyme replacement therapy is actively being pursued by several pharmaceutical companies. For several of the other conditions, somatic stem cell therapy offers some promise but is years away from routine clinical use. In Marfan syndrome, clinical trials of drugs that modulate activity of TGF-β are underway. Additionally, close medical management for individuals detected as being at heightened risk for cardiovascular, skeletal, and ocular complications will remain a mainstay.

REVIEW QUESTIONS

1. Osteogenesis imperfect syndromes demonstrate

A. intergenic heterogeneity.
B. intragenic heterogeneity.
C. variable expression.
D. pleiotropy.
E. all of the above.

Answer: E All four of the choices are correct. Mutations in multiple genes can cause OI (intergenic heterogeneity). With a single locus, many different mutant alleles have been discovered (intragenic heterogeneity). Within a given type of OI, relatives with the same mutation can demonstrate different features of varying severity (variable expression). Multiple organ systems are affected in OI (pleiotropy).

2. Which of the following is not a common feature of Marfan syndrome?

A. Pulmonary arteriovenous malformation
B. Aortic root dilatation
C. Mitral valve prolapse
D. Pulmonic artery dilatation
E. Aortic dissection

Answer: A All four of the latter choices are common features. Arteriovenous malformations are common in hereditary hemorrhagic telangiectasia but not in Marfan syndrome.

3. Hypertension is a relatively common feature in which syndrome?

A. Osteogenesis imperfect
B. Hurler syndrome
C. Marfan syndrome
D. Vascular Ehlers-Danlos syndrome
E. Pseudoxanthoma elasticum

Answer: E Because of partial occlusion of the renal arteries, elevated blood pressure can occur in PXE. None of the other syndromes has a predisposition to hypertension.

4. Which of the following is not a currently accepted approach to management of Marfan syndrome?

A. Prophylactic surgery of the aortic root
B. Exercise restriction
C. Annual echocardiography
D. Gene therapy
E. Chronic β-adrenergic blockade

Answer: D At the present time, no approach to correcting the specific mutation in *FBN1* is feasible. All of the other approaches are thought to be beneficial.

5. If treatment is not offered, which of the following conditions is associated with the best prognosis?

A. Ehlers-Danlos syndrome, hypermobility type
B. Osteogenesis imperfect, type II
C. Marfan syndrome
D. Hurler syndrome
E. Ehlers-Danlos syndrome, vascular type

Answer: A The hypermobility form of Ehlers-Danlos syndrome has little to no added mortality. Osteogenesis imperfect type II is usually lethal in infancy. Marfan syndrome has reduced life expectancy because of aortic dissection. Patients with Hurler syndrome rarely survive to their third decade. Patients with the vascular form of Ehlers-Danlos syndrome are at high risk of death from arterial or bowel rupture.

THE SYSTEMIC AUTOINFLAMMATORY DISEASES

RICHARD M. SIEGEL AND DANIEL L. KASTNER

DEFINITION

The systemic autoinflammatory diseases (Table 261-1) are a group of illnesses characterized by seemingly unprovoked inflammation, without evidence of high-titer autoantibodies or antigen-specific T cells, thus distinguishing them from the more classic autoimmune diseases. The first conditions recognized as autoinflammatory were the hereditary recurrent fevers, a group of mendelian disorders characterized by episodic or fluctuating degrees of fever and localized inflammation. The scope of autoinflammatory disease has been broadened to include other heritable illnesses, including disorders in which purulent or granulomatous inflammation predominates, as well as inherited disorders of the complement system (Chapter 50).[1-6] In addition, in numerous autoinflammatory conditions, some of which manifest in childhood and others that occur later in life, there is a complex interaction of genetic susceptibilities and environmental factors. These illnesses include systemic-onset juvenile idiopathic arthritis (Still's disease), Behçet's disease, and even the crystalline arthritides. Recent advances in the genetics and pathophysiology of the inherited autoinflammatory diseases suggest that these conditions are inborn errors of innate immunity, the phylogenetically more primitive part of the immune system that uses germline membrane and intracellular receptors expressed in granulocytes and macrophages to mount the body's first line of defense against pathogens (Chapters 45 and 48).

HEREDITARY RECURRENT FEVER SYNDROMES

Familial Mediterranean Fever

DEFINITION

Familial Mediterranean fever (FMF) is a recessively inherited illness that typically manifests with 12- to 72-hour episodes of fever and localized serosal, synovial, or cutaneous inflammation. Between attacks, patients usually feel completely well, although biochemical evidence of inflammation may remain, and some patients eventually develop systemic amyloidosis. Before the identification of the causative gene, FMF was defined purely clinically; clinical features remain an important part of the diagnosis, because some patients with typical disease have only one, or sometimes no, demonstrable mutation in *MEFV,* the only known causative gene.

EPIDEMIOLOGY

FMF is most common in individuals of Jewish, Arab, Armenian, Turkish, and Italian ancestry. The frequency of asymptomatic carriers of a single *MEFV* mutation in these populations is as high as 1 in 5, a finding that suggests a selective advantage for heterozygotes. With genetic testing, FMF is now frequently recognized in both Ashkenazi (eastern European) and non-Ashkenazi Jewish populations, as well as in Mediterranean populations previously thought not to be at risk. Mutation-positive individuals with typical symptoms have been documented worldwide. FMF usually manifests in childhood, sometimes even in infancy, although approximately 10% of patients experience their first attack as adults; infrequently, FMF first occurs in persons older than 40 years.

PATHOBIOLOGY

MEFV, the gene for FMF, was identified by positional cloning in 1997. It encodes a 781–amino acid protein denoted pyrin (or marenostrin) that is expressed in granulocytes, monocytes, and dendritic cells, as well as in peritoneal, synovial, and dermal fibroblasts. The N-terminal 92 amino acids of pyrin are the prototype for a motif, the PYRIN domain, that is involved in protein-protein interactions; this domain defines a family of more than 20 human proteins, including pyrin itself, involved in the regulation of cytokine production (particularly the interleukin-1 [IL-1] family), nuclear factor kappa B (NF-κB) activation, and apoptosis. More than 50 FMF-associated mutations in pyrin have been identified, many of which reside in the C-terminal domain encoded by exon 10 of *MEFV.* An even larger number of variants of unknown significance have been described in individual patients with a spectrum of inflammatory phenotypes.

CLINICAL MANIFESTATIONS

Episodes of FMF are more properly termed recurrent than periodic, and some patients associate attacks with psychological stress or physical exertion. Women of childbearing age sometimes experience their attacks with menses, with remissions during pregnancy. Some patients are unaware of fever during the attacks, but it is almost always observed when sought.

Serosal involvement in FMF is usually peritoneal or pleural. Abdominal attacks are the most frequent, and they may vary from mild discomfort to frank peritonitis, with boardlike rigidity, direct and rebound tenderness, and air-fluid levels on upright films of the abdomen. Regardless of the severity of the abdominal attack, constipation is much more common than diarrhea. When a laparotomy or laparoscopy is performed during an attack, a small amount of sterile exudate rich in polymorphonuclear leukocytes is found. Except for serosal inflammation, the appendix is normal. Repeated abdominal attacks may cause peritoneal adhesions, but ascites is rare. Pleurisy, usually unilateral, may accompany abdominal pain, or it may occur independently. Physical findings, if present, may include diminished breath sounds and a pleural friction rub, whereas x-ray films may show a small effusion or atelectasis. With multiple attacks, pleural thickening may develop. Symptomatic nonuremic pericardial involvement in FMF has been reported but is unusual.

In adults, the arthritis of FMF typically manifests as monoarticular involvement of the knee, hip, or ankle, and attacks of arthritis may persist for up to 1 week at a time. In children, oligoarticular or polyarticular joint involvement may occur. Large joint effusions are sometimes present, and the synovial fluid may have as many as 100,000 leukocytes/mm^3. In approximately 5% of patients who are not treated with prophylactic colchicine, chronic arthritis (usually of the hip or knee) may develop, often necessitating joint replacement surgery. Regardless of colchicine treatment or a particular human leukocyte antigen (HLA-B27) status, some patients with FMF develop sacroiliitis. Arthralgia without frank arthritis is common in FMF.

Cutaneous manifestations of FMF tend to be less common than serosal or synovial involvement. The characteristic skin lesion of FMF is erysipeloid erythema, a painful, demarcated erythematous area most often seen on the lower leg, ankle, or dorsum of the foot. This rash may occur independently, or it may accompany an episode of arthritis. Histologically, a mixed perivascular cellular infiltrate is seen. Other acute manifestations of FMF include unilateral scrotal inflammation (the tunica vaginalis is an embryologic remnant of the peritoneal membrane) and myalgia, either with fever or, especially in children, without fever and induced by vigorous exercise. Various forms of vasculitis also have been associated with FMF; Henoch-Schönlein purpura may occur in children with FMF; less frequently, polyarteritis nodosa is seen.

COMPLICATIONS

Before the widespread use of colchicine prophylaxis, systemic AA amyloidosis (Chapter 188) was a frequent complication of FMF, caused by the ectopic deposition of a misfolded fragment of serum amyloid A (SAA), an acute phase reactant, in the gastrointestinal tract, kidneys, spleen, lung, testes, and adrenals. Malabsorption and nephrotic proteinuria leading to renal failure are the most common manifestations of AA amyloidosis. Cardiomyopathy is less common, and neuropathy and arthropathy are rare. Several risk factors for amyloidosis development in FMF have been identified, including late diagnosis of FMF, colchicine noncompliance, male gender, and specific

TABLE 261-1 SYSTEMIC AUTOINFLAMMATORY DISEASES: A PARTIAL LISTING

INHERITED AUTOINFLAMMATORY DISEASES	INHERITANCE/ETIOLOGY	GENES OR RISK FACTORS	OMIM*
HEREDITARY RECURRENT FEVER SYNDROMES			
Familial Mediterranean fever (FMF)	Autosomal recessive	*MEFV*†	249100
Tumor necrosis factor receptor–associated periodic syndrome (TRAPS)	Autosomal dominant	*TNFRSF1A*†	142680
Hyperimmunoglobulinemia D with periodic fever syndrome (HIDS)	Autosomal recessive	*MVK*†	260920
Familial cold autoinflammatory syndrome (FCAS)	Autosomal dominant	*NLRP3* (formerly *CIAS1*)†	120100
Muckle-Wells syndrome (MWS)	Autosomal dominant	*NLRP3* (formerly *CIAS1*)†	191900
Neonatal-onset multisystem inflammatory disease (NOMID)/chronic infantile neurologic cutaneous and articular (CINCA) syndrome	Sporadic, autosomal dominant	*NLRP3* (formerly *CIAS1*)†	607115
GRANULOMATOUS DISORDERS

genotypes of the *MEFV* and *SAA* genes. Amyloidosis in FMF is less common in the United States than in the Middle East. Abdominal fat aspirates are much less sensitive than rectal or renal biopsy in detecting the amyloidosis of FMF. The latter procedure may be preferred, because of the increasing recognition of nonamyloid glomerular disease in FMF. With early diagnosis, aggressive suppression of the acute phase response with colchicine or adjunctive agents may lead to improvement, but for patients with renal failure, early renal transplantation is preferred.

DIAGNOSIS

Based on a simple recessive model of inheritance, two mutations in *MEFV,* in *trans,* should be identified to establish the genetic diagnosis of FMF. Nevertheless, the interpretation of genetic testing is complicated by complex alleles consisting of various combinations of mutations in *cis,* as well as by the observations that as many as one third of patients with clinically typical FMF have only one demonstrable mutation in *MEFV,* and a few patients with typical disease have no identifiable *MEFV* mutations. These latter two findings suggest that, under some circumstances, one *MEFV* mutation may be sufficient for symptoms or that additional genes for FMF exist.

For these reasons, clinical data remain an essential part of the diagnosis of FMF, and genetic testing plays an adjunctive role in settings in which clinical experience is limited.[7] Clinical criteria emphasize attack duration (12 to 72 hours); recurrence of symptoms (three or more episodes); documented fever (rectal temperature > 38° C); painful manifestations in the abdomen, chest, joints, or skin; and the absence of other causative factors. The differential diagnosis includes the other hereditary recurrent fever syndromes (Table 261-2), as well as other conditions specific to the clinical setting. For patients with recurrent abdominal pain, considerations include gynecologic disorders, porphyria (Chapter 210; which can be distinguished by hypertension during attacks, dominant inheritance, and urine porphyrins), and hereditary angioedema (Chapter 252; which usually does not cause fever). The syndrome of periodic fever with aphthous stomatitis, pharyngitis, and cervical adenopathy is probably the most common cause of unexplained recurrent fever in children and is also included in the differential diagnosis. In patients presenting primarily with recurrent monoarthritis, joint aspiration for cultures and crystals may aid in excluding bacterial and crystalline arthritis, respectively.

Still's disease in children (systemic-onset juvenile idiopathic arthritis) and adults (adult-onset Still's disease) is also considered in the differential diagnosis. *Adult-onset Still's disease*[8] (see Table 261-1) is an uncommon autoinflammatory condition of unknown cause that is not considered to be hereditary. It is characterized by spiking fever, an evanescent salmon-pink maculopapular rash, arthritis, and neutrophilic leukocytosis. It can be clinically distinguished from FMF by the pattern of fever (intermittent quotidian in Still's disease vs. discrete episodes in FMF), the pattern of arthritis (chronic polyarthritis vs. intermittent monoarthritis), the characteristic skin involvement (evanescent rash vs. erysipeloid erythema), and the presence of lymphadenopathy (more common in Still's disease).

TABLE 261-2 CLINICAL FEATURES OF SELECTED HEREDITARY RECURRENT FEVER SYNDROMES

CLINICAL FEATURE	FMF	TRAPS	HIDS	FCAS	MWS	NOMID/CINCA
Typical ethnicity	Arab, Armenian, Italian, Jewish, Turkish	Any ethnicity	Dutch, other North European	European	European	Any
Attack duration	12-72 hr	Days to weeks	3-7 days	12-24 hr	1-2 days	Continuous, with flares
Abdominal attacks	Sterile peritonitis, constipation more often than diarrhea	Severe pain, vomiting, peritonitis	Sterile peritonitis, diarrhea, rarely constipation	Nausea	Abdominal pain	Not common
Pleural attacks	Common	Common	Rare	Not seen	Rare	Rare
Joint/bone involvement	Monoarthritis, rarely protracted arthritis in knee or hip	Arthritis in large joints, arthralgia	Arthralgia, symmetrical polyarthritis	Polyarthralgia	Polyarthralgia, oligoarthritis, clubbing	Epiphyseal overgrowth, contractures, intermittent or chronic arthritis, clubbing
Skin rash	Erysipeloid erythema on lower leg, ankle, foot	Migratory rash, underlying myalgia	Diffuse maculopapular rash, urticaria	Cold-induced urticaria-like rash	Urticaria-like rash	Urticaria-like rash
Lymphatic involvement	Splenomegaly, occasional lymphadenopathy	Splenomegaly, occasional lymphadenopathy	Cervical adenopathy in children	Not seen	Rare	Hepatosplenomegaly, adenopathy
Neurologic involvement	Aseptic meningitis?	Controversial	Headache	Headache	Sensorineural deafness	Sensorineural deafness, chronic aseptic meningitis, intellectual disability, headache
Ophthalmologic involvement	Rare	Conjunctivitis, periorbital edema, rarely uveitis	Uncommon	Conjunctivitis	Conjunctivitis, episcleritis	Uveitis, conjunctivitis, progressive vision loss
Vasculitis	Henoch-Schönlein purpura (HSP), polyarteritis nodosa	HSP, lymphocytic vasculitis	Cutaneous vasculitis common, rarely HSP	Not seen	Not seen	Occasional
Systemic amyloidosis	Risk depends on *MEFV* and *SAA* genotypes; more common in Middle East	Occurs in ~10%; risk increased with cysteine mutations	Rare	Rare	Occurs in ~25%	May develop in some, usually in adulthood

FCAS = familial cold autoinflammatory syndrome; FMF = familial Mediterranean fever; HIDS = hyperimmunoglobulinemia D with periodic fever syndrome; MWS = Muckle-Wells syndrome; NOMID/CINCA = neonatal-onset multisystem inflammatory disease/chronic infantile neurologic cutaneous and articular syndrome; TRAPS = tumor necrosis factor receptor–associated periodic syndrome.

TREATMENT

Rx

The mainstay of therapy for FMF is daily oral colchicine, which can prevent both acute attacks of FMF and the development of systemic amyloidosis. Colchicine probably works by several mechanisms, including its effects on inhibiting leukocyte adhesion and modulating cytokine production. In adults, the therapeutic dose is 1.2 to 1.8 mg/day, and nearly 90% of patients note significant improvement at this dose. The major side effects are gastrointestinal, and they can usually be minimized by gradually increasing the dosage and avoiding milk products in patients who develop lactose intolerance. Most experts continue to prescribe colchicine to patients during pregnancy, with the recommendation that amniocentesis be performed to exclude trisomy 21, for which there may be a slightly increased risk. Use of colchicine in lactating women is considered safe. Intravenous colchicine should be used with extreme caution, if at all, in FMF, because fatal toxicity has been reported in patients already receiving oral colchicine who are given the drug intravenously. IL-1 inhibitors[9] may be effective in patients who are poorly responsive to colchicine or who cannot tolerate therapeutic doses.

Tumor Necrosis Factor Receptor–Associated Periodic Syndrome

DEFINITION

Worldwide, the tumor necrosis factor (TNF) receptor–associated periodic syndrome (TRAPS) is the second most frequently diagnosed hereditary recurrent fever syndrome, behind FMF. TRAPS is defined by recurrent episodes of fever and localized inflammation, in many ways resembling FMF, but differing in key details (noted later) and caused by mutations in the 55-kD receptor for TNF (TNFRSF1A, TNFR1, p55, CD120a). Whereas a positive genetic test is not necessary to diagnose FMF, the diagnosis of TRAPS requires the identification of a TNF receptor mutation. One of the first well-characterized families with what was later defined as TRAPS was of Irish ancestry, and the condition was termed *familial Hibernian fever* to emphasize the ethnic background and clinical differences from FMF. However, with the discovery of TNF receptor mutations in families of other ancestries, the ethnically neutral TRAPS nomenclature was proposed.

PATHOBIOLOGY

The p55 TNF receptor is composed of four cysteine-rich extracellular domains, a transmembrane region, and an intracellular death domain. To date, nearly all of the more than 90 mutations described are in the extracellular domains and approximately one third are missense substitutions of cysteine residues that abolish highly conserved disulfide bonds. The initial description of TRAPS documented a defect in activation-induced ectodomain cleavage of the p55 receptor in patients with the C52F *TNFRSF1A* mutation, possibly leading to a defect in homeostasis by impaired downregulation of membrane receptors and diminished shedding of potentially antagonistic soluble receptor molecules. More recent studies indicate a more complex pathogenetic picture, because not all mutant receptors exhibit this shedding defect. Additional mechanisms by which p55 mutations may lead to autoinflammation include impaired leukocyte apoptosis and impaired intracellular receptor trafficking, with possible constitutive activation of mitogen-activated protein (MAP) kinases by intracellular aggregates of mutant receptors.[10]

DIAGNOSIS

Although genetic testing is necessary for the diagnosis of TRAPS, certain clinical clues can help distinguish TRAPS from FMF. These include ethnicity (FMF is seen predominantly in Mediterranean and Middle Eastern populations, whereas TRAPS has a more widespread distribution), mode of inheritance (autosomal recessive in FMF, dominant in TRAPS), and duration of attacks, which tends to be longer in TRAPS and sometimes approaches continuous symptoms. The rash of FMF is typically erysipeloid erythema on the lower extremity, whereas patients with TRAPS often have a distinctive erythematous rash, often with underlying myalgia, which may migrate on the trunk or centrifugally on the extremities. Ocular involvement, with periorbital edema, conjunctivitis, and occasionally even uveitis, is observed in

TRAPS but not in FMF. Finally, whereas colchicine is much more effective than corticosteroids in FMF, the opposite is true in TRAPS. Nevertheless, aside from the difference in duration and susceptibility to pharmacologic intervention, the abdominal, pleural, synovial, and even scrotal manifestations of the two diseases are rather similar. The usual age of onset for TRAPS is also in childhood, and systemic AA amyloidosis is seen in approximately 10% of untreated patients with TRAPS. As in FMF, life expectancy in TRAPS is normal in patients whose disease is not complicated by amyloidosis.

As noted earlier, the diagnosis of TRAPS is established by the identification of *TNFRSF1A* mutations in the appropriate clinical setting. One variant, the substitution of glutamine for arginine at residue 92 (R92Q), is present in more than 1% of whites and may be associated with a broader spectrum of symptoms than is typically seen in TRAPS, including early inflammatory arthritis or, in some cases, no symptoms at all. The substitution of lysine for proline at residue 46 (P46L) is common among African American patients with TRAPS and is associated with a receptor shedding defect, but it is also seen among healthy African American controls. These findings establish a "gray zone" for the diagnosis of TRAPS and emphasize the potential role of polymorphisms in the recurrent fever genes in other more common phenotypes.

TREATMENT

Rx

The treatment of TRAPS depends on the frequency and severity of attacks. Patients with relatively infrequent, mild episodes may respond to nonsteroidal anti-inflammatory drugs (NSAIDs). Patients with more severe attacks that occur infrequently may be treated with corticosteroids, although increasing doses may be required as the episodes become more frequent and toxicities may become limiting. For patients with severe attacks occurring once a month or more frequently, treatment with etanercept, the soluble p75 TNF receptor:Fc fusion protein, may be warranted. This may be a unique effect of etanercept, because there is anecdotal evidence that monoclonal antibodies against TNF may actually exacerbate TRAPS. Consistent with a model implicating multiple cytokines in the pathogenesis of TRAPS, IL-1 inhibitors have also been found effective in TRAPS.[11]

INTERLEUKIN-1–ASSOCIATED AUTOINFLAMMATORY DISEASES

The IL-1–associated autoinflammatory diseases are linked by markedly increased expression or cellular responsiveness to this cytokine, and dramatic resolution of symptoms with IL-1 blockade. Interleukin-1α and Interleukin-1β (IL-1α and IL-1β) are structurally related cytokines released from cells triggered by a number of inflammatory stimuli, such as lipopolysaccharide. They mediate inflammatory responses by binding to a common receptor that is present on the surface of a wide variety of cell types and signals to activate inflammatory genes through the nuclear factor kappa B (NF-KB) transcription factor complex. IL-1 is part of a larger family of cytokines including IL-18, IL-33, and IL-36, which bind to related receptors and share the property of not having a characteristic signal peptide that normally targets cytokines to secretory vesicles. Because of this, IL-1 family cytokines may be secreted only by dead or dying cells, functioning as molecular markers of cellular stress, which can trigger beneficial inflammatory responses to infection and injury. IL-1β and IL-18 are unique in that they are not biologically active until cleaved by the protease caspase-1. Caspase-1 is itself activated in cytoplasmic protein complexes containing various sensor proteins such as NLRP3, and the adapter protein ASC. These complexes are referred to as *inflammasomes* because of their ability to trigger IL-1–mediated inflammation. Autoinflammatory diseases caused by mutations in genes encoding proteins that process or sense IL-1 are described later.

Cryopyrin-Associated Periodic Syndromes: The Cryopyrinopathies

Three rare, recurrent febrile disorders usually beginning early in life have been associated with mutations in *NLRP3* (formerly *CIAS1*), the gene encoding a protein variously named cryopyrin, NLRP3, NALP3, PYPAF1, or CATERPILLER 1.1, a key component of the NLRP3 inflammasome that activates caspase-1. These disorders are referred to as cryopyrinopathies or cryopyrin-associated periodic syndromes (CAPS). The least severe clinical phenotype is familial cold autoinflammatory syndrome (FCAS; formerly called familial cold urticaria), which is dominantly inherited and is notable for day-long attacks of chills, fever, headache, diffuse urticarial skin rash, arthralgia, and conjunctivitis, precipitated by generalized cold exposure. Amyloidosis is rare in FCAS. Of intermediate severity is Muckle-Wells syndrome (MWS), also dominantly inherited, in which 1- to 2-day episodes of chills, fever, urticarial rash, limb pain, and arthritis occur independently of cold exposure. Sensorineural hearing loss is common in MWS, and systemic amyloidosis also may occur. The most severe *NLRP3*-associated phenotype is neonatal-onset multisystem inflammatory disease (NOMID), known in Europe as chronic infantile neurologic cutaneous and articular (CINCA) syndrome. It is usually sporadic owing to the reduced reproductive fitness of most affected individuals. Fever and constitutional symptoms occur almost daily, often from birth, with generalized urticarial skin rash, a peculiar arthropathy characterized by epiphyseal overgrowth of the long bones, and central nervous system (CNS) involvement that includes chronic aseptic meningitis, uveitis, and cochlear inflammation, which may lead to intellectual disability, blindness, and deafness. In all three cryopyrinopathies, the rash is not true urticaria because there is a neutrophilic rather than a mast cell infiltrate and serum histamine levels are normal.

The protein mutated in all three disorders is NLRP3, a critical component of the eponymous NLRP3 inflammasome, which serves as an intracellular scaffold for the processing of IL-1β. The alternative name of this protein, cryopyrin, refers to its aminoterminal PYRIN domain, the basis for a structural and functional relationship to the protein mutated in FMF. Disease-associated cryopyrin mutations are thought to decrease the threshold for inflammasome activation, thereby increasing IL-1β production. The discovery that the NLRP3 inflammasome is also necessary for IL-1β production in response to crystalline forms of monosodium urate and calcium pyrophosphate connected the pathophysiology of these rare autoinflammatory diseases to crystal-induced arthritis (Chapter 273), which shares some clinical features, such as episodic, self-limited attacks, with autoinflammatory diseases.

Because there are patients with FCAS, MWS, and NOMID/CINCA without demonstrable *NLRP3* mutations, these diagnoses remain clinical, although genetic testing serves as a valuable adjunct and has greatly increased the recognition of all three conditions. Deep sequencing has identified somatic *NLRP3* mutations in some patients with symptoms consistent with CAPS who are negative for mutations by standard genetic testing. In addition, overlap syndromes that are intermediate between FCAS and MWS and between MWS and NOMID/CINCA have been reported.

TREATMENT

Rx

Blockade with anakinra, a recombinant IL-1 receptor antagonist, is effective in controlling fever and acute phase reactants in all three cryopyrinopathies, and longitudinal analysis of a large series of patients at the National Institutes of Health showed that long-term treatment with anakinra markedly decreased CNS inflammation and end-organ damage in NOMID/CINCA, which led to the regulatory approval of anakinra for the treatment of this condition in the United States and Europe. Recent studies have also documented the efficacy of rilonacept, another soluble IL-1 blocker, and canakinumab, a monoclonal antibody against IL-1β, in FCAS and MWS, although these agents may be less effective against NOMID/CINCA because of reduced penetration into the CNS. The efficacy of canakinumab suggests that the major biologic effect of cryopyrin in humans is mediated through IL-1β rather than by IL-1α or other distinct inflammatory pathways.

Deficiency of Interleukin-1 Receptor Antagonist

Deficiency of the IL-1 receptor antagonist (DIRA) is characterized by the neonatal onset of a pustular skin rash, multifocal osteomyelitis, periostitis, and, rarely, vasculitis.[12] Fever is not a prominent finding, although acute phase reactants are markedly elevated. DIRA is caused by recessively inherited loss-of-function mutations in *IL1RN*, which encodes the IL-1 receptor antagonist (IL-1Ra). Patients usually present within the first 2 weeks of life with skin lesions ranging from discrete crops of pustules to generalized severe pustulosis or ichthyosiform lesions. Histologic examination demonstrates extensive neutrophilic infiltrates in the dermis and epidermis. Typical radiographic findings include multifocal osteolytic lesions, periosteal elevation of the long bones, heterotopic ossification of the proximal femurs, and widening of the anterior rib ends. Bone biopsies demonstrate sterile purulent osteomyelitis, fibrosis, and sclerosis. To date, five different *IL1RN* mutations have been identified, three of which are truncating point mutations that drastically reduce IL-1Ra messenger RNA and protein levels. The fourth is a 15bp in-frame deletion, and the fifth is a 175-kilobase genomic deletion in

chromosome 2q that subsumes *IL1RN* and five other genes in the IL-1 family. In DIRA, the lack of IL-1Ra leads to unopposed IL-1β and IL-1α signaling, whereas in the cryopyrinopathies, *NLRP3* mutations lead to inflammasome activation and increased IL-1β production. DIRA patients respond dramatically to anakinra, a recombinant form of the protein they lack.

OTHER INHERITED SYSTEMIC AUTOINFLAMMATORY DISEASES

Syndrome of Pyogenic Arthritis with Pyoderma Gangrenosum and Acne

The syndrome of pyogenic arthritis with pyoderma gangrenosum and acne (PAPA) is a rare, dominantly inherited autoinflammatory disease characterized by intermittent episodes of sterile pyogenic arthritis, pyoderma gangrenosum, and severe cystic acne. It is caused by mutations in proline-serine-threonine phosphatase–interacting protein 1 (PSTPIP1), also known as CD2BP1. PSTPIP1 is a cytoskeletal protein that interacts with certain other proteins involved in the immune response, including CD2; the Wiskott-Aldrich syndrome protein (WASP); a phosphatase denoted PTP-PEST; and pyrin, the FMF protein. PAPA mutations abrogate the binding of PSTPIP1 to PTP-PEST, leading to hyperphosphorylation of PSTPIP1 and increased binding to pyrin. Both in patients and in cell lines, this finding is associated with markedly increased IL-1β production. Early in life, PAPA tends to present with monoarticular or pauciarticular pyogenic arthritis, sometimes induced by trauma. In the absence of treatment, arthritis may progress to severe joint damage and ankylosis. As patients reach puberty, skin manifestations begin to predominate, including disfiguring cystic acne. Pathergy also may develop, and extensive pyoderma gangrenosum may require opiates for pain control. The diagnosis of PAPA syndrome is made by documenting *PSTPIP1* mutations in the appropriate clinical setting. High doses of corticosteroids have been used in PAPA, with varying success, and patients with arthritis sometimes require aspiration, intra-articular corticosteroids, or open drainage. Newer investigational approaches for PAPA syndrome focus on the use of targeted cytokine inhibitors. Anecdotal evidence supports the use of anakinra for the arthritis and monoclonal anti-TNF antibodies for the pyoderma gangrenosum of PAPA.

Granulomatous Inflammatory Arthritis, Dermatitis, and Uveitis (Blau's Syndrome)

Blau's syndrome is a rare, dominantly inherited illness characterized by the following features: early-onset granulomatous synovitis often complicated by cyst formation and camptodactyly (flexion contractures of the fingers and toes); granulomatous anterior and posterior uveitis, sometimes causing retinal detachment, glaucoma, cataracts, and blindness; and an intermittent papular rash with noncaseating granulomas. Lung or other visceral involvement is generally not present. However, visceral involvement of the liver and spleen is observed in early-onset sarcoidosis (Chapter 95), which is phenotypically quite similar to Blau's syndrome. Both Blau's syndrome and some cases of early-onset sarcoidosis are caused by mutations in *NOD2/CARD15*. Distinct variants of *NOD2/CARD15* have been associated with susceptibility to Crohn's disease, which manifests as granulomatous inflammation of the gastrointestinal tract (Chapter 141). The protein encoded by this gene is thought to be an intracellular sensor of bacterial products. Crohn's disease—associated mutations in the ligand-binding, leucine-rich repeat region of the protein may alter responses to bacterial products in the gastrointestinal tract to cause inflammation, whereas Blau's syndrome mutations in the nucleotide binding domain may lead to constitutive extraintestinal inflammation. Topical and systemic corticosteroids are currently the mainstay of treatment of Blau's syndrome. There are case reports of the efficacy of TNF and IL-1 inhibitors in this disease.

Hyperimmunoglobulinemia D with Periodic Fever Syndrome

Hyperimmunoglobulinemia D with periodic fever syndrome (HIDS) was first described in 1984 as an FMF-like illness seen in six patients of Dutch ancestry. Besides the difference in ethnicity, a key distinction was the observation of extremely high levels of immunoglobulin D (IgD) in the serum of these patients, thus prompting the HIDS nomenclature. HIDS is now recognized in a broader ethnic distribution, although northern Europeans still predominate. Overall, HIDS is still quite rare. Family studies documented autosomal recessive inheritance. In 1999, patients with HIDS were found to have mutations in *MVK,* which encodes the mevalonate kinase enzyme involved in the biosynthesis of cholesterol and nonsterol isoprenes. Enzyme activity in patients is markedly reduced, but not absent. The elevated immunoglobulin D (IgD) levels seen in HIDS appear to be an epiphenomenon and do not correlate with disease severity either among patients or in a given patient over time, although IgD may contribute to the release of proinflammatory cytokines in vitro. Moreover, modest elevations of IgD are seen in several inflammatory conditions, including chronic infections, and can be observed in other hereditary recurrent fever syndromes. Up to 20% of patients (particularly young children) with typical recurrent fevers and *MVK* mutations have normal serum IgD levels. Current data suggest that isoprenoid deficiency may play a more important pathogenic role in the pathophysiology of HIDS. In vitro studies suggest that isoprenoid deficiency may lead to excessive IL-1β production, and increased body temperature can further decrease mevalonate kinase enzymatic activity, thereby creating a vicious circle in which infection or immunization can precipitate HIDS attacks. One of the well-recognized clinical characteristics of HIDS is the provocation of attacks by immunizations. Other distinguishing clinical features include a very early age of onset (average age, 6 months), a duration of attacks intermediate between FMF and TRAPS (3 to 7 days), prominent cervical lymphadenopathy during attacks, polyarticular joint involvement, a diffuse maculopapular rash, the predominance of diarrhea over constipation with abdominal attacks, and the infrequency of pleuritic attacks or systemic amyloidosis.

The diagnosis of HIDS can be established in a patient with recurrent episodes of fever and typical associated findings by documenting either two mutations in *MVK* or elevated levels of mevalonic acid, the substrate for mevalonate kinase, in the urine during attacks. Approximately 10% of patients with otherwise typical disease have only a single identifiable *MVK* mutation. The significance of elevated IgD without genetic or biochemical findings remains unknown. NSAIDs or corticosteroids are sometimes useful in the treatment of the arthritic manifestations of HIDS. Colchicine is generally not effective. Numerous agents are investigational in HIDS, including the statins, TNF inhibitors, and IL-1 inhibitors. Patients with HIDS have a normal lifespan, and attacks may become somewhat less frequent in adulthood.

Proteasome-Associated Systemic Inflammatory Diseases

Recently, a constellation of diseases have been described linked to recessive loss of function mutations in *PSMB8,* which encodes the β5i subunit of the proteasome, also known as LMP7. An autosomal recessive syndrome in adults characterized by recurrent fevers, progressive lipodystrophy, joint contractures, and cardiac manifestations was linked to homozygous missense mutations in *PSMB8.*[13] Patients with a pediatric syndrome termed CANDLE (chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature) were found to have homozygous missense and nonsense mutations in *PSMB8,* with some patients having only one known *PSMB8* mutation. It is not yet clear whether these syndromes represent identical diseases related to loss of function of β5i. The β5i proteasome subunit is one of the subunits that that are induced in immune cells through immune stimuli such as interferons, altering the proteasome so that it more efficiently processes peptides for antigen presentation to T cells. However, there is no indication of a T cell component to this disease, and studies have shown that the β5i proteasome subunit can be expressed in nonimmune cells such as adipocytes. A striking interferon transcriptional signature, similar to that seen in systemic lupus erythematosus, was observed in circulating blood cells from patients with CANDLE. Defective degradation of proteins in cells lacking β5i may result in buildup of ubiquitinated proteins, which somehow triggers interferon production, or PSMB8 deficiency may enhance interferon signaling by stabilizing components of the interferon signal transduction machinery that are negatively regulated by ubiquitin-proteasome degradation. Whichever the mechanisms, the link to interferon hyperactivity suggests that blocking interferons with antibodies or inhibitors of interferon signal transcution may be effective in the therapy of CANDLE and possibly other PSMB8-associated syndromes.

New Autoinflammatory Syndromes and the Promise of Whole-Exome Sequencing

Recent years have seen a dramatic acceleration in the pace of discovery of new mendelian inflammatory diseases as a result of the availability of whole-exome sequencing, which allows unbiased identification of disease-causing mutations in protein coding sequences, although it should be noted that accurate clinical description of these syndromes is as important as the genetic tools for identification of new syndromes. These discoveries have confirmed

the role of gene products in human inflammation that were identified in other animal model systems and identified new genes and proteins not previously thought to be involved in the regulation of inflammation. Early-onset, apparently sporadic, cases of inflammatory syndromes have often turned out to be due to de novo mutations in a child when screened against parental DNA. For example, inherited gain-of-function mutations in *CARD14,* encoding an adapter protein in innate immune sensing, cause dominantly inherited familial psoriasis, and a more severe gain-of-function de novo mutation in the same gene caused infantile-onset severe pustular psoriasis. Recessive mutations causing systemic autoinflammatory disease also have been identified by whole-exome sequencing from just a few families. Recent examples of novel diseases discovered through these methods include a syndrome characterized by fevers, early-onset strokes, and vasculopathy or frank vasculitis caused by autosomal recessive mutations in *CECR1,* encoding adenosine deaminase 2 (ADA2), a serum protein with newly recognized effects on macrophage differentiation and vascular development.[14] Recessive mutations in *HOIL1* that impair the addition of linear ubiquitin chains to receptor signaling complexes cause a complex syndrome marked by autoinflammation and immunodeficiency and intramuscular glycogen deposition. Gain-of-function mutations in *PLCG2,* encoding phospholipase Cγ2, an enzyme with essential functions in B-cell receptor and Fc Rceptor signaling, cause a dominantly inherited autoinflammatory syndrome characterized by blistering skin lesions, bronchiolitis, arthralgia, ocular inflammation, and enterocolitis in the absence of autoantibodies.

REVIEW QUESTIONS

1. Which of the following is not commonly associated with the development of AA amyloidosis?

A. Hyper-IgD syndrome (HIDS)
B. Familial Mediterranean fever (FMF)
C. Tumor necrosis factor receptor–associated periodic syndrome (TRAPS)
D. Muckle-Wells syndrome

Answer: A All of the listed periodic fever syndromes are commonly associated with the development of AA amyloidosis with the exception of hyper-IgD syndrome, which generally has a benign course.

2. Patients with which monogenic autoinflammatory disease often have a history of flaring after routine immunizations?

A. FMF
B. HIDS
C. TRAPS
D. FCAS

Answer: B Of these syndromes, only HIDS has a substantiated association of flares with routine immunizations. Psychological stress is often cited as a trigger for flares in FMF and TRAPS, and cold exposure triggers a systemic inflammatory flare and hivelike skin lesions in FCAS.

3. A 30-year-old woman of Armenian and Jewish ancestry presents with a life-long history of unexplained febrile episodes. These attacks are variable in length, with the shortest lasting a few days and the longest lasting over 1 month. The fevers are accompanied by severe abdominal pain or pleuritic chest pain, periorbital edema, arthralgia, and a painful migratory erythematous rash. Corticosteroids ameliorate her symptoms. During pregnancy 7 years ago she was totally free of fevers, but she developed a severe attack in the postpartum period. She is currently not experiencing an attack, but has an erythrocyte sedimentation rate of 85 (Westergren), C-reactive protein of 100 mg/L, urine protein-to-creatinine ratio of 5.3, and serum creatinine of 2.5. Which of the following is most likely true?

A. The patient probably has familial Mediterranean fever, and should undergo genetic testing for *MEFV* mutations, have a rectal biopsy to rule out amyloidosis, and commence treatment with intravenous colchicine.
B. The patient has chronic atypical neutrophilic dermatosis with lipodystropy and elevated temperature (CANDLE syndrome), with the T75M mutation in *PSMB8,* encoding a component of the immunoproteasome.
C. The patient has a mutation at a cysteine residue in the extracellular domain of the p55 TNF receptor and possible amyloidosis. She should undergo a rectal biopsy and should be treated with etanercept or anakinra in an effort to normalize her acute phase reactants.
D. The patient has a mutation in the *NLRP3 (CIAS1)* gene, and could be treated with anakinra, rilonacept, or canakinumab for neonatal-onset multisystem inflammatory disease (NOMID).

Answer: C Despite the demographic information that may point toward FMF, the presence of longer disease flares of longer than 7 days, periorbital edema, painful migratory rash, and remission of symptoms with pregnancy are all characteristic of the TNFR1-associated periodic syndrome (TRAPS). Patients with TRAPS and structure-disrupting mutations in TNFR1 have an elevated risk for amyloidosis. TRAPS does not have a predilection for a specific ethnic group or geographic location.

4. A 3-year-old boy of northern European ancestry presents to the autoinflammatory disease clinic for an initial evaluation. Per his mother's report, he began experiencing febrile attacks at the age of 3 months that last 4 to 5 days and occur every 1 to 2 months. Associated symptoms include a nonpruritic macular rash and oral ulcers, and on three occasions he has had genital ulcers. He tends to have flares approximately 2 days after immunizations and after routine viral illnesses. There is no family history of febrile illnesses. He is treated with ibuprofen and acetaminophen and has been given a couple of courses of prednisolone without complete resolution of symptoms. He had been well before his visit, but his mother thinks he is starting to have a flare. On physical examination, he has conjunctival injection, cervical lymphadenopathy but no rashes, oral or genital ulcers, or arthritis. Laboratory studies reveal an ESR of 57 mm/hour, CRP of 55 mg/L, and IgD level at the top of the normal range. Which of the following is most likely true?

A. The patient probably has periodic fever with aphthous stomatitis, pharyngitis, and cervical adenitis (PFAPA). He should be given either 1 mg/kg of prednisolone at the onset of symptoms or anakinra 2 mg/kg SC for 1 to 2 days at the onset of symptoms.
B. The patient has Behçet's disease and should consider colchicine for his oral ulcers. He should undergo HLA typing to assess for the presence of HLA-B51 or other Behçet's-associated MHC findings.
C. The patient has hyperimmunoglobulinemia D syndrome and should initiate therapy with anakinra at the time of flares or weekly etanercept. He should be tested for mutations in the *MVK* gene.
D. The patient has cyclic neutropenia and should be tested for mutations in the *ELA-2* gene. He should also have weekly CBC drawn to assess for periodic neutropenia.

Answer: C Despite the oral and genital ulcers that might suggest Behçet's disease, the history of flares after vaccinations or viral illness, the pattern and age of onset, and the ethnic background more strongly suggest that the patient has hyperimmunoglobulinemia D syndrome. IgD levels can be normal in this disease, and a normal IgD should not rule out this diagnosis, which can be confirmed by finding a heterozygous mutation in the mevalonate kinase gene.

5. A 16-year-old high school student is evaluated in the emergency department for 18 hours of abdominal pain, pleurisy, and fever. At that time, he had diffuse rebound tenderness, temperature of 102.5° F (39.2°degrees C), and WBC of 17,000/mm^3. He was admitted to general surgery and after 12 hours of persistent symptoms, he was taken to the operating room for exploratory surgery. A normal-appearing appendix was laparascopically removed. Postoperatively, the fever persisted and he was noted to have a left pleural effusion. Additional history reveals that he has had similar episodes of febrile illness in the past. On physical examination, he has no rash but has moderate abdominal tenderness with guarding and a left pleural friction rub. Laboratory data reveal an ESR of 80 mm/hour and a negative ANA and RF. While waiting for the results of genetic testing, which of the following medications is *most* appropriate to start at this time?

A. Indomethacin, 50 mg orally three times daily
B. Prednisone, 40 mg orally daily
C. Colchicine, 0.6 mg orally twice daily
D. Anakinra, 100 mg subcutaneously daily
E. Acetylsalicylic acid, 1000 mg orally daily

Answer: C The duration of fevers, association with pleural and peritoneal inflammation, and lack of other localizing symptoms are most consistent in this case with familial Mediterranean fever. Colchicine is effective in the prophylaxis of future attacks in FMF. Indomethacin and prednisone can be of some value in terminating attacks but should be reserved for refractory cases. Anakinra can be effective in the treatment of refractory FMF, but there is no need to use this agent in patients who respond to colchicine.

OSTEOARTHRITIS

JOEL A. BLOCK AND CARLA SCANZELLO

DEFINITION

Osteoarthritis (OA) is a heterogeneous disease that has many names, including degenerative joint disease and osteoarthrosis. It is a joint disease characterized clinically by pain and functional loss. Although local inflammation of involved joints is common, OA is not associated with a systemic inflammatory process, in contrast to other arthritides. It is the most common form of arthritis and accounts for the overwhelming majority of arthritis cases, and its prevalence is expected to rise dramatically during the next 20 years as global populations age. OA is often neglected either because it is not a fatal disease or because many physicians assume it is a normal part of aging and is not inherently treatable. Yet it results in vast direct medical costs and significant loss of work; it is the leading indication for total joint replacement and is a leading cause of work disability. Formal definitions of OA have evolved as our understanding of pathophysiology has progressed. Whereas it conventionally had been considered primarily a degenerative process of cartilage, it is now clear that OA involves the entire joint. Thus, a modern definition of OA is a *painful* degenerative process involving progressive deterioration of all joint structures and remodeling of subchondral bone that is not primarily inflammatory. It is important to distinguish true OA from asymptomatic structural degeneration of joints that is virtually universal during normal aging.

EPIDEMIOLOGY

As an age-related disease, OA prevalence has risen substantially with the aging population of the developed world; an estimated 27 million people had physician-diagnosed OA in the United States in 2005, increased from 21 million a decade earlier, and this number is expected to reach 67 million patients with clinically significant OA by 2030. For epidemiologic studies, OA is often defined radiographically by the presence of osteophytes, joint space narrowing, and subchondral sclerosis. However, a substantial number of individuals have these x-ray changes but remain clinically asymptomatic. Thus, estimates of OA prevalence vary widely depending on whether one is assessing *radiographic* or *symptomatic* OA. In either case, the lifetime risk is exceedingly high. There is general concordance among epidemiologic studies across North American, Asian, and European populations that the prevalence of radiographic OA in the knees, hips, and hands is quite low before age 45 and increases dramatically with aging, with most people having x-ray evidence of OA in at least one joint by the seventh decade. Symptomatic knee OA affects between 7% and 17% of those older than 44 years, with rates increasing with age; women have higher prevalence than men, and African Americans have higher prevalence than white Americans. Symptomatic hip OA is less prevalent than knee OA, with overall rates between 6.7% and 9.7% among those over age 44; as with knee OA, prevalence is higher among the elderly, women, and African Americans.[1] Symptomatic hand OA affects at least 6.8% of those older than 25, occurring in women more than two-fold more frequently than in men. Hand OA may be less common in African Americans than in white Americans.

Risk factors for the development of OA and for specific joint involvement have been extensively studied. Among nonmodifiable risk factors, the strongest is aging. This is true both for radiographic changes of OA and for symptomatic involvement. In addition, female sex is a risk for prevalence and severity of OA, especially after menopause. There is a significant heritable component, particularly for hand OA and hip OA. This component is estimated at 48 to 65% for so-called generalized OA characterized by osteophytes of the distal interphalangeal joints (Heberden nodes) or the proximal interphalangeal joints (Bouchard's nodes).

Modifiable OA risk factors may provide clues for preventive strategies. The most important of these is obesity, which alone confers an approximately three-fold increased risk for incident OA. Occupational and lifestyle activities that involve repeated trauma or excessive loading may be associated with increased risk for OA. These include chronic squatting, bending, and lifting such as by warehouse workers and laborers, who have increased knee involvement, and, classically, pneumatic drill operators who develop OA of the wrist and elbow. Significant trauma, such as major knee or ankle injury, is strongly associated with subsequent development of OA in the injured joint. Aberrant loading of joints is an important risk factor for the development and progression of OA. For example, excessive loading of the knee has been observed to result in significantly increased risk for progression to advanced knee OA. In addition, joint alignment is an important parameter in OA, and malalignment at the knee is among the strongest predictors of OA progression.[2]

PATHOBIOLOGY

Although degeneration of articular cartilage is a central common pathway in OA, multiple joint and periarticular tissues are compromised and contribute to clinical manifestations. Pathologic changes in synovium, ligaments, supporting musculature, and fibrocartilagenous structures such as the menisci in the knee are common.[3] Unlike autoimmune arthritides, OA does not affect extra-articular organs. However, the chronic pain of OA involves both the peripheral and central nervous system (CNS) and OA-related disability degrades the general physical and mental health of the patient. Appreciation of the global effects of OA has important implications for current and future treatment approaches.

Tissues Central to the Osteoarthritis Process

Cartilage

The hallmark of osteoarthritis is progressive deterioration of articular cartilage. Normal articular cartilage distributes loads across joint surfaces and allows for almost frictionless joint motion. These functions are furnished by the extracellular matrix, which accounts for more than 90% of the tissue volume and is organized by a network of collagen type II fibers, which provides tensile strength, entrapping aggrecan complexes, a proteoglycan that confers compressive stiffness and resilience (Fig. 262-1A and C). There is one major cell type, the chondrocyte, that synthesizes these matrix components. In mature cartilage, turnover of extracellular matrix molecules, particularly collagen type II, is slow.

Cartilage change in OA begins with swelling of the matrix, then progresses through stages of surface roughening, fibrillation, fissuring, and eventually full-thickness erosion. These are accompanied by activation of chondrocytes to increase synthesis of proteolytic enzymes that degrade matrix.[4] Matrix metalloproteinase-13 (MMP-13; collagenase-3) plays a central role in collagen type II degradation, while ADAMTS-4 and -5 (a disintegrin and metalloproteinase with thrombospondin motifs-4 and -5) proteases are important

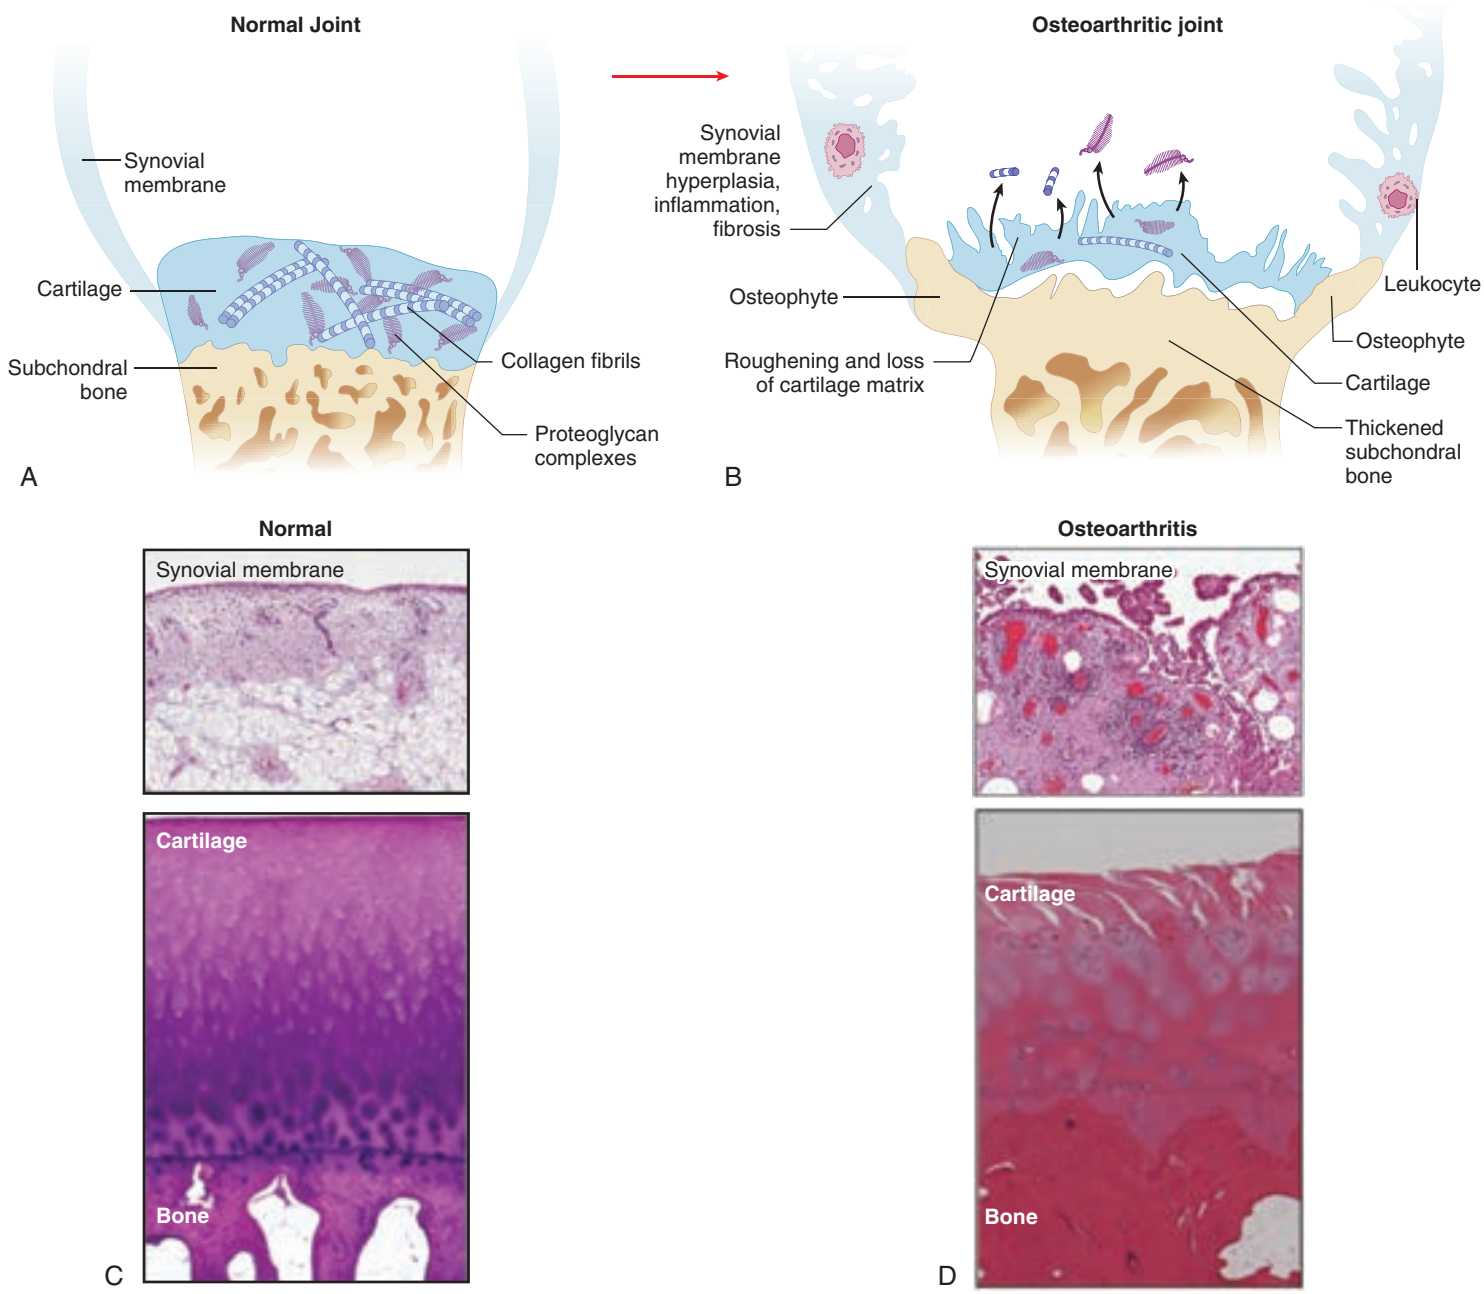

FIGURE 262-1. Pathologic features of osteoarthritic joint tissues. A, Features of a normal adult synovial joint. Healthy adult articular cartilage is characterized by a smooth surface and extracellular matrix (ECM) composed of a collagen type II fibrillar network and large proteoglycan complexes. The ECM is produced and maintained by the cellular components of cartilage, chondrocytes. The subchondral bone consists of a thin cortical layer and underlying trabecular bone. The synovial membrane lines the joint capsule and attaches at the cartilage-bone interface. In the normal state, it consists of a lining layer 1 or 2 cells thick, with underlying vascularized loose connective tissue. **B,** Typical changes to tissues seen in osteoarthritis (OA). Enzymatic activities (ADAMTS-4,5 and MMP-13 in particular) cleave proteoglycan and collagen components of the ECM, leading to loss of these molecules from the matrix. As the process advances, the articular cartilage thins and fibrillates and eventually fissures down to the underlying bone are seen. Simultaneously, a remodeling response in the bone is observed. Thickening of the cortical subchondral bone layer occurs, and new bone growth at the margins appears as osteophytes. The synovial membrane changes observed in OA patients include lining layer hyperplasia, inflammation in the form of leukocyte infiltration, and fibrosis which can be seen to varying degrees. Photomicrographs of human joint tissues showing these features are depicted in **C** (normal tissues) and **D** (OA tissues). (C and D courtesy of Edward F. DiCarlo, MD. Hospital for Special Surgery, New York, NY).

for loss of aggrecan, but other enzymes participate (see Fig. 262-1B and D). Concomitantly, the activated chondrocytes proliferate to form clonal clusters and produce inflammatory mediators, including interleukin-1α and β, (IL-1α and IL-1β), IL-6, tumor necrosis factor-α (TNF-α) and nitric oxide (NO), which accelerate the degradative cycle and stimulate chondrocyte apoptosis. Thus, both cellular *and* molecular components of cartilage are lost as the process progresses.[5]

Bone

The cortical bone underlying articular cartilage (subchondral bone) supports load-bearing and transmits mechanical signals to articular chondrocytes. In OA, there is increased remodeling, likely in response to abnormal biomechanical loading. This may result in thinning (attrition) and reduced bone density, leading to subchondral cyst formation in early disease, but progresses to subchondral sclerosis as bone formation outpaces resorption (see Fig. 262-1B and D).[6] Remodeling at joint margins and entheses results in osteophytes (bone spurs). An important role for the growth factors transforming growth factor-β (TGF-β) and bone morphogenetic protein-2 (BMP-2) in driving osteophyte formation has been demonstrated in animal models.

Synovium

Synovial involvement in OA is more variable than in rheumatoid arthritis, but low-grade synovitis, characterized by infiltration of macrophages and lymphocytes, increased vascularity, synovial lining hyperplasia, and fibrosis,

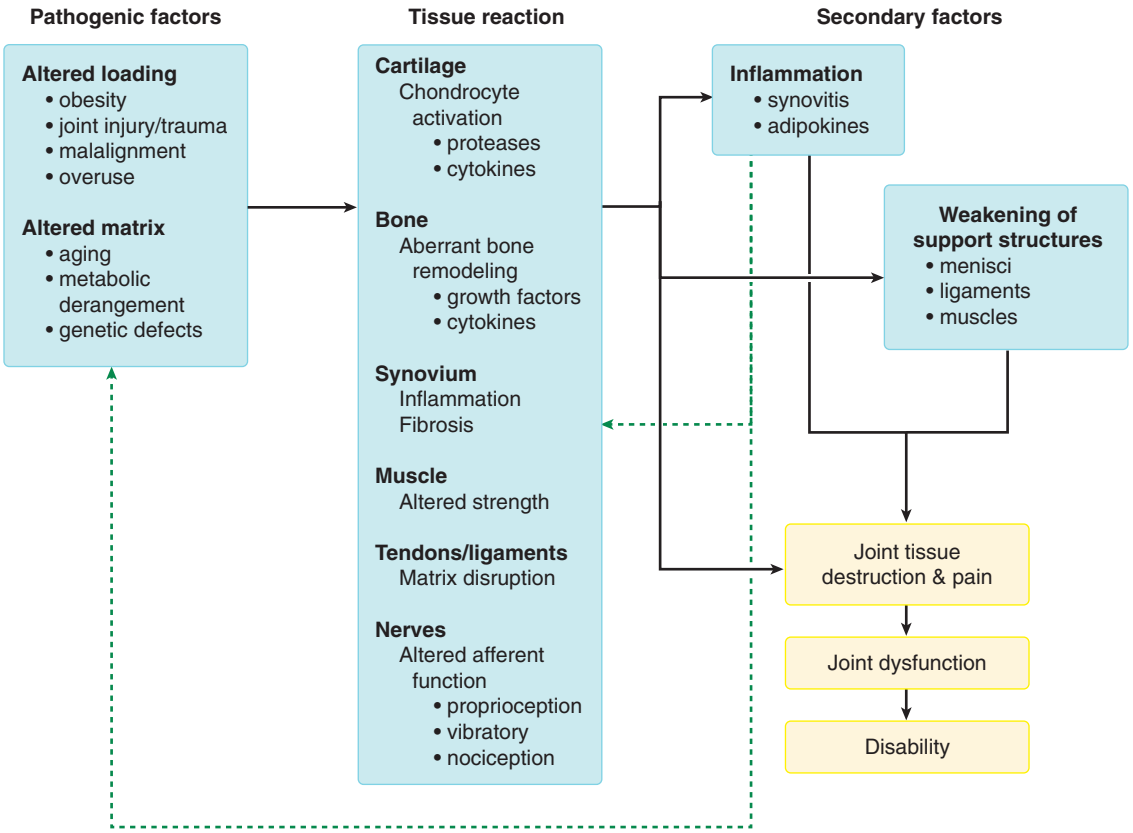

FIGURE 262-2. Schematic of the pathophysiology of osteoarthritis. A variety of stimuli can alter biomechanical loading patterns of joint tissues or exert biologic pressure on the extracellular matrix. These result in specific responses in the various joint tissues. Aided by secondary factors, these lead to tissue degeneration, pain, and ultimately joint dysfunction.

is common and occurs in up to 75% of patients (see Fig. 262-1B and D). Although this synovial reaction is likely a secondary response to molecular breakdown products present in the OA joint, it results in release of cytokines (e.g., IL-6, TNF-α), chemokines (IL-8, monocyte chemoattractant protein 1 [MCP-1], C-C motif chemokine 19 [CCL19]), enzymatic mediators of cartilage catabolism, and growth factors involved in bone remodeling, and when present it is associated with more severe symptoms and possibly more rapid progression of cartilage degradation.[7]

Menisci and Ligaments

Traumatic and athletic injuries to the menisci and ligaments are known risk factors for incident OA. However, meniscal and ligamentous abnormalities are common in patients with OA even without injury and are detectable in 80% and 30% (respectively) of patients undergoing magnetic resonance imaging (MRI). These structures are sensitive to the same inflammatory and enzymatic mediators that promote cartilage deterioration in OA, and their compromise promotes degenerative injuries, accelerated cartilage erosion, joint instability, and mechanical symptoms (i.e., locking or catching).

Muscles

Periarticular muscle weakness and atrophy are characteristic of hip and knee OA. Such weakness is associated with altered gait kinematics and pathologic joint loading, but it remains unclear whether this is a cause or an effect of OA.

Peripheral and Central Nervous System

Somatosensory deficits associated with neuromuscular function, including proprioceptive and widespread vibratory deficits, have been described.[8] Also, patients with OA exhibit signs of peripheral and CNS sensitization in the form of hyperalgesia and allodynia. Inflammatory mediators (e.g., MCP-1) and growth factors (e.g., nerve growth factor [NGF]) have been implicated in pain pathways in OA.[9] Additional work is necessary to fully understand the mechanisms leading to symptomatic OA, but pain in OA is clearly multifactorial, involving the peripheral and the central nervous systems in addition to joint tissues and inflammation.

Pathogenic Factors (Fig. 262-2)

Biomechanics

Aberrant loading of joints mediates evolution of structural joint degeneration and may contribute to initiation of the process. This is evident in the high risk that malalignment of the knee carries for knee OA progression. Weight-bearing regions of OA joints bear greater loads during ambulation than normal, and these loading patterns have been shown to be predictive of subsequent progression of lower extremity joint disease longitudinally. Mechanistically, abnormal biomechanical loading promotes pathologic activation of chondrocytes and bone remodeling, and may be precipitated by joint injury, congenital dysplasias, malalignment, joint instability (e.g., in the setting of aging or heritable connective tissue diseases), and abnormal neuromuscular control (e.g., neuropathic diseases), each of which is a risk factor for OA.

Metabolic Factors

Several metabolic conditions, including alkaptonuria, acromegaly, hemochromotosis, and the metabolic syndrome, among others, predispose individuals to early OA, though they have different mechanisms and disease patterns. In the metabolic syndrome, obesity increases loads on weight-bearing joints, but its association with OA of non–weight-bearing joints in the hands suggests a nonmechanical etiology as well. A possible mechanism may be related to the overproduction of adipokines, IL-6, and leptin leading to chronic low-grade systemic inflammation that may potentiate molecular deterioration of joint tissues and contribute to joint symptoms.[10]

Genetic Factors

Rare single-gene defects may lead to early or aggressive OA. Heritable defects in the collagen II gene have occasionally been described in families with chondrodysplasias, as have lubricin defects. However, variations in multiple genes are likely implicated in the majority of OA cases. Genome-wide association studies have identified polymorphisms in genes involved in proliferation, skeletal development (e.g., GDF5), and regulation of body weight associated with risk for radiographic knee and hip OA.[11] Additional polymorphisms have been associated with pain in OA (e.g., *PACE4* and *TRPV1*).

Aging

Aging-related molecular and cellular changes likely contribute to OA pathogenesis.[12] Modifications of extracellular matrix components, such as accumulation of advanced-glycation end products, and carboxylation associated with oxidative-stress, occur with advancing age. These can alter protein folding, weaken tissues, and increase susceptibility to proteolytic cleavage. Age-related changes to chondrocytes and other cells include the "senescence-associated secretory phenotype" associated with decreased proliferative capacity but increased secretory activity that may promote abnormal chondrocyte responses to injury and aberrant loading. Nonetheless, the link between aging-related changes and symptoms remains poorly understood.

CLINICAL MANIFESTATIONS OF OSTEOARTHRITIS

Symptoms

Pain is the most prominent symptom of OA. Although often limited to affected joints, it can become widespread over time.[13] The quality of pain experienced is variable, ranging from "aching" joint pain to less localized periarticular or radiating pain. OA pain is typically worsened by joint use while stiffness is exacerbated by prolonged inactivity. Morning stiffness may occur but is brief, lasting less than 30 minutes. Other symptoms include joint instability, limitation of motion, locking, and a grinding feeling with motion. Symptom severity varies over time, but with advanced disease, pain becomes persistent and can disturb sleep.

Patterns of Joint Involvement

The joint pattern may help distinguish OA from other forms of arthritis (Fig. 262-3).

Lower Extremities

The large weight-bearing joints (knees and hips) are most commonly affected. Knee OA encompasses any of the three compartments. The medial compartment is involved in the majority of patients and may lead to varus (bow-legged) deformity. Lateral compartment OA may result in valgus (knock-kneed) deformity, and patellofemoral OA typically causes pain exacerbated by descending stairs. Meniscal or ligamentous degeneration often accompanies OA and exacerbates knee instability. Effusions, synovial (Baker's) cysts, and anserine or prepatellar bursitis may be present and cause additional pain. Hip OA often begins with restricted internal rotation and progresses to limited motion in all directions and limb length discrepancy. Pain is felt in the groin area and may radiate to the anterior thigh and knee and be confused with knee pain. It also must be differentiated from lateral thigh pain, which more likely originates from other structures (e.g., trochanteric bursa, iliotibial band, lumbar spine). In the foot, OA typically involves the first metatarsophalangeal joint, resulting in bunion deformity.

Spine

Spinal OA typically involves the lumbar and cervical regions, affecting the apophyseal (facet) and uncovertebral (joints of Luschka) joints. Low-grade inflammation and bone remodeling can lead to local pain, and nerve root compression by osteophytes causes radicular, radiating pain. Degenerative disc disease often coexists with spinal OA, and together they contribute to spinal stenosis causing muscle weakness, paresthesias, and numbness. In severe cases, cord impingement with myelopathy may result.

Upper Extremities

The small joints of the hands are most commonly affected, specifically the distal and proximal interphalangeal joints (DIPs and PIPs) and first carpometacarpal (CMC) joints. Osteophytosis of DIPs and PIPs leads to bony, palpable Heberden and Bouchard nodes, respectively. This pattern is more common in white women and is termed *primary generalized OA*. Patients may experience difficulty grasping, opening jars, buttoning clothes, and turning doorknobs. Erosive or inflammatory OA is a less common but distinct subset in which erosions develop in the DIPs and PIPs, and the patient experiences repeated episodes of acute inflammatory symptoms.

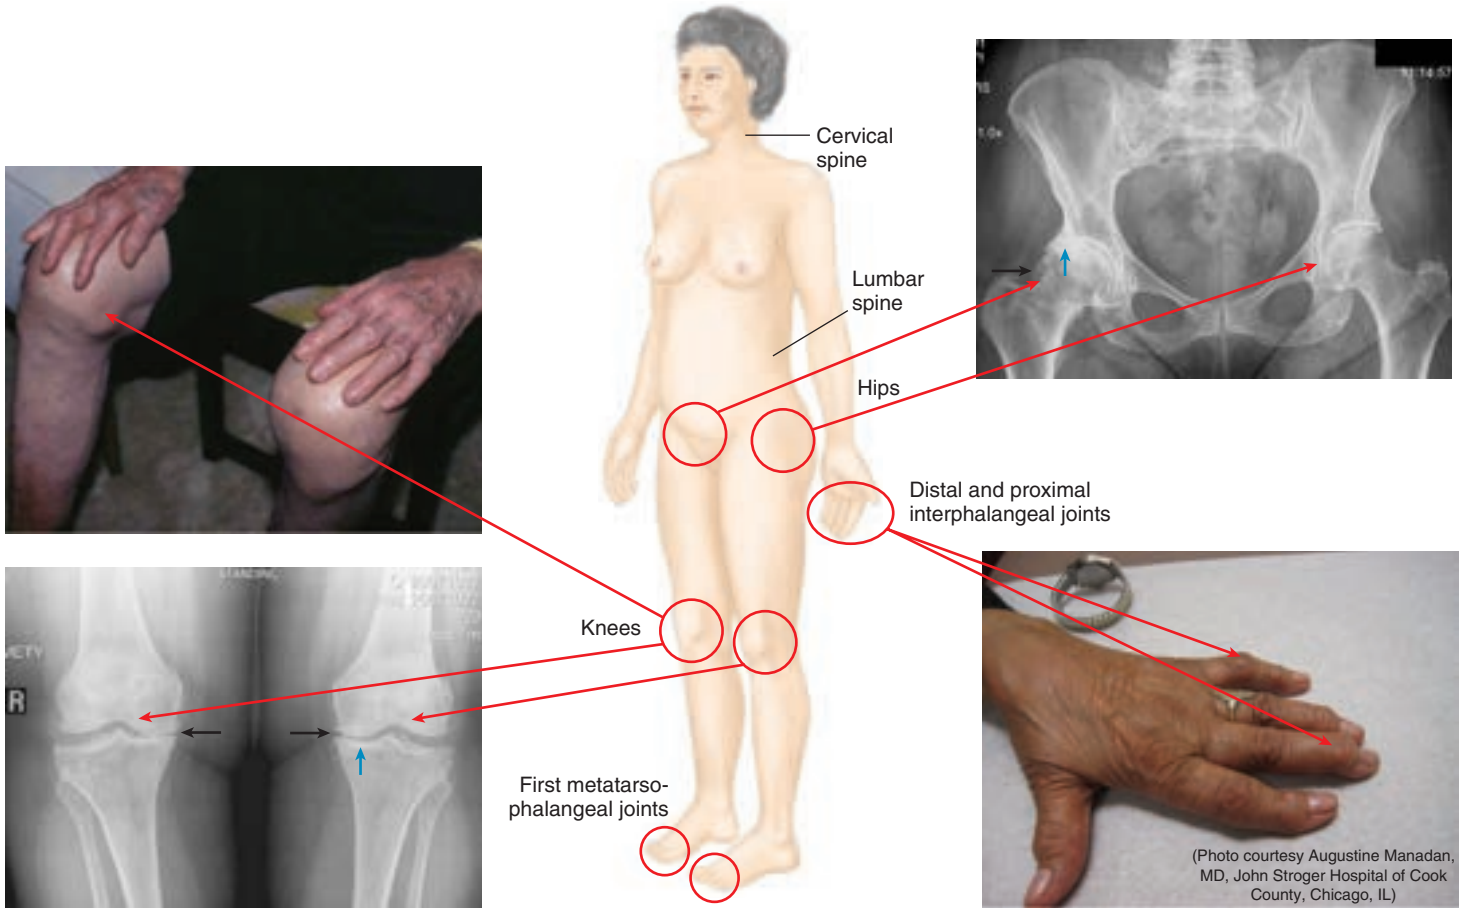

FIGURE 262-3. Commonly affected joints in osteoarthritis. Joints in which symptomatic osteoarthritis typically develops are depicted in the whole-body drawing in the center. The distal and proximal interphalangeal joints of the hands characteristically exhibit palpable bony bumps (*right lower panel*). Synovial effusions and bony outgrowths, or osteophytes, may be visualized in the knee (*left upper panel*), and radiographic involvement of the knee (*left lower panel*) or of the hip (*right upper panel*) shows characteristic features of joint space narrowing, osteophytes (*black arrows*), and subchondral sclerosis (*blue arrows*).

DIAGNOSIS

The diagnosis of OA depends primarily on the clinical presentation; unlike other rheumatic diseases, imaging and laboratory analysis have relatively small roles in diagnosis. Because OA primarily affects tissues of the joint and does not involve systemic inflammation, laboratory tests are more useful for excluding competing diagnoses than for establishing an OA diagnosis.

Physical Examination

When cartilage surfaces become roughened, crepitus (palpable or audible crackling) may be detected by physical examination. As cartilage is further compromised, small fragments can dislodge and, if sufficiently large, may restrict joint motion and cause locking.

Osteophytes can be palpated in superficial joints as bony projections and may result in deformities. Their growth is sometimes inflammatory, with erythema, tenderness, and swelling. Heberden and Bouchard nodes of the DIP and PIP joints, respectively, are typical, but squaring of the first CMC joint and palpable knee osteophytes are also common. These deformities may eventually restrict joint range of motion. Classically, severe joint inflammation is not appreciated; however, effusions are common and may cause mild joint warmth.

Laboratory Evaluation

Blood Tests

OA is limited to joints; thus, tests of systemic inflammation and those that assess critical organ function are generally normal. These include the sedimentation rate, conventional C-reactive protein, and other acute phase reactants, as well as the blood count and the comprehensive metabolic panel. Nonetheless, OA is prevalent among the elderly and concomitant diseases may confound the interpretation of laboratory testing. Tests for autoantibodies are unremarkable, though low-titer detection of nonspecific rheumatoid factors and antinuclear antibody (ANA) may be seen in the normal aging population.

Synovial Fluid

When sampled, synovial fluid total leukocyte counts are typically less than 1500 to 2000 cells/mm^3 with a predominance of lymphocytes rather than neutrophils. Incidental findings of crystals, such as calcium pyrophosphate dihydrate, or of cartilage fragments may sometimes be observed.

Biomarkers

There has been an aggressive search for macromolecules measurable in blood, synovial fluid, or urine that provide prognostic or diagnostic value in OA. A variety of macromolecules, typically breakdown or cleavage products of cartilage or bone matrix, have been identified that have a statistical correlation with OA progression or pain. The OA Initiative is an ongoing longitudinal study of several thousand individuals, spearheaded by the National Institutes of Health, to identify novel body fluid and imaging biomarkers that may provide predictive information about OA onset and progression. But no biomarkers have yet been demonstrated to be useful for clinical evaluation.

Imaging

Radiography

Conventional radiography is the mainstay for imaging OA. Characteristic features include narrowed joint space, osteophytes, and subchondral bone sclerosis (see Fig. 262-3). Not all patients have all three features, and there is an imperfect relationship between radiographic appearance and clinical symptoms. Disease progression can be monitored by longitudinal imaging, both by qualitative grading and by quantitative assessment of joint space narrowing.

Magnetic Resonance Imaging

MRI provides the most detailed images of joint structures and, in contrast to radiography, detects subtle defects of articular cartilage.[14] In addition, MRI detects subchondral bone marrow lesions that are associated with symptomatic disease. MRI remains predominantly a research tool in OA, where it has been helpful in identifying soft tissue pathologic conditions and measuring early cartilage pathology; clinically, it has little role in routine OA evaluation and management. MRI is often used in OA to exclude other potential sources of pain, such as degenerative menisci, ligamentous tears, and other intraarticular pathology.

Ultrasonography

Although operator dependent, careful ultrasonography reveals outstanding details of joint structure and does not expose the patient to ionizing radiation. It may identify osteophytes undetectable by standard radiography, and articular cartilage lesions can often be observed. Its primary use, though, may be to detect local synovitis that is prevalent in OA; it remains unclear whether it can play a significant role in diagnosis.

Radionuclide Imaging

Whereas radioisotope scanning formerly had utility in OA, it has been largely supplanted by more sensitive and specific modalities for detecting articular pathology.

TREATMENT Rx

Many physicians persist in counseling their symptomatic patients that there is nothing to be done, and that OA is an inevitable sign of "getting old." Although no interventions have been demonstrated to alter the natural history of structural joint degeneration, symptomatic OA is not inevitable, and many strategies provide relief and maintain function among those with even advanced OA.[15] Patient education and support are critical; self-help programs alone have been shown to improve outcomes in OA. Patients should be provided thorough information about the natural course of OA, their role in disease management, and appropriate expectations. In general, the goals of OA therapy are similar to the treatment of any disease—to maintain or restore function, relieve symptoms, and prevent disease progression.

Maintenance of Function

Strategies to retain function and independence in patients with OA include ambulatory assistive devices, such as canes and walkers, which provide stability in addition to reducing loading across arthritic joints. Motorized carts can assist individuals with severe knee or hip OA to retain independence in the community. Physical therapy can help to retain strength and range of motion, and occupational therapy can provide customized assist devices and braces. Whenever possible, counseling on weight loss for overweight or obese patients should be provided as weight loss can improve both pain and function.

Symptom Palliation

A variety of strategies can provide effective pain palliation in OA. These include physical measures, medical therapy, and surgical interventions.[16]

Physical Measures

Exercise is especially important in OA, both to improve function and to palliate pain.[17] Exercises aimed at strengthening muscles surrounding affected joints are of value physiologically and have been consistently demonstrated to provide significant pain relief. Patients should be encouraged to exercise regularly and may benefit from physical therapy for instruction in appropriate strength training and to improve and maintain range of motion. During painful flares and immediately after exertion, application of heat or ice to affected joints can be useful.

Pain may be mediated by aberrant biomechanical loading. Therefore, canes and walkers, which significantly reduce loads across the knee during gait, can reduce pain and improve stability. Similarly, unloading knee braces, when tolerated, may provide palliation for knee OA.

Medication

Most patients will need more pain relief than is provided by physical measures. Among the elderly, choice of medication is often influenced by comorbidities. Topical agents may reduce risk for of systemic adverse effects and are appropriate when only a few joints are symptomatic. Topical capsaicin has been approved for knee OA; its use requires frequent application and careful handwashing after contact. Topical nonsteroidal anti-inflammatory drugs (NSAIDs) are available, including salicylic acid and diclofenac.

When physical measures and topical agents are insufficient, oral analgesics are used. Many specialty organizations, including the American College of Rheumatology,[18] suggest that acetaminophen may be beneficial, especially among patients with contraindications to NSAIDs such as renal dysfunction or cardiac disease. Nonetheless, acetaminophen may not be effective for long-term analgesia and chronic use carries its own potential toxicities, including liver damage and hypertension. Therefore, acetaminophen may be most properly used for short-term flares of OA pain, typically lasting no more than a few weeks. Approved alternatives to acetaminophen include tramadol and opiates, which though demonstrated to relieve OA pain, also substantially increase morbidity among the elderly, especially the risk for traumatic falls. Finally, neuroactive agents are widely used for OA pain. One such medication, duloxetine hydrochloride, a serotonin and norepinephrine reuptake inhibitor (SNRI), received U.S. Food and Drug Administration approval in 2010 for the treatment of musculoskeletal pain, including OA, based on positive results in clinical trials.

NSAIDs have been demonstrated to be effective for OA pain and may maintain efficacy for years.[A1] These medications remain the mainstay of OA medical therapy, but are not an option for many patients with renal, cardiac, or gastrointestinal conditions. Proton pump inhibitors or misoprostol can provide gastric protection in middle-aged and elderly patients and those at risk for gastrointestinal bleeding. Cyclooxygenase-2 inhibitors also may be used; in the United States, celecoxib is the only representative of this class available. Six weeks of low-dose oral prednisolone (7.5 mg daily) is also effective, and its benefits can persist for at least another six weeks.[A4]

Intra-articular Therapy

Intra-articular glucocorticoids may provide short-term relief of OA pain, often lasting months.[A5] Their use is limited to three or four times per year in any single joint because of theoretical concerns of toxicity to articular cartilage. A variety of hyaluronan derivatives are available for injection to relieve OA pain, but controversy exists as to whether they are more effective than placebo. Originally developed to supplement viscosity of synovial fluid in an attempt to improve articular lubrication, residence time in the joint is too brief to have this effect.

Surgical Approaches

Joint replacement surgery restores function and relives pain in the majority of patients and is the most important therapeutic advance in OA treatment to date (Chapter 276). It should be reserved for those in whom pain or joint dysfunction significantly limits normal life activities despite optimal medical and physical management. The presence of advanced structural degeneration of the joints alone, without severe symptoms, should not be an indication for arthroplasty. Knees and hips are most frequently replaced, but good results are now obtained in other joints as well. The durability of joint prostheses is limited, so joint replacement surgery should be delayed in younger patients when practical. Aside from total joint replacement, there are a variety of temporizing strategies that may be used in joints that have less severe structural degeneration, including realignment osteotomy in the knee and hemiarthroplasty.

Delay of Disease Progression

There has been extensive effort to identify disease-modifying OA drugs (DMOADS) that would retard disease progression and affect OA morbidity. To date, no true DMOADs have been identified, although investigation continues into agents targeting cartilage and joint tissue metabolism and inflammation. There remains optimism that as the mechanism of joint degeneration becomes more fully elucidated, rational drug discovery may identify effective DMOADs. In addition, tissue engineering approaches and mesenchymal stem cell technology may permit the development of functional joint tissue replacement in the future. Current cartilage replacement techniques are not indicated for OA treatment, but are restricted to patients with isolated chondral defects.

Biomechanically Active Approaches

OA progression is at least partly mediated by aberrant loading of joints, so improving loading patterns should affect structural progression. At present, no approaches to alter loading have yet been shown to substantially affect OA progression, but specialized footwear, gait modifications, and mechanically derived exercise regimens are under active investigation.

Complementary and Alternative Approaches

Similar to what occurs with other chronic pain conditions, the overwhelming majority of patients with OA try complementary approaches (Chapter 39). Among the more popular are glucosamine, chondroitin, and acupuncture. None has been clearly demonstrated to substantially retard joint degeneration and independently funded trials have been negative, but many patients feel pain improvement. In any blinded study of OA pain, a substantial placebo response is typically observed. Many complementary approaches have been systematically studied, and controversy remains regarding the incremental pain relief provided by these modalities over that obtained with placebo. Regardless, many of these approaches can be safely used by individual patients who derive relief from them.

PROGNOSIS

Once structural joint damage is present, it is likely to progress, although at variable rates. Slowly progressive structural disease in the absence of severe symptoms may never require surgical intervention, whereas rapidly progressive symptomatic disease might prompt early intervention. The causes of this variability remain unclear, but several factors may contribute to an individual's prognosis. Female gender, obesity, and pain severity are associated with both the incidence and progression of radiographic knee OA, and joint malalignment (varus or valgus) is a strong predictor of progression. Symptomatically, MRI or sonographically detected synovial thickening or effusion may predict progressive cartilage defects and pain severity. In the hip, joint shape is predictive of radiographic progression, as is meniscal pathology (tears, extrusion, and maceration). MRI-identified subchondral bone marrow lesions are associated with pain severity and progressive cartilage loss.

PREVENTION

No current treatments substantially alter OA progression, but some strategies reduce the risk for development of OA and ameliorate symptomatic progression. Obesity may be the most modifiable of the strong OA risk factors. Weight loss in adulthood reduces the risk for incident radiographic and symptomatic OA and reduces pain severity in patients who already have OA.[A1] Exercise is an important component of weight strategies and ameliorates pain, but specific types of exercise have not yet shown consistent preventive effects. Strategies to decrease joint injuries in young athletes are critical to reducing post-traumatic OA,[19] and proper conditioning has been shown to reduce knee injuries among female soccer players.[A7] New insights into the biology and biomechanics of OA in the coming years may be expected to yield novel strategies to prevent the onset and progression of the disease.

BURSITIS, TENDINITIS, AND OTHER PERIARTICULAR DISORDERS AND SPORTS MEDICINE

JOSEPH J. BIUNDO

DEFINITION

An array of painful and sometimes disabling musculoskeletal syndromes exist that are not articular in origin but arise from tendons and bursae. These conditions are referred to by various names, in addition to *tendinitis* and *bursitis,* including the terms *nonarticular rheumatism, soft tissue diseases, regional rheumatic pain syndromes, overuse syndromes*, and *repetitive use syndromes* (Tables 263-1 and 263-2). These entities are often ignored, misdiagnosed as arthritis, or attributed to the aging process; awareness of the existence of these conditions and knowledge of basic musculoskeletal anatomy (Figs. 263-1 and 263-2) are the fundamental requirements for diagnosis. This knowledge is coupled with brief but specific physical diagnosis techniques. The accurate diagnosis and successful treatment of these conditions is gratifying to the clinician because many people can be relieved of their chronic painful syndromes.

Various terms regarding tendon injuries are used and may be confusing. The main term used is *tendinitis. Tendinosis* has been proposed as the correct terminology because there are degenerative changes in the tendon but very few inflammatory cells. In addition, fatty mucoid degeneration and hyaline

features occur in these tendon syndromes. These tendon conditions are described by some as a *tendinopathy* because use of this term avoids the need to decide whether inflammation is a factor. Also, tendons may *rupture* or *tear,* partially or completely. The term *tendon insufficiency* is used when the tendon is stretched or is partially or even completely torn. The terms *tenosynovitis* and *peritendinitis* refer to an inflammatory response of the tenosynovium or peritendon, respectively.

Tendon syndromes are basically "overuse" injuries. Tendinitis may occur when the tendon repeatedly bears more load than it can withstand. This may result from excessively high loads across normal tendons or from normal loads across degenerated tendons. In addition to load and repetitiveness, tendon changes resulting from immobility and from aging may play a role, as may the use of certain medications such as fluoroquinolones and corticosteroids.[1]

Bursae are closed sacs lined by a synovial membrane and serve as a cushion. They are located between tendon and bone, tendon and tendon, or bone and skin and allow smooth gliding between these structures. A bursa, which normally has a small amount of bursal fluid, can become inflamed from trauma or overuse, or become infected, producing a bursitis. When this occurs, some swelling and pain of the bursa may be present.

EPIDEMIOLOGY

The incidence of the nonarticular syndromes of bursitis and tendinitis is high. They are more common than both rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE). For example, the incidence of shoulder pain, largely a result of rotator cuff tendinitis and rotator cuff tear, was approximately 20% in a population older than 70 years of age.

DIAGNOSIS

A precise history is needed to identify the conditions present, and more than one syndrome can occur concomitantly. A working knowledge of regional anatomy and an approach that uses a regional differential diagnosis will help in obtaining a specific diagnosis. A complete neuromusculoskeletal examination should be performed, emphasizing careful palpation, passive range of motion (ROM), and active ROM alone or sometimes with resistance. Systemic and infectious causes must be considered. Diagnostic ultrasonography and magnetic resonance imaging (MRI) are sometimes useful in confirming a diagnosis.

TREATMENT

Rx

Treatment of tendinitis and bursitis includes use of nonsteroidal anti-inflammatory drugs (NSAIDs), relative rest of the injured site, stretching and strengthening exercises, friction massage, use of modalities (heat, ice, and ultrasound), splinting, corticosteroid injections,[2] and surgery. A comprehensive management of these regional syndromes should be undertaken, rather than relying on oral medications alone. The causative aspects should be evaluated, and activity modification should be advised as needed. The goals of therapeutic exercise are to increase flexibility by stretching, increase muscle strength by resistive exercises, and improve muscle endurance by some repetitive regimen. Caution should be exerted in performing corticosteroid injections; the injections should not be placed into the tendon proper, but rather into the peritendinous sheath. The injected solution should be placed beneath the subcutaneous tissue, to avoid skin and subcutaneous fat atrophy, and

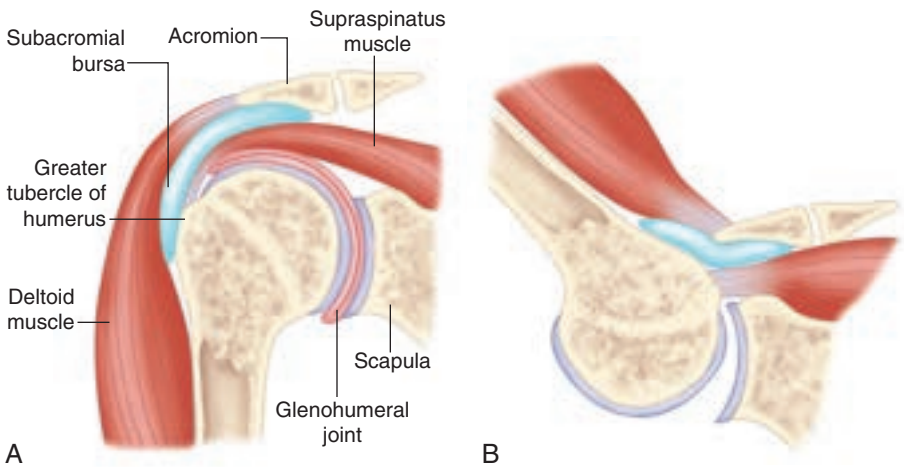

FIGURE 263-1. Relationship of subacromial bursa (shown in *blue*) to supraspinatus muscle and acromion process. A, In the position of adduction of the humerus. injections should not be given too frequently, to avoid the possibility of weakening and rupture of the tendon. The accuracy of injections may be improved with concomitant use of diagnostic ultrasonography to assist with determining the correct needle site. Also, fluoroscopically guided injections can be used to increase accuracy.

SPORTS MEDICINE INJURIES

An overlap exists between commonly occurring conditions of tendinitis and bursitis and those attributed to sports injuries (Table 263-3). For example, lateral epicondylitis, frequently referred to as *tennis elbow,* occurs more commonly secondary to non–sports-related causes. In contradistinction, iliotibial band syndrome is usually related to sports. Other entities that occur more often in relation to sports include ligamentous knee injuries, patellar tendinitis, ankle sprains, turf toe, and acromioclavicular separations. It is important in both categories to know the anatomy and biomechanics of the condition, so as to better diagnose and treat the problem. Sports-related injuries are helped with the classic RICE treatment, consisting of *r*est, *i*ce, *c*ompression, and *e*levation. Often, anti-inflammatory and analgesic drugs are used. However, there is less use of corticosteroid injections in athletic injuries than in routine cases of tendinitis and bursitis.

DISORDERS OF THE SHOULDER REGION

Shoulder pain is one of the most common musculoskeletal complaints in people older than 40 years of age. In younger people, athletic injuries are a frequent source of such pain.

Rotator cuff tendinitis, or impingement syndrome, is the most common cause of shoulder pain.[2] Tendinitis (and not bursitis) is the primary cause of pain, but secondary involvement of the subacromial bursa occurs in some cases. The condition may be acute or chronic and may or may not be associated with calcific deposits within the tendon. The key finding is pain in the rotator cuff on active abduction, especially between 60 and 120 degrees, and sometimes when lowering the arm. In more severe cases, pain may begin on initial abduction and continue throughout the ROM. Typically, chronic rotator cuff tendinitis manifests as an ache in the shoulder, usually over the lateral deltoid, and occurs with various movements, especially abduction and internal rotation. Other symptoms include difficulty in dressing oneself and night pain because of difficulty in positioning the shoulders. The physical findings include pain and loss of active abduction and internal rotation, less pain on passive motion, tenderness of the area of supraspinatus insertion, and a positive impingement sign (Fig. 263-3, Neer's sign, which is pain occurring in forced flexion.[3] The causes of rotator cuff tendinitis are multifactorial, but relative overuse, especially from overhead activity causing impingement of the rotator cuff, is commonly implicated. Treatment consists of rest and modalities such as hot packs, ultrasound, or cold applications, with specific ROM exercises as soon as tolerated. NSAIDs are often beneficial, but the most frequent treatment is injection of a depot corticosteroid into the subacromial bursa, the floor of which is contiguous with the rotator cuff. Disodium ethylenediaminetetraacetic acid (EDTA) administered by phonophoresis and mesotherapy to patients with calcific tendinitis of the shoulder has been found to be effective in pain reduction, improvement in shoulder function, and disappearance of calcifications. Extracorporeal shock wave therapy can also be beneficial for chronic calcific tendinitis.

In a rotator cuff tear, an acute tear after trauma is usually easily recognized. The trauma may be superimposed on an already degenerative and possibly even partially torn cuff. In cases of trauma resulting in a ruptured cuff, fracture of the humeral head and dislocation of the joint also should be considered. However, most patients with a tear recall no trauma. In these cases, degeneration of the rotator cuff occurs gradually, resulting ultimately in a complete tear. Rotator cuff tears are classified as small (≤1 cm), medium (1 to 3 cm), large (3 to 5 cm), or massive (>5 cm). Shoulder pain, weakness on abduction, and loss of motion occur in varying degrees, ranging from severe pain and mild weakness to no pain and marked weakness. A positive drop-arm sign with inability to maintain actively 90 degrees of passive shoulder abduction may be present in patients with large or massive tears. Small complete tears

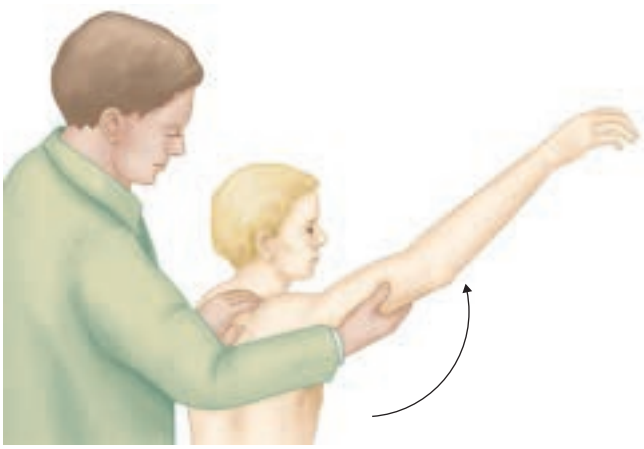

FIGURE 263-3. **The impingement sign is elicited by forced forward elevation of the arm.** Pain results as the greater tuberosity impinges on the acromion. The examiner's hand prevents scapular rotation. This maneuver may be positive in other periarticular disorders. (From Neer CS II. Impingement lesions. *Clin Orthop*. 1983;173:70-77.)

FIGURE 263-4. Injection of de Quervain tenosynovitis.

and incomplete tears of the rotator cuff are treated conservatively with rest, physical therapy, and NSAIDs. Although its role has not yet been established by careful studies, a subacromial injection of a corticosteroid may relieve pain. Surgical repair may be indicated in younger patients.

Bicipital tendinitis is manifested by pain, most often in the anterior region of the shoulder and occasionally more diffusely. The pain may be acute but is usually chronic and is related to impingement of the biceps tendon by the acromion. Tenosynovitis of the long head of the biceps is present, and the tendon may be frayed and fibrotic. Palpation over the bicipital groove reveals localized tenderness. The patient's response should be compared with the response to palpation of the opposite side (i.e., tendon with normal tenderness). Pain may be reproduced over the bicipital tendon in some cases by supination of the forearm against resistance (Yergason's sign), shoulder flexion against resistance (Speed's test), or extension of the shoulder. Treatment of bicipital tendinitis consists of rest, hot packs, ultrasound, and, as pain subsides, passive and then active ROM exercises. NSAIDs may be helpful, and occasionally a small amount of corticosteroid carefully injected into the tendon sheath may be of benefit. Rupture of the biceps tendon can occur at the superior edge of the bicipital groove, producing a characteristic bulbous enlargement of the lateral half of the muscle belly.

Adhesive capsulitis (frozen shoulder) is associated with generalized pain and tenderness and severe loss of active and passive motion in all planes. It is rare before 40 years of age but may occur secondary to any type of shoulder problem. However, not every stiff and painful shoulder is necessarily adhesive capsulitis. Inflammatory arthritis and diabetes can cause adhesive capsulitis. Additional factors such as immobility, low pain threshold, depression, and neglect or improper initial treatment also favor the development of a frozen shoulder. Many cases, however, are idiopathic. The joint capsule adheres to the anatomic neck, and the axillary fold binds to itself, causing restricted motion. The capsule becomes thickened and contracted. Arthrography can help confirm this diagnosis by showing a decrease in volume of the shoulder joint capsule. Oral steroids improve pain and range of motion in the short term, but a frozen shoulder is probably best treated with a comprehensive program involving NSAIDs and corticosteroid injections into the glenohumeral joint and the subacromial bursa. Physical therapy consists of ice packs, ultrasound, transcutaneous electrical nerve stimulation, and gentle ROM exercises, beginning with pendulum exercises and wall climbing with the fingers and progressing to active ROM and strengthening exercises.

DISORDERS OF THE ELBOW REGION

Olecranon bursitis occurs frequently and involves the subcutaneous olecranon bursa, either secondary to trauma or as an idiopathic condition. The bursa is characteristically swollen and tender on pressure, but pain may be minimal and usually no motion is lost. Aspiration may yield clear or blood-tinged fluid with a low viscosity or grossly hemorrhagic fluid. Inflammatory olecranon bursitis may be caused by gout, RA, or calcium pyrophosphate deposition disease, and infection can also cause a bursitis. Aspiration alone and protection from trauma are usually sufficient to resolve the condition. A small dose of corticosteroid may be injected into the bursa. With septic olecranon bursitis, localized erythema is the major clue. Heat, pain, and a positive culture are also frequently present.

Lateral epicondylitis, or tennis elbow, is a common condition in those who overuse their arms.[4] Localized tenderness directly over or slightly anterior to the lateral epicondyle is the hallmark of this disorder. Pain may occur during handshakes, while lifting a briefcase, or with other similar activities. Probably less than 10% of patients actually acquire lateral epicondylitis through playing tennis. Job and recreational activities, including gardening and athletics, are the usual causes. Pathologically, the condition consists of degeneration of the common extensor tendon, particularly of the extensor carpi radialis brevis tendon.[5] Treatment is aimed at altering activities and preventing overuse of the forearm musculature. Ice packs, heat, and NSAIDs are of some benefit. A forearm brace also can be used. A local corticosteroid injection with a 25-gauge needle over the lateral epicondyle often produces satisfactory initial relief. Isometric strengthening is important as the initial part of a rehabilitation program.

Medial epicondylitis, or golfer's elbow, which mainly involves the flexor carpi radialis, is less common and less disabling than lateral epicondylitis. Local pain and tenderness over the medial epicondyle are present, and resistance to wrist flexion exacerbates the pain.

DISORDERS OF THE WRIST AND HAND

A ganglion is a cystic swelling that arises from a joint or tendon sheath and occurs most commonly over the dorsum of the wrist. It is synovial lined and contains thick, jelly-like fluid. Ganglia apparently develop secondary to trauma or prolonged wrist extension. Usually, the only symptom is swelling, but occasionally a large ganglion produces discomfort on wrist extension.

De Quervain's tenosynovitis may result from repetitive activity that involves pinching with the thumb while moving the wrist. The symptoms are pain, tenderness, and occasionally swelling over the radial styloid. Pathologic findings include inflammation and narrowing of the tendon sheath around the abductor pollicis longus and extensor pollicis brevis. A positive Finkelstein test result is usually seen; pain increases when the thumb is folded across the palm and the fingers are flexed over the thumb as the examiner passively deviates the wrist toward the ulnar side. However, this test also may be positive in patients with osteoarthritis (OA) of the first carpometacarpal joint and must be differentiated from this common condition. Treatment involves splinting, local corticosteroid injection (Fig. 263-4), and NSAIDs as indicated. Rarely, surgical removal of the inflamed tenosynovium is needed.

Volar flexor tenosynovitis consists of inflammation of the tendon sheaths of the flexor digitorum superficialis and flexor digitorum profundus tendons in the palm. It is extremely common but often unrecognized. Pain in the palm is felt on finger flexion, but in some cases the pain radiates to the proximal interphalangeal (PIP) and metacarpophalangeal (MCP) joints on the dorsal side, misleading the examiner. The diagnosis is made by palpation and identification of localized tenderness and swelling of the volar tendon sheaths. The middle and index fingers are most commonly involved, but the ring and little fingers also can be affected. Often a nodule composed of fibrous tissue can be palpated in the palm just proximal to the MCP joint on the volar side. The nodule interferes with the normal tendon gliding and can cause a triggering or locking, which may be intermittent and may produce an uncomfortable sensation. Similar involvement can occur at the flexor tendon of the thumb. The most common cause is overuse trauma of the hands from gripping with increased pull on the flexor tendons. It may be part of inflammatory conditions, such as RA, psoriatic arthritis, or apatite crystal deposition disease. It is seen frequently in conjunction with OA of the hands. Injection

of a long-acting steroid into the tendon sheath usually relieves the problem, although surgery on the tendon sheath may be needed in unremitting cases.

Gamekeeper's thumb (skier's thumb) is caused by trauma to the thumb resulting in instability of the first MCP joint. This instability is due to laxity or rupture of the ulnar collateral ligament. It is treated by immobilization, but surgical repair may be necessary.

Avulsion of flexor digitorum profundus (jersey finger) may result from trauma, usually in football, when a player grabs onto a jersey. The distal phalanx, usually the fourth, is hyperextended while the digitorum profundus is contracting maximally. The avulsion of the tendon results in an inability to flex the distal phalanx of that digit. Surgery is required to correct the problem.

DISORDERS OF THE HIP REGION

Although trochanteric bursitis is common, it frequently goes undiagnosed. It occurs predominantly in middle-aged to elderly people, and somewhat more often in women. The main symptom is aching over the trochanteric area and lateral thigh. Walking, various hip movements, and lying on the involved hip may intensify the pain. Onset may be acute, but more often it is gradual, with symptoms lasting for months. In chronic cases, the patient may fail to locate or describe the pain adequately, or the physician may fail to note the symptoms or interpret them correctly. Occasionally, the pain has a pseudoradiculopathic quality, radiating down the lateral aspect of the thigh. In a few cases, the pain is so severe that the patient cannot walk and complains of diffuse pain of the entire thigh. The best way to diagnose trochanteric bursitis is to palpate over the trochanteric area and elicit point tenderness. In addition to specific pain on deep pressure over the trochanter, other tender points may be noted throughout the lateral aspect of the thigh muscle. Pain may be worse with external rotation and abduction against resistance. Although bursitis has historically been described as the principal problem, the condition may actually arise at the insertions of the gluteus medius and gluteus minimus tendons.[6] Local trauma and degeneration play a role in the pathogenesis, leading to tendinosis and/or tendon tears. Conditions that may contribute to trochanteric bursitis, apparently by adding stress to the area, include OA of the lumbar spine or of the hip, leg-length discrepancy, and scoliosis. Treatment consists of local injection of depot corticosteroid using a 22-gauge, 3.5-inch needle to ensure that the bursal area is reached (Fig. 263-5). NSAIDs, weight loss, and strengthening and stretching of the gluteus medius muscle and iliotibial band help in management.

Coccydynia is manifested by pain in the coccyx area when pressure is applied to the area. This most notably occurs on sitting. The patient squirms from buttock to buttock to relieve the pressure and consequent pain and often chooses to sit on a cushion. The symptoms may be chronic and severe. The condition may relate to a fall on the coccyx, dropping to a hard chair when sitting, or some related trauma to the coccyx. However, at times no obvious cause can be detected. Women are much more frequently affected, perhaps because the lordosis that often occurs in women exposes the coccyx to more trauma. The diagnosis is confirmed by finding localized tenderness over the coccyx on palpation. A plain x-ray film can be obtained to exclude a fracture or dislocation of the coccyx. Treatment with a local injection of 1 mL of a long-acting corticosteroid and 2 mL of a 2% lidocaine solution is usually very effective. The exact nature of the pathology of coccydynia has not been studied, but it is presumed to be a bone bruise.

In iliopsoas bursitis, groin and anterior thigh pain are present and worsen on passive hip hyperextension and sometimes on flexion, especially with resistance. Tenderness is palpable over an involved bursa. The patient may hold the hip in flexion and external rotation to eliminate pain and may limp to prevent hyperextension of the hip. The iliopsoas bursa lies behind the iliopsoas muscle, anterior to the hip joint and lateral to the femoral vessels. It communicates with the hip in 15% of cases. The diagnosis is more apparent if a cystic mass is seen (~30% of cases); however, other causes of cystic swelling in the femoral area must first be excluded. A bursal mass can cause femoral venous obstruction or femoral nerve compression. As with most cases of bursitis, acute or recurrent trauma and inflammatory conditions such as RA may lead to iliopsoas bursitis (also called *iliopectineal bursitis*). Iliopsoas tendinitis may overlap with the bursitis or occur independently in a similar clinical picture. The diagnosis is confirmed by plain x-ray with injection of a contrast medium into the bursa, or by ultrasonography, computed tomography, or MRI. Iliopsoas bursitis/tendinitis usually responds to conservative treatment including physical therapy and corticosteroid injections. With recurrent involvement, excision of the bursa may be necessary.

FIGURE 263-5. Injection of trochanteric bursitis.

Ischial or ischiogluteal bursitis is caused by trauma or by prolonged sitting on hard surfaces, as evidenced by the name *weaver's bottom*. Pain is often exquisite when sitting or lying down. The hamstring muscles originate from the ischial tuberosity, and the ischiogluteal bursa is superficial to the tuberosity. Because the bursa is superficial to the tuberosity, separating the gluteus maximus from the tuberosity, the pain may radiate down the back of the thigh. Point tenderness over the ischial tuberosity is present. Use of cushions, hamstring stretching, and local injection of a corticosteroid are helpful.

DISORDERS OF THE KNEE REGION

Anserine bursitis is seen predominantly in overweight, middle-aged to elderly women with large legs and OA of the knees. The symptoms are pain and tenderness over the medial aspect of the knee approximately 2 inches below the joint margin, with the pain worsened by climbing stairs. The pes anserinus (Latin for "goose foot") is composed of the conjoined tendons of the sartorius, gracilis, and semitendinosus muscles. The bursa extends between the above tendons and the tibial collateral ligament. Tendinitis of these tendons, rather than bursitis, is the predominate cause of the syndrome. The diagnosis is made by eliciting exquisite tenderness over the bursal area. Anserine bursitis is often overlooked because it frequently occurs concomitantly with OA of the knee, which, when present, is the assumed cause of pain; however, in some cases of dual involvement, anserine bursitis is the principal source of pain. The treatment is rest, stretching of the adductor and quadriceps muscles, and a corticosteroid injection into the bursa and tendon insertion site.

Prepatellar bursitis manifests as a swelling superficial to the kneecap and results from trauma such as frequent kneeling, leading to the name *housemaid's knee*. The prepatellar bursa lies anterior to the lower half of the patella and the upper half of the patellar ligament. The pain is generally slight unless pressure is applied directly over the bursa. The infrapatellar bursa, which lies between the patellar ligament and the tibia, is also subject to trauma and swelling. Chronic prepatellar bursitis can be treated by protecting the knee from the irritating trauma.

Patellar tendinitis (jumper's knee) is seen predominantly in athletes engaging in activities such as repetitive running, jumping, or kicking. Pain and tenderness are present over the patellar tendon.

Iliotibial band syndrome manifests by lateral knee pain caused by friction between the iliotibial band and the lateral femoral condyle. It is an overuse injury and is seen in runners, cyclists, and other athletes performing repetitive knee flexion activities.

Popliteal cysts,[7] also known as Baker's cysts, are not uncommon, and the clinician should be well aware of the possibility of their dissection or rupture. A cystic swelling behind the knee with mild or no discomfort can be the only initial finding. With further distention of the cyst, however, a greater awareness and discomfort are experienced, particularly on full flexion or extension. The cyst is best seen when the patient is standing and examined from behind. Any knee disease having a synovial effusion can develop into a popliteal cyst. Popliteal cysts are most common secondary to RA, OA, or internal derangements of the knee. There are a few reported cases secondary to gout and Reiter's syndrome. A syndrome of pseudothrombophlebitis may occur as a result of cyst dissection into the calf or actual rupture of the cyst. Findings include diffuse swelling of the calf, pain, and sometimes erythema and edema of the ankle. An ultrasound or arthrogram of the knee confirms both the cyst and the possible dissection or rupture. A cyst related to an inflammatory arthritis is treated by injection of a depot corticosteroid into the knee joint, and possibly into the cyst itself, which usually resolves the problem. If the cyst results from OA or an internal derangement of the knee, surgical repair of the underlying joint lesion is usually necessary to prevent a recurrence of the cyst.

In the knee area, tendon ruptures may occur, and quadriceps tendon rupture is involved approximately 50% of the time; otherwise, patellar tendon rupture occurs. Quadriceps tendon rupture is generally caused by sudden violent contractions of the quadriceps muscle when the knee is flexed. A hemarthrosis of the knee joint may follow. Patients with chronic renal failure, RA, hyperparathyroidism, or gout and patients with SLE taking steroids have been reported to have spontaneous ruptures of the quadriceps tendon. The patient experiences a sudden sharp pain and cannot extend the leg. X-ray studies may show a high-riding patella. The tendon is usually found to be degenerated, and surgical repair is often indicated. Rupture of the patellar tendon has been associated with a specific episode of trauma, repetitive trauma from sporting activities, and systemic diseases.

Meniscal tears are common causes of knee "locking" and pain. Physical examination may show pain, with or without clicking, when the hip and knee are bent to 90°. Magnetic resonance imaging is the diagnostic test of choice. Physical therapy is often as effective as surgery.[A5]

DISORDERS OF THE ANKLE AND FOOT REGION

Achilles tendinitis usually results from trauma, athletic overactivity, or improperly fitting shoes with a stiff heel counter, but it also can be caused by inflammatory conditions such as ankylosing spondylitis, Reiter's syndrome, gout, RA, and calcium pyrophosphate dihydrate crystal deposition disease.[9] Pain, swelling, and tenderness occur over the Achilles tendon at its attachment and in the area proximal to the attachment. Crepitus on motion and pain on dorsiflexion may be present. Management includes NSAIDs, rest, shoe corrections, heel lift, gentle stretching, and sometimes a splint with slight plantar flexion. Local injection of platelet-rich plasma (PRP) has become an increasingly used treatment for releasing growth factors into degenerative tendons; however, more recent randomized, placebo-controlled trials for treatment of chronic Achilles and other tendinopathies have found PRP injections to be ineffective in improving pain and activity.[A1] The Achilles tendon is vulnerable to rupture when involved with tendinitis, and treatment with a corticosteroid injection could increase this possibility.

Achilles tendon rupture is well known and occurs with a sudden onset of pain during forced dorsiflexion. An audible snap may be heard, followed by difficulty in walking and standing on toes. Swelling and edema over the area usually develop. Diagnosis can be made with the Thompson test, in which the patient kneels on a chair with the feet extending over the edge and the examiner squeezes the calf and pushes toward the knee. Normally this produces plantar flexion, but in a ruptured tendon, no plantar flexion occurs. Achilles tendon rupture usually occurs during athletic events or with trauma from jumps or falls. The tendon is more prone to tear in people with preexisting Achilles tendon disease and in those taking corticosteroids. Orthopedic consultation should be obtained, and immobilization or surgery may be selected, depending on the situation.

For acute, severe ankle sprain, a below-knee cast or Aircast produces a faster recovery than a tubular compression bandage, but there is no difference in outcomes at 9 months.[A8] Plantar fasciitis, which is seen primarily in persons between 40 and 60 years of age, is characterized by pain in the plantar area of the heel. The onset may be gradual, or it may occur with trauma or overuse from some activity, such as athletics, prolonged walking, using improper shoes, or striking the heel with some force. Plantar fasciitis may be idiopathic; it also is likely to be present in younger patients with spondyloarthritis (Chapter 265). The pain characteristically occurs in the morning on arising and is most severe for the first few steps. After an initial improvement, the pain may worsen later in the day, especially after prolonged standing or walking. The pain is burning, aching, and occasionally lancinating. Palpation typically reveals tenderness anteromedially on the medial calcaneal tubercle at the origin of the plantar fascia. Treatment includes relative rest with a reduction in stressful activities, NSAIDs, use of heel pad or heel cup orthosis, arch support, and stretching of the heel cord and plantar fascia. A local corticosteroid injection, using a 25-gauge needle, is often of help.

In posterior tibial tendinitis, pain and tenderness occur just posterior to the medial malleolus; it can be caused by trauma, excessive pronation, RA, or spondyloarthropathy. Extension and flexion may be normal, but pain is present on resisted inversion or passive eversion. The discomfort is usually worse after athletic activity, and swelling and localized tenderness may be present. Treatment usually includes rest, NSAIDs, and possibly a local injection of corticosteroid. Immobilization with a splint is sometimes needed.

Posterior tibialis tendon rupture, which is not commonly recognized, is a cause of progressive flat foot. It can result from trauma, chronic tendon degeneration, or RA. An insidious onset of pain and tenderness may be noted along the course of the tendon just distal to the medial malleolus, along with swelling medial to the hind foot. The unilateral deformity of hind foot valgus and forefoot abduction is an important finding. The forefoot abduction can best be seen from behind; more toes are seen from this position than would be seen normally. The result of the single heel rise test is positive when the patient is unable to rise onto the ball of the affected foot while the contralateral foot is off the floor. Treatment usually includes rest, NSAIDs, and possibly an orthosis. Surgical repair of the tendon is sometimes indicated. Manifestations of retrocalcaneal bursitis include pain at the back of the heel, tenderness of the area anterior to the Achilles tendon, and pain on dorsiflexion. Local swelling is present, with bulging on the medial and lateral aspects of the tendon. Retrocalcaneal bursitis, also called sub-Achilles bursitis, may coexist with Achilles tendinitis, and distinguishing the two is sometimes difficult. This condition may be secondary to RA, spondylitis, a reactive arthritis, gout, or trauma.

Turf toe is an injury of the big toe originally described during play on artificial turf. It results from hyperextension of the first metatarsophalangeal (MTP) joint when a fixed, dorsiflexed foot is forced into the ground. The plantar capsular ligament may be sprained or torn.

Stress fracture is also known as march fracture or fatigue fracture because it was first associated with spontaneous fracture after long marches in army recruits. Pain, swelling, tenderness, and occasionally erythema develop over the metatarsal area, usually without any clear history of trauma. On questioning, however, the episode of spontaneous pain related to onset of the fracture can be identified in some cases. The neck of the second metatarsal bone is most frequently involved, but the third metatarsal is also a site of fracture. Aside from prolonged marching, other athletic events with overactivity, including jogging, are common causes. Stress fractures may be seen in patients with RA and in elderly people. The difficulty in diagnosing stress fractures is that the initial x-ray films usually show no abnormalities or, at most, only a faint fracture line. A repeat x-ray examination several weeks later shows healing with callus formation. Bone scans aid the early diagnosis of stress fractures by showing an increase in uptake over the fracture site. Usually these fractures heal spontaneously, and rest and strapping of the foot are helpful. Occasionally, a cast is needed.

REVIEW QUESTIONS

1. A 78-year-old woman who has had periodic discomfort in her neck and radiating to both shoulders for several years had a fall, landing on her outstretched right arm. She had pain in the right shoulder and weakness on use. At the urgent care center she was found to have some pain on passive motion and was unable to actively abduct the right shoulder. She had a positive drop arm sign of the right shoulder but not of the left one. All upper extremity deep tendon reflexes were normal. Which of the following is the *most likely* diagnosis?

A. Rotator cuff tendinitis is the main diagnosis.
B. X-ray examination of the humerus of the injured side is not indicated in this case because tendon injuries are not visualized on plain x-ray film of the shoulder.
C. Bicipital tendinitis is the likely diagnosis.
D. A tear of the rotator cuff best fits as the diagnosis.
E. Cervical spine disc herniation is the most likely diagnosis based on the history of neck pain and arm weakness.

Answer: D Acute trauma is often the cause of rotator cuff tears, although most tears occur gradually through chronic tendinitis. The positive drop arm sign is typical of a significant rotator cuff tear. Sometimes with trauma, a humeral fracture can occur along with the rotator cuff tear. Pain on abduction and especially on resisted abduction are seen in rotator cuff tendinitis; also, the drop arm sign is typically negative. Bicipital tendinitis usually does not cause shoulder weakness. The clinical picture does not fit a cervical disc herniation, and the reflexes are normal.

Biundo, JJ: Regional Rheumatic Pain Syndromes, Primer on the Rheumatic Diseases, Thirteenth Edit. 2006

2. A 51-year-old male insurance agent, whose hobby is wood working, complains of right hand pain of approximately 4 months' duration. He had been doing more wood working during that period until the hand pain began to limit this activity. On examination there were no Heberden's nodes of the DIP joints, and the PIP and MCP were not tender or swollen. Moderate-to-severe tenderness on palpation was present over the palm side of the hand at the region of the second and third metacarpal bones. Some swelling was detected at these sites. Crepitus was noted on palpation on flexion of these two digits. Which of the following is the *most likely* diagnosis?

A. Because rheumatoid arthritis is a likely diagnosis, you should obtain RF, ANA, and hand x-ray films.
B. Because of his age, he most likely has osteoarthritis of the hand.
C. He fits the picture of volar flexor tenosynovitis
D. A C7 radiculopathy would best explain pain in this part of his hand.
E. Overuse of his hands has caused carpal tunnel syndrome.

Answer: C Volar flexor tenosynovitis is one of the most common musculoskeletal syndromes and is frequently overlooked. It is manifest by pain in the palm of the hand. The volar flexor tendon sheath is tender on palpation and thickened. Triggering or snapping of the digit sometimes occurs, especially when more chronic. Overuse of the hand is the usual cause, but is also seen in association with OA of the hands and diabetes. Stretching of the involved digit and an injection of a small amount of a corticosteroid into the tendon sheath is usually helpful.

Biundo, JJ: Regional Rheumatic Pain Syndromes, Primer on the Rheumatic Diseases, Thirteenth Edit. 2006

3. A 48-year-old male professional cellist, whose hobby is gardening, has had a 4-month history of right shoulder pain. Pain occurs on various movements of the shoulder, and there is some limitation of movement. Night pain in bed is also reported. On examination, pain limits active abduction to 90 degrees. Less pain is noted on passive abduction, and 180 degrees of abduction is present. The drop arm sign is negative, but pain occurs on active internal rotation of the shoulder. There is no crepitus. Which of the following is the *most likely* diagnosis?

A. Rotator cuff tendinitis is the most likely diagnosis.
B. Rotator cuff tear best fits this clinical picture.
C. Rupture of the biceps tendon is the diagnosis because the drop arm sign is negative.
D. Adhesive capsulitis (frozen shoulder) is the diagnosis.
E. OA of the shoulder (glenohumeral joint) is the likely diagnosis, and a plain x-ray film of the shoulder is needed to confirm the diagnosis.

Answer: A The typical physical examination findings of rotator cuff tendinitis are pain on active abduction, less pain on passive abduction, and more pain on resistive abduction. Loss of motion on active movements can occur when more severe. Also, pain may occur on active internal and on external rotation. In addition to the physical examination, ultrasonography and MRI can detect tendinitis, but not plain x-ray examination. In adhesive capsulitis restriction, the range of motion in all directions is usually seen. The full range on abduction and other motions in this case are not typical of a frozen shoulder. OA of the shoulder would not have had a pain history of only 4 months, and it is a much less frequent entity than rotator cuff tendinitis. Crepitus on range of motion is very common in OA of the glenohumeral joint.

Biundo, JJ: Regional Rheumatic Pain Syndromes, Primer on the Rheumatic Diseases, Thirteenth Edit. 2006

4. A 76-year-old woman with a known history of moderate OA of both knees and a partially torn right medial meniscus experienced pain in her right knee after stooping down to clean something off the floor. The next day she had discomfort and fullness behind her right knee and swelling of her lower leg and ankle. She was able to walk but had a limp. She was seen that day by her primary care physician for evaluation. Which of the following is the *best* course of action?

A. Begin treatment with heparin or enoxaparin for a deep vein thrombosis.
B. Give oral prednisone for 5 days as a tapering dose for an acute flare of the OA of her knee.
C. Obtain a new x-ray film of the knees, with a standing AP and lateral view of the involved leg.
D. Because of the acute flare of knee symptoms, give colchicines for a possible acute attack of gout.
E. Obtain a Doppler ultrasound of the right leg for a deep vein thrombosis and an ultrasound image of the right knee to identify a Baker's cyst that has dissected, causing a pseudothrombophlebitis picture.

Answer: E Popliteal cysts, also known as Baker's cysts, are often asymptomatic. However, at times they may enlarge as a result of increasing pressure from a synovial effusion of the knee, flowing through a one-way valve from the knee to the popliteal cyst. The cyst can at times dissect downward, causing swelling of the leg and simulating thrombophlebitis. Thus, the name given to the syndrome is pseudothrombophlebitis. The swelling of the leg may resolve on its own after several days. Often, a corticosteroid injection into the knee joint may help by decreasing the inflammation and synovial effusion of the knee. OA of the knee should not produce swelling of the lower leg, nor should gout. Treatment with anticoagulants should not be given unless the diagnosis of DVT were confirmed.

Biundo, JJ: Regional Rheumatic Pain Syndromes, Primer on the Rheumatic Diseases, Thirteenth Edit. 2006

5. A 52-year-old moderately obese man complains of pain in his right foot that has been present for approximately 4 months. The pain has become worse recently, and he has had to stop the walks he was taking for exercise. The pain is described to be more in the rear foot and is particularly bad when he first gets out of bed in the morning. He has no history of gout or other arthritis except for some back pain. On examination there is no joint swelling. He does have pes cavus, and tenderness of the plantar surface of the rear foot. His calf muscles are also tight. What is the *most likely* diagnosis and/or the *best* course of evaluation and treatment?

A. Order an MRI of the foot or technetium bone scan for possible stress fracture.
B. Inject the calcaneus with a steroid, because that is the best initial treatment for heel pain.
C. Make a tentative diagnosis of plantar fasciitis and treat with analgesics, stretching of calf and plantar fascia, and use of a heel cushion as the initial treatment.
D. Obtain uric acid level and start treatment with colchicine.
E. Obtain orthopedic consultation for possible Achilles tendon tear.

Answer: C The complaint of morning foot pain, which is called "first step pain," is typical of plantar fasciitis. Tenderness often elicited on pressure exerted on the plantar surface of the calcaneus. Trauma to the foot from prolonged walking, tight calf muscles, high arched foot with tight plantar fascia, and obesity are factors related to acquiring plantar fasciitis. A steroid injection of the cacaneal area is often helpful, but is not the first line of treatment. With Achilles tendinitis/tear the pain is in the posterior heel and not the plantar surface. A stress fracture is more likely to occur in the metatarsal area and only very rarely occur in the calcaneus.

RHEUMATOID ARTHRITIS

JAMES R. O'DELL

DEFINITION

Rheumatoid arthritis (RA) is a chronic systemic inflammatory disease of unknown etiology that primarily targets synovial tissues. It is relatively common, with a prevalence of slightly less than 1% in adults all over the

world. RA shortens survival and significantly affects quality of life in many patients. Essentially all patients exhibit some systemic features such as fatigue, low-grade fevers, anemia, and elevations of acute phase reactants (erythrocyte sedimentation rate [ESR] or C-reactive protein [CRP]). This systemic inflammation is believed to be responsible for vascular endothelial damage and a marked increased risk for coronary artery disease and congestive heart failure in patients with RA.[1] However, the primary target of RA is the synovium and it is responsible for most of the protean clinical features. Synovial tissues proliferate in an uncontrolled fashion, resulting in excess fluid production, destruction of cartilage, erosion of marginal bone, and stretching and damage of the tendons and ligaments.

In the past two decades, the treatment of RA has changed dramatically. Current therapeutic strategies should result in over 50% of patients achieving clinical remissions with treatment with appropriate disease-modifying antirheumatic drugs (DMARD) or combinations of DMARDs.

EPIDEMIOLOGY

RA is present all over the world, with a prevalence of 0.5 to 1% of adults and with some differences in certain population groups. For reasons that are still unclear, the prevalence in women is two or three times greater than that in men. RA can occur at any age, but onset before the age of 45 years in men is uncommon. The relatively few well-done inception cohorts suggest that the yearly incidence of RA is approximately 40 per 100,000 for women and about half that for men. These figures vary significantly based on the age of the cohort. The best available data suggest that the incidence of RA in women increases with age until approximately 60 years of age and then plateaus. The incidence rate is much lower in young men, approximately one third that in women, but increases steadily with age and approaches that of women older than 65 years. Because the incidence of RA increases or is stable with age and RA is a lifelong disease, the prevalence of RA increases with each decade. Recent data suggest that the incidence of RA, particularly rheumatoid factor (RF)-negative RA, may be decreasing. The reasons for this are unclear, but, if elucidated, they could provide valuable insights into the etiology and pathogenesis of RA and might allow the implementation of strategies to prevent clinical disease.

RA has a significant genetic component; therefore, it is not surprising that RA is reportedly very unusual in certain populations and more common in others. Most notably, cohorts have been described in rural Nigeria in which no individuals are affected with RA; in contrast, a prevalence of RA of 5% has been found in some studies of Chippewa, Yakima, and Inuit Native American tribes.

PATHOBIOLOGY

Genetics

Genetics play a significant role in determining both the risk for developing RA and the severity of the disease.[2] Twin studies reveal a concordance rate for RA that averages 15% for monozygotic twins and approximately 5% for dizygotic twins. These data in monozygotic twins simultaneously reveal both the significance of genetic factors and the fact that they are clearly not the only important factor, or else the concordance rate would approach unity.

It has been clearly shown that RA is a multigene disease with important contributions from both human leukocyte antigen (HLA) and non-HLA genes. The association of certain HLA alleles, specifically HLA-DR4, with an increased risk for developing RA and of having more severe disease has long been recognized. This association is explained by a particular amino acid sequence in the third hypervariable region on the DRβ1 chain. HLA-DR molecules are present on the surface of antigen-presenting cells and allow T cells to recognize antigen in the context of DR. Hypervariable regions on the DR molecule are particularly important for antigen recognition. E-Table 264-1 details the amino acid sequence of several DRβ1 chains that are associated with RA and some that are not. The amino acid sequence associated with RA has been called the *shared epitope* or the *at-risk allele*. It has been shown by a number of investigators that patients with the shared epitope have more severe RA and more extra-articular manifestations than those who are negative. Furthermore, individuals with two copies of the shared epitope, particularly those with HLA-DR4, have a further increased risk for the development of severe RA. This association with a particular antigen recognition site may ultimately aid understanding of the antigen or antigens that are important for triggering RA. Proteins in which arginine has been converted to citrulline are bound with greater avidity by the shared epitope. The importance of certain DRβ1 alleles in RA supports the concept that T cells are integrally involved in the pathogenesis.

Population-based studies have suggested that only 30 to 50% of the genetic risk for RA is explained by genes located in the HLA region. A functional polymorphism for the gene that encodes intracellular protein tyrosine phosphatase nonreceptor 22 *(PTPN22)* has been reproducibly associated with RA and a number of other autoimmune diseases, including type 1 diabetes, systemic lupus erythematosus, Graves' disease, and Hashimoto's thyroiditis. Genome-wide association studies have identified at least 80 other candidate genes associated with RA, including polymorphisms for signal transducer and activator of transcription (STAT4), tumor necrosis factor receptor–associated factor 1 (TRAF-1), and CD40. To complicate things further, HLA-DRB1 03 is associated with lower titers of anti–citrullinated peptide antigen (ACPA) antibodies but is associated with increased risk for cyclic citrullinated peptide–negative RA.

The shared epitope is present in approximately 25 to 35% of the white population, but the chance of developing RA among individuals who carry this allele is only approximately 1 in 25. Therefore, despite identifying the most important genetic risk factor for RA, this test has little or no clinical utility. The role of epigenetics in RA is currently receiving attention and may provide important insights.

Etiology

Clearly, other factors, in addition to genetics, are active in precipitating or triggering RA. RA appears to require the complex interaction of genetic and environmental factors with the immune system and ultimately in the synovial tissues throughout the body (Fig. 264-1).[3] Sera collected before the development of clinical RA show that immunologic changes predate clinical manifestations by years. Autoantibodies, particularly ACPA antibodies and rheumatoid factor (RF), are present in the sera of many individuals 5 to 10 years before the clinical onset of disease. By following cohorts of people at high risk for RA, investigators are learning much about these early immunologic changes and ultimately it is hoped about the triggers for the disease.

The use of oral contraceptives has been associated with a decrease in the incidence of RA; because the effect appears to be strongest for oral contraceptives that have high estrogen content, it is postulated that estrogen is responsible for this protective effect. Studies that have tried to address the question of postmenopausal estrogen use and its effect on RA have yielded conflicting results.

Smoking has long been associated with a significant increase in the risk for developing RA, but more recently it has been shown that this is true only for ACPA-positive patients and is not associated with ACPA-negative disease. Furthermore, smoking appears to be a risk factor for RA only in those patients who are positive for shared epitope. Purported triggers for RA in addition to smoking have included bacteria *(Mycobacteria, Streptococcus, Mycoplasma, Escherichia coli, Helicobacter pylori)*, viruses (rubella, Epstein-Barr virus, parvovirus), and periodontal disease.

A = alanine; D = aspartic acid; E = glutamic acid; HLA = human leukocyte antigen; K = lysine; MLC = mixed leukocyte cultures; Q = glutamine; R = arginine; * = the same amino acid in that position as for DRB1*0401.

Pathogenesis

The pathogenesis of RA is complex, and there are almost certainly multiple triggering mechanisms, including but not limited to smoking, infection, molecular mimicry, immune complexes, altered T-cell repertoire, and T-cell reactivity. Furthermore, it is likely that the triggers may be different based on the genetic background. As mentioned previously, smoking is a well-known trigger for some individuals but appears to be a risk factor only in those patients who possess the shared epitope.

Rheumatic fever, reactive arthritis (formerly known as *Reiter's syndrome*), and, more recently, Lyme arthritis are examples of arthritic syndromes for which infectious triggers have clearly been demonstrated, but these triggering agents are often difficult or impossible to isolate at the time when the arthritic syndromes occur. Many other examples exist in animal models of arthritis, including syndromes induced by mycobacteria and streptococci. Reactive arthritis (Chapter 265) has clearly been shown to occur when any one of a myriad of different but specific infectious triggers is presented to a specific location in the body (the gastrointestinal or genitourinary tract) of individuals with a certain genetic background, in most cases HLA-B27. Additionally, in this syndrome, the age and gender of the individual and hence the maturity of the immune system may be critical in the development of clinical disease, which occurs primarily between the ages of 15 and 40 years in males. Once unraveled, the pathophysiology of RA is likely to be similarly complex.

Despite the absence of clear evidence linking any infectious agent to RA, it is widely believed that ultimately an important triggering role will be elucidated for infectious or other environmental agents. Once triggers for RA are identified, strategies for prevention can be addressed, but this information may not help individuals with established disease. Possibly infections involving the innate immune system are causative in an early subclinical phase of the rheumatoid disease process, with the agents being absent once clinical disease develops.

The relative roles of the cellular versus the humoral immune system in the initiation and perpetuation of RA are much debated; both appear to be important. Most likely, the mechanisms of initiation of the disease process are different from those that perpetuate the chronic disease. T cells, particularly of the activated T_H1 and T_H17 types, appear to predominate in synovial tissues. These T cells, presumably activated by some as yet unknown antigen presented by macrophages, B cells, or synoviocytes in the context of HLA-DR, secrete cytokines that drive further synovial proliferation. It is believed by many that, although RA may initially be triggered by exogenous antigens, the process, once initiated, may be perpetuated by autoantigens. Macrophage-derived cytokines, particularly interleukin-1 (IL-1) and tumor necrosis factor-α (TNF-α), play central roles in this ongoing inflammatory process. As definitive proof, biologic products directed against these cytokines have shown significant efficacy in the treatment of RA.

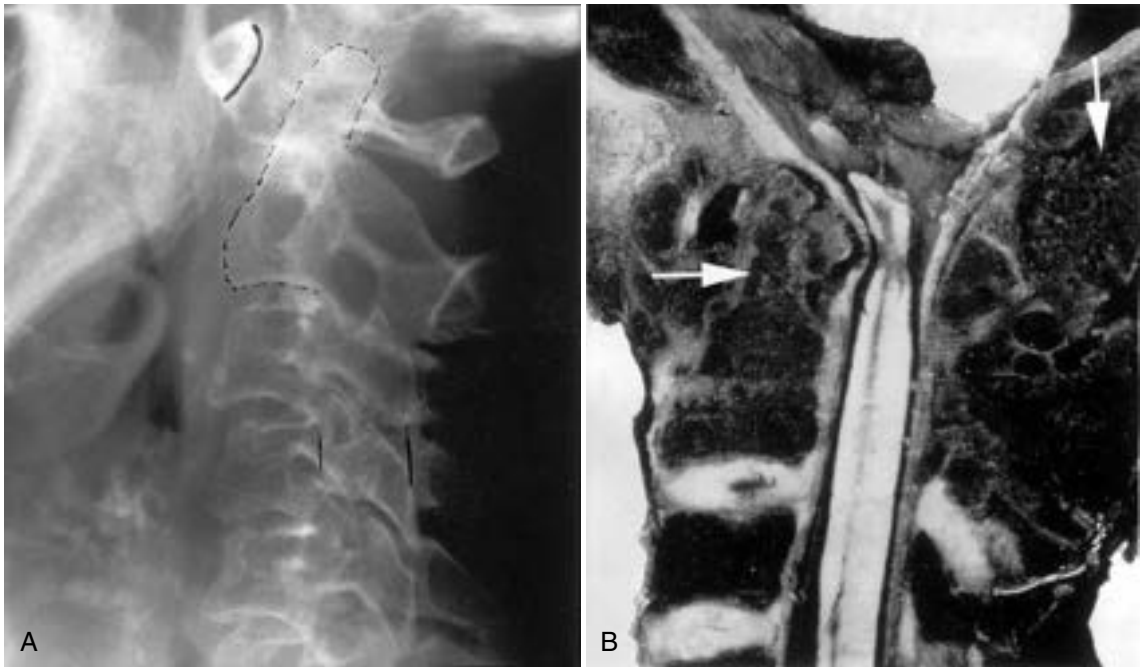
The humoral immune system also plays a role. RF has long been a serologic marker of RA and is well known to correlate with more severe disease, including erosions of bone, and with the presence of extra-articular features. The reason that RF is produced in excess and the exact role that it plays remain elusive. RF production may increase complement activation and result in the release of lysosomal enzymes, kinins, and oxygen free radicals. ACPA antibodies exhibit a high specificity (95 to 99%) for RA, although their sensitivity for RA with currently available assays is only approximately 70%. Even though both RF and ACPA antibodies also correlate with more aggressive erosive disease, this link is strongest for ACPA antibodies.

Pathology

The synovial tissues are the primary target of the autoimmune inflammatory process that is RA; the reason for this remains elusive. However, the generalized inflammation of RA also involves the vascular endothelium and results in significant premature atherosclerosis. Once RA is initiated, the synovial tissues throughout the body become the site of a complex interaction of T cells, B cells, macrophages, and synovial cells (Fig. 264-2). The resultant proliferation of the synovial tissues (synovitis) causes the production of excessive amounts of synovial fluid and the infiltration of pannus into adjacent bone and cartilage. Synovitis results in the destruction of cartilage and marginal bone and in the stretching or rupture of the joint capsule or tendons and ligaments. In patients, these effects are manifested by the deformities (Fig. 264-3 and E-Fig. 264-1) and disabilities that make up the clinical picture of RA.

FIGURE 264-3. Severe advanced rheumatoid arthritis of the hands. There is massive tendon swelling over the dorsal surface of both wrists, severe muscle wasting, ulnar deviation of the metacarpophalangeal joints, and swan-neck deformity of the fingers. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine,* 3rd ed. London: Mosby; 2003.)

B = B lymphocyte; C = complement; GM-CSF = granulocyte-macrophage colony-stimulating factor; IgG, IgM = immunoglobulin G, M; IL = interleukin; M = macrophage; P = plasma cell; PGE_2 = prostaglandin E_2; RF = rheumatoid factor; T = T lymphocyte; TGF-β = transforming growth factor-β; TNF-α = tumor necrosis factor-α.



E-FIGURE 264-1. Subluxation of the cervical spine in patients with rheumatoid arthritis. A, In a lateral radiograph of the cervical spine, the body of C2 and its odontoid process are outlined by the *broken lines* and the posterior aspect of the anterior segment of C1 is indicated by a *solid line*. Normally, a space of only 2 to 3 mm separates C1 from C2. The space between C1 and the odontoid of C2 is markedly increased, indicative of subluxation of C1 and C2. **B,** Lateral view of a pathologic specimen from a patient who died of C1-C2 subluxation. The *horizontal arrow* shows the odontoid process that subluxed posteriorly, severely compressing and almost severing the cord. The *vertical arrow* shows a bone graft that had been put in place posteriorly in an attempt to prevent subluxation. Below the *arrow,* a nonhealing area is present through the bone graft, and inferior to that a wire fixation suture is still in place.

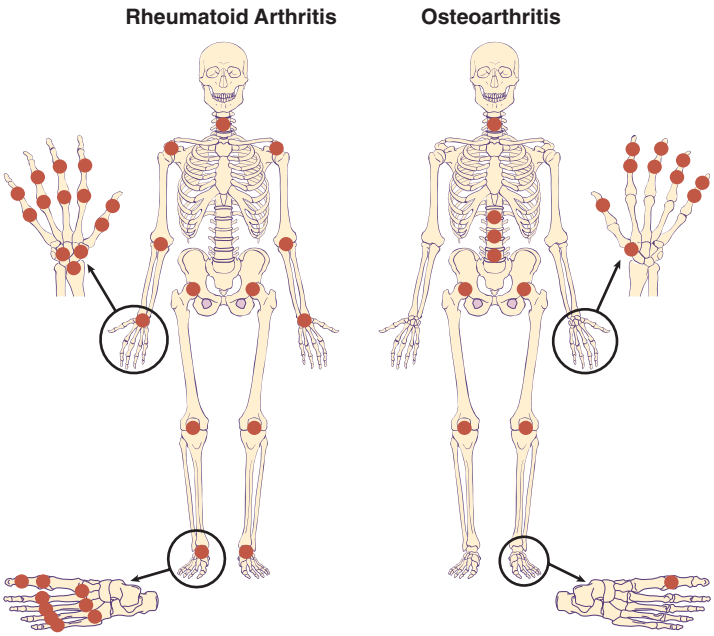


FIGURE 264-4. Distribution of involved joints in the two most common forms of arthritis: rheumatoid arthritis and osteoarthritis. *Shaded circles* are shown over the involved joint areas.

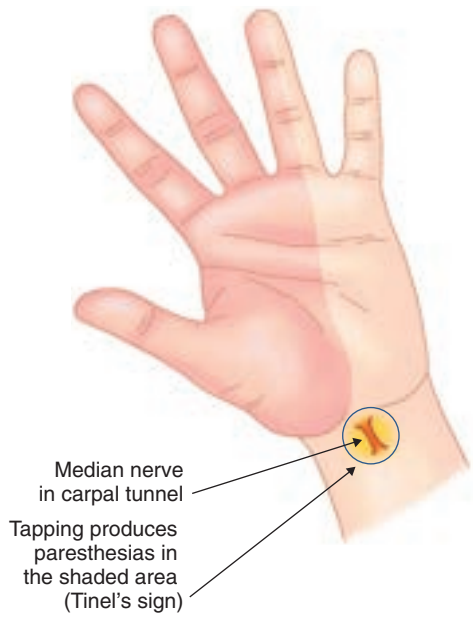

FIGURE 264-5. Carpal tunnel syndrome. Distribution of pain and/or paresthesias (*shaded area*) when the median nerve is compressed by swelling in the wrist (carpal tunnel).

CLINICAL MANIFESTATIONS

Articular Manifestations

RA can affect any of the synovial (diarthrodial) joints (Fig. 264-4). Most commonly, the disease starts in the metacarpophalangeal (MCP), proximal interphalangeal (PIP), and metatarsophalangeal (MTP) joints, followed by the wrists, knees, elbows, ankles, hips, and shoulders, in roughly that order. Early treatment limits the joints involved. Less commonly, and usually later, RA may involve the temporomandibular, cricoarytenoid, and sternoclavicular joints. RA may involve the upper part of the cervical spine, particularly the C1-C2 articulation, but, unlike the spondyloarthropathies (Chapter 265), it does not involve the rest of the spine. RA patients are at an increased risk for osteoporosis (Chapter 243), and this risk should be considered and dealt with early.

Hands

The hands are a major site of involvement, and a significant portion of the disability that RA causes is because of damage and dysfunction of the hands. Typically disease starts with swelling of the PIPs and MCPs. The distal interphalangeal (DIP) joints are almost never involved; significant involvement of the DIP joints should suggest the possibility of a different diagnosis (i.e., osteoarthritis or psoriatic arthritis). Figure 264-3 illustrates the classic ulnar deviation of the MCP joints and swan-neck deformities (hyperextension of the PIP joints) that are commonly seen in late disease. Boutonnière (or buttonhole) deformities also occur as a result of hyperflexion of the PIP joints. If the clinical disease remains active, hand function deteriorates. Sudden loss of function of individual fingers may occur as a result of tendon rupture, which requires the expertise of a hand surgeon to repair.

Feet

Feet, particularly the MTP joints, are involved early in most patients with RA. Radiographic erosions occur at least as early in the feet as in the hands. Subluxation of the toes is common and leads to the dual problem of breakdown of the skin and ulcers on the top of the toes and malalignment of the MTP heads. Painful ambulation develops owing to loss of the cushioning pads that usually protect the heads of the MTP joints.

Wrists

The wrist joints are involved in most patients with RA; radial deviation is the rule, and patients with severe involvement may progress to volar subluxation. Even early in the course of the disease, synovial proliferation in and around the wrists may compress the median nerve, causing carpal tunnel syndrome (Fig. 264-5). Later, this synovial proliferation may invade tendons and lead to rupture of extensor tendons.

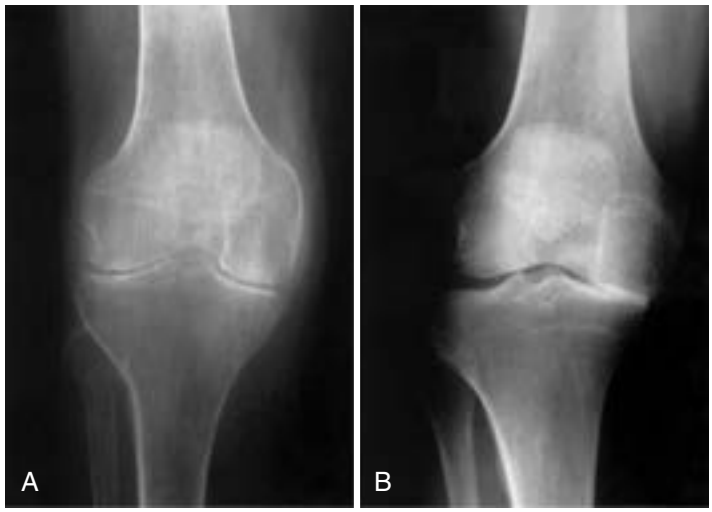

FIGURE 264-6. Radiographs of the knees in the two most common forms of arthritis: rheumatoid arthritis and osteoarthritis. A, Severe involvement in rheumatoid arthritis, with almost complete symmetrical loss of joint space in both the medial and the lateral compartments, but with little subchondral sclerosis or osteophyte formation. **B,** Typical osteoarthritis, with severe, near-total loss of joint space of one compartment and a normal or actually increased joint space of the other compartment. Note also the significant subchondral sclerosis in the involved area, typical of osteoarthritis.

Large Joints

Involvement of knees, ankles, elbows, hips, and shoulders is common. Characteristically, the whole joint surface is involved in a symmetrical fashion. Therefore, RA is symmetrical not only from one side of the body to the other but also within the individual joint. In the case of the knee (Fig. 264-6A), the medial and lateral compartments are both severely narrowed in RA; in contrast, in patients with osteoarthritis (see Fig. 264-6B) typically only one compartment of the knee is involved.

Synovial cysts may occur around any of the joints (large or small), and they occasionally manifest as soft, fluctuant masses that present diagnostic challenges. When the knee produces excess synovial fluid, it may accumulate in the popliteal space (popliteal or Baker's cyst) (E-Fig. 264-2). These cysts can cause problems by pressing on the popliteal nerve, artery, or veins. Baker's cysts may dissect into the tissues of the calf (usually posteriorly), or they may rupture into the upper calf. Dissection may produce only minor symptoms, such as a feeling of fullness; rupture of the cyst with extravasation of the

E-FIGURE 264-2. Arthrogram with a radiocontrast agent injected into the knee. The dye flows into the popliteal space and through a narrow channel into a large synovial cyst (Baker's cyst) that has dissected into the soft tissue of the calf.

inflammatory content produces significant pain and swelling and may be confused with thrombophlebitis, the so-called pseudothrombophlebitis syndrome. Ultrasonography of the popliteal fossa and calf is useful to establish the correct diagnosis and rule out thrombophlebitis, which may be precipitated by popliteal cysts. Treatment of popliteal or any other cyst should be directed at interrupting the inflammatory process through an intra-articular injection of corticosteroid into the associated joint.

Neck

Although most of the axial skeleton is spared in RA, the cervical spine is commonly involved, particularly the C1-C2 articulation. Bony erosions and ligament damage can occur in this area and may lead to subluxation (see E-Fig. 264-1). Most often, subluxation at C1-C2 is minor and without accompanying symptoms; patients and caregivers need only be cautious and avoid actively forcing the neck into positions of flexion. Occasionally, subluxation at C1-C2 is severe and leads to compromise of the cervical cord with symptoms and in some cases death.

Other Joints

Wherever synovial tissue exists, RA can cause problems. The temporomandibular, cricoarytenoid, and sternoclavicular joints are examples of other joints that may be involved in RA. The cricoarytenoid joint is responsible for abduction and adduction of the vocal cords. Involvement of this joint may lead to a feeling of fullness in the throat, to hoarseness, and, rarely, when the cords are essentially fused in a closed position, to a syndrome of acute respiratory distress with or without stridor. In this latter situation, emergent tracheotomy may be life-saving.

Extra-Articular Manifestations

Systemic features of RA such as fatigue, weight loss, and low-grade fevers occur frequently. As with all the other extra-articular features, they are more common in those patients who possess RF or ACPA antibodies or both (Table 264-1) and respond to treatment of the RA.

Skin

Subcutaneous nodules are seen in approximately one fifth of patients with RA, almost exclusively in those who are RF positive. Patients with nodules who are RF negative should be carefully scrutinized for a different diagnosis, such as chronic tophaceous gout. Nodules may occur almost anywhere (e.g., lungs, heart, eye), but most commonly they occur subcutaneously on extensor surfaces (particularly the forearms) (Fig. 264-7), over joints, or over pressure points. Rheumatoid nodules are firm on examination, usually are not tender, have a characteristic histologic picture, and are thought to be initiated by small vessel vasculitis. A syndrome of increased nodulosis, despite good control of the joint disease, has been described with methotrexate therapy (Fig. 264-8).

Small vessel vasculitis,[4] manifested as digital infarcts or leukocytoclastic vasculitis, may occur in RA (Fig. 264-9) and should prompt more aggressive DMARD treatment. A vasculitis of small and medium arteries that is indistinguishable from polyarteritis nodosa also can be seen with RA and requires aggressive systemic therapy. Finally, pyoderma gangrenosum occurs with increased frequency in association with RA.

TABLE 264-1 EXTRA-ARTICULAR MANIFESTATIONS OF RHEUMATOID ARTHRITIS

Skin	Nodules, fragility, vasculitis, pyoderma gangrenosum
Heart	Pericarditis, premature atherosclerosis, vasculitis, valve disease, and valve ring nodules
Lung	Pleural effusions, interstitial lung disease, bronchiolitis obliterans, rheumatoid nodules, vasculitis
Eye	Keratoconjunctivitis sicca, episcleritis, scleritis, scleromalacia perforans, peripheral ulcerative keratopathy
Neurologic	Entrapment neuropathy, cervical myelopathy, mononeuritis multiplex (vasculitis), peripheral neuropathy
Hematopoietic	Anemia, thrombocytosis, lymphadenopathy, Felty's syndrome
Kidney	Amyloidosis, vasculitis
Bone	Osteopenia

Cardiovascular Involvement

Cardiac involvement directly related to RA is uncommon; however, patients with RA have a significantly increased morbidity and mortality from coronary artery disease and congestive heart failure. A meta-analysis of observational studies has shown that the risk for incident cardiovascular disease is increased by 48% in patients with RA compared with that in the general population. The reasons are not clear, but chronic inflammation appears to be the major cause. Some of the medications used to treat RA and a sedentary lifestyle may be additional risk factors for the development of coronary artery disease. Pericardial effusions are common in RA (50% by echocardiography) but usually are asymptomatic. Rarely, long-standing pericardial disease may result in a fibrinous pericarditis, and patients may present clinically with constrictive pericarditis (Chapter 77). A population-based inception cohort of patients with RA in Olmstead County, Minnesota, has shown an increased incidence of venous thromboembolism compared with subjects without RA.

FIGURE 264-7. Rheumatoid nodules. Large rheumatoid nodules are seen in a classic location along the extensor surface of the forearm and in the olecranon bursa.

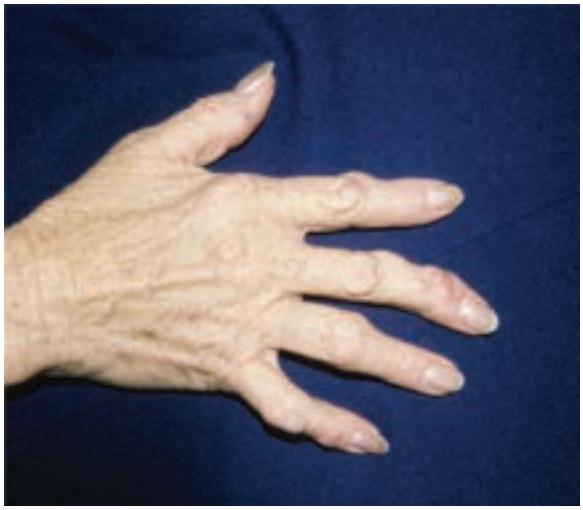

FIGURE 264-8. Rheumatoid nodulosis. In this patient, multiple rheumatoid nodules are present over joints. In some cases, nodules may dominate the clinical picture. Rarely, this may be seen as a side effect of methotrexate therapy.

FIGURE 264-10. Rheumatoid nodules in the lung. Chest radiograph demonstrates discrete rheumatoid nodules in both right and left lower lobes. (Courtesy Dr. Martin Lidsky, Houston, TX.)

Pulmonary Manifestations

Pulmonary manifestations of RA include pleural effusions, rheumatoid nodules, and parenchymal lung disease (Chapters 84 and 92). Pleural effusions occur more commonly in men and are usually small and asymptomatic. Of interest, pleural fluid in RA is characterized by low levels of glucose and low pH and, therefore, may at times be confused with empyema. Rheumatoid nodules may occur in the lung, especially in men (Fig. 264-10); these are usually solid but may calcify, cavitate, or become infected. Rarely, pulmonary nodules rupture and produce a pneumothorax. If patients with RA are exposed to coal or silica dust, diffuse nodular densities may occur (Caplan's syndrome). Differentiating rheumatoid nodules from lung cancer can be problematic, particularly if the lesion is solitary. Therefore, the presence of pulmonary nodules in a patient with RA should precipitate an aggressive diagnostic evaluation.

Diffuse interstitial fibrosis occurs in RA and may progress to a honeycomb appearance on radiography with increasing dyspnea. Rarely, bronchiolitis obliterans can be seen, with or without organizing pneumonia.

Ophthalmologic Manifestations

The most common manifestation of RA in the eye is keratoconjunctivitis sicca (dry eyes) from secondary Sjögren's syndrome (Chapter 268). Patients may have associated xerostomia (dry mouth), parotid gland swelling, or, occasionally, lymphadenopathy. Scleritis also can occur and may be painful, with progression to thinning of the sclera, with deep pigment showing through on physical examination, and may progress to perforation (scleromalacia perforans). Rarely, tendonitis of the superior oblique muscles can result in double vision (Brown's syndrome).

Neurologic Manifestations

Peripheral nerve entrapment syndromes, including carpal tunnel syndrome (median nerve at the wrist), and tarsal tunnel syndrome (anterior tibial nerve at the ankle), are common in RA. Vasculitis can lead to a stocking and glove neuropathy or mononeuritis multiplex, both of which may require aggressive therapy. Subluxations at C1-C2 may produce myelopathy (see E-Fig. 264-1). Rheumatoid nodules in the central nervous system have been described but are rare and usually asymptomatic.

Felty's Syndrome

Felty's syndrome is the triad of RA, splenomegaly, and neutropenia. This complication is seen in patients with severe, RF/ACPA-positive disease and may be accompanied by hepatomegaly, thrombocytopenia, lymphadenopathy, and fevers. Most patients with Felty's syndrome do not require special therapy; instead, treatment should be directed toward their severe RA. If severe neutropenia (Chapter 167) exists (<500 cells/μL) and is accompanied by recurrent bacterial infections or chronic, nonhealing leg ulcers, splenectomy may rarely be indicated.

Some patients with RA, who were previously thought to have Felty's syndrome, have peripheral white blood cell counts dominated by large granular lymphocytes with almost complete absence of neutrophils. This condition is known as the *large granular lymphocyte syndrome* and is thought to be a variant of T-cell leukemia. In the setting of RA, this syndrome has a good prognosis, with the neutropenia often responding dramatically to methotrexate therapy.

TABLE 264-2 CLASSIFICATION CRITERIA FOR RHEUMATOID ARTHRITIS*

Morning stiffness (≥1 hr)
Swelling (soft tissue) of three or more joints
Swelling (soft tissue) of hand joints (PIP, MCP, or wrist)
Symmetrical swelling (soft tissue)
Subcutaneous nodules
Serum rheumatoid factor
Erosions and/or periarticular osteopenia in hand or wrist joints seen on radiograph

*Criteria 1 through 4 must have been continuously present for 6 wk or longer, and criteria 2 through 5 must be observed by a physician. A classification of rheumatoid arthritis requires that 4 of the 7 criteria be fulfilled.
MCP = metacarpophalangeal; PIP = proximal interphalangeal.

Clinical Course

Although the presentation is variable, most patients with RA have insidious onset of pain, stiffness, or swelling in multiple small joints over the course of weeks to months. Systemic features such as fatigue, low-grade fevers, and weight loss also may be present. Less commonly, the onset can be fulminant, occurring almost overnight, or patients may exhibit persistent monoarthritis or oligoarthritis for prolonged periods before manifesting the more typical pattern of joint involvement. Rarely, particularly men, develop extra-articular features of RA before the joint problems appear.

The distribution of involved joints is a critical clue to the underlying diagnosis. The joints that are involved in RA at presentation are variable; typically, the symptoms start in the small joints of the hands (PIP and MCP joints) and in the toes (MTP joints). Importantly, RA usually spares the DIP joints and the small joints of the toes (see Fig. 264-4). Later, RA moves, or some would say "metastasizes," to larger joints: wrists, knees, elbows, ankles, hips, and shoulders (roughly in that order). Although the patient's history of joint symptoms (arthralgia) is important, the diagnosis of RA requires the presence of inflammation (swelling, warmth, or both) on examination of the joints.

Morning stiffness is a hallmark of inflammatory arthritis and is a prominent feature of RA. Patients with RA are characteristically at their worst in the morning or after prolonged periods of rest. This stiffness in and around joints often lasts for hours, and quantifying it is one way to measure improvement. Stiffness is relieved by warmth and activity, and reducing or eliminating joint stiffness is a clear goal of therapy.

DIAGNOSIS

All current treatment paradigms for RA stress the early and aggressive use of DMARDs. Therefore, the importance of accurate early diagnosis of RA cannot be overemphasized. There is no one single finding on physical examination or laboratory testing that is pathognomonic of RA. Instead, the diagnosis of RA requires a collection of historical and physical features, as well as an alert and informed clinician.

Classification

There are currently two classification systems for RA: one designed for clinical use and one designed for studies. Table 264-2 lists the current clinical classification for RA; although designed for classification, these criteria are widely used as a diagnostic aid. The first five criteria are all clinical; in other words, they are established by physical examination or by talking with the patient. Only the last two criteria require laboratory tests or radiographs. The first four criteria must be present for at least 6 weeks before a diagnosis of RA should be made. This caveat is important, because a host of conditions, including many virus-related syndromes, can cause self-limited polyarthritis syndromes that look identical to RA, including at times the presence of RF. Such conditions usually last only 2 to 3 weeks. New classification criteria for RA have been developed for use in clinical trials and, although less specific, improve early classification.[5] These American College of Rheumatology/European League Against Rheumatism criteria do not require 6 weeks of disease and give significant weight to the presence of high-titer RF or ACPA positivity. The presence of ACPA antibodies, even in the first few weeks of an inflammatory arthritis, is strongly suggestive of ongoing aggressive RA.[6] The 2010 American College of Rheumatology/European League Against

TABLE 264-3 DIFFERENTIAL DIAGNOSIS OF RHEUMATOID ARTHRITIS

DISORDER	SUBCUTANEOUS NODULES	RHEUMATOID FACTOR

TABLE 264-4 KEYS TO OPTIMIZE OUTCOME OF TREATMENT OF RHEUMATOID ARTHRITIS

Early, accurate diagnosis
Early DMARD therapy
Strive for remission in all patients
Monitor carefully for treatment toxicities
Consider and treat comorbid conditions*

*Important comorbid conditions include cardiovascular disease, increased susceptibility to infections, and osteoporosis.
DMARD = disease-modifying antirheumatic drug.

Rheumatism collaborative initiative classification criteria for RA are shown in E-Figure 264-3.

Laboratory Findings

Historically, the most characteristic laboratory abnormality in RA is the presence of RF, which is found in approximately 80% of patients. RF was first described in the 1930s and is an antibody that recognizes the Fc portion of immunoglobulin G as its antigen. The presence of RF is strongly associated with more severe articular disease, as well as with essentially all the extra-articular features previously discussed. Importantly, RF is seen in association with many diseases other than RA, particularly in disease processes that provide chronic stimulation of the immune system (Table 264-3). ACPA antibodies, found in approximately 75% of patients with RA, have a high specificity (93 to 98%), are often present before clinical disease is diagnosed, and are associated with aggressive erosive disease. Approximately 15% of RA patients are negative for both RF and ACPA (seronegative). RA is associated with many other autoantibodies, including antinuclear antibodies (~30%) and antineutrophil cytoplasmic antibodies, particularly of the perinuclear type (~30%) (Chapter 257).

Most patients with RA have an anemia of chronic disease, and the degree is proportional to the activity of the disease. Therapy that controls the disease will normalize the hemoglobin levels. Other causes of anemia should also be considered in RA, particularly iron deficiency anemia from gastrointestinal blood loss. Thrombocytosis is common, with platelet counts returning to normal as the inflammation is controlled. Acute phase reactants such as ESR and CRP levels parallel the activity of the disease, and their persistent elevation portends a poor prognosis in terms of both joint destruction and mortality. White blood cell counts may be elevated, normal, or, in the case of Felty's syndrome, profoundly depressed. Eosinophilia is present in some patients with RA.

Synovial fluid in RA is characterized by white blood cell counts in the range of 5000 to 100,000/mm^3, with approximately two thirds of the cells being polymorphonuclear leukocytes. There are no synovial fluid findings that are pathognomonic of RA.

Differential Diagnosis

The accurate diagnosis of RA early in its course, although challenging, is critical if patients are to benefit maximally from therapeutic intervention. Once disease has been present and active for years and the characteristic deformities and radiographic changes have occurred, the diagnosis is all too obvious. Once RA has progressed to that point, deformities may no longer be amenable to medical therapy.

Many diseases can mimic RA (see Table 264-3). Early in the course of disease, self-limited viral syndromes need to be considered, especially hepatitis B and C, parvovirus, rubella (infection or vaccination), and Epstein-Barr virus. At any time, systemic lupus erythematosus, psoriatic arthritis, and reactive arthritis may present differential diagnostic challenges. In the case of these three mimics, a targeted history and examination to elucidate their associated clinical features, such as rashes, oral ulcers, nail changes, dactylitis, urethritis, and renal, pulmonary, gastrointestinal, or ophthalmologic involvement, is critical. Especially in elderly patients with fulminant-onset RA, remitting RF-negative symmetrical synovitis with pitting edema (the so-called RS3PE syndrome) and paraneoplastic syndromes should be considered. Chronic tophaceous gout also may mimic severe nodular RA. Hypothyroidism not only causes many rheumatic manifestations but also occurs commonly in conjunction with RA and, therefore, should be kept in mind.

TREATMENT

General Measures

RA is a lifelong disease process that has no known cure; the diagnosis is made based on clinical criteria, and many different options exist for treatment. These factors magnify the importance of the patient-physician relationship and place a premium on the art rather than the science of medicine. Optimal care for patients with RA requires effective ongoing interactions between primary care physicians and rheumatologists, and, in some cases, physical therapists, occupational therapists, and orthopedic surgeons.[7] Because of the serious nature of the disease, the rapid introduction of new treatments, and the need for expertise in monitoring these therapies, all patients with RA should be evaluated early and followed closely by a rheumatologist.

The goal of therapy is disease remission (Table 264-4) or very low disease activity.[8] When RA is treated early, remission is possible in over 50% of patients. However, remissions require the ongoing use of DMARDs and are not always durable. Essentially all patients with RA should be treated with DMARDs.[9,10] Some combination of nonsteroidal anti-inflammatory drugs (NSAIDs), steroids, and DMARDs is necessary in many patients. In many patients with RA, combinations of different DMARDs (conventional and biologic) are necessary for optimal control. Therapy should be escalated rapidly to ensure maximal suppression of disease while minimizing toxicity and expense. Patients with RA should be educated about their disease and its treatment. Patients should have an opportunity to spend time with physical therapists and occupational therapists to learn about range-of-motion exercises, joint protection, and assistive devices.

Medical Therapy

In the treatment of RA, three types of medical therapies are used: NSAIDs, glucocorticoids, and DMARDs (both conventional and biologic). Initial therapy should always include a DMARD.

Nonsteroidal Anti-inflammatory Drugs

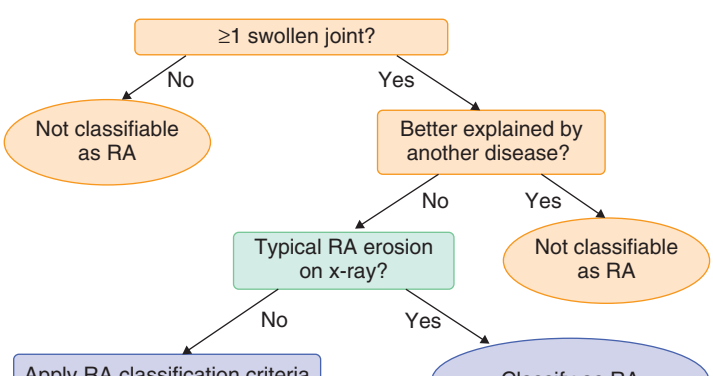
NSAIDs are important for the symptomatic relief they provide to patients with RA; however, they play only a minor role in altering the underlying disease process (Chapter 37). Therefore, NSAIDs should rarely, if ever, be used to treat RA without the concomitant use of DMARDs. Many clinicians waste valuable time switching from one NSAID to another before starting DMARD therapy.

Much has been written about the gastrointestinal toxicity of NSAIDs, and these concerns are particularly relevant to patients with RA, who often have significant risk factors, including age and concomitant steroid use. Therefore, cyclooxygenase-2 (COX2)-selective agents have been a popular choice for patients with RA. The evidence linking these agents to increased cardiovascular toxicity has been particularly troubling for patients with RA, who are already at high risk for myocardial infarction. Therefore, if COX2-selective agents are used, they should be kept at a low dose. Consideration should be given to low-dose aspirin prophylaxis in RA, but this may increase the gastrointestinal toxicity of NSAIDs. The use of concomitant misoprostol or proton pump inhibitors should be considered in all patients with RA who are taking NSAIDs. Additionally, the potential for NSAIDs to decrease renal blood flow and to increase blood pressure should be kept in mind.

Glucocorticoids

Glucocorticoids have had a significant role in the treatment of RA for more than half a century (Chapter 35). Indeed, RA was chosen as the first disease to be treated with this new therapy, partly because it was thought that RA was

ACR / EULAR RA Classification Criteria



Joint Involvement (0-5)	
1 medium-large joint	0
2-10 medium-large joints	1
1-3 small joints	2
4-10 small joints	3
>10 joints (at least one small joint)	5
Serology (0-3)	
Neither RF or ACPA positive	0
At least one test low positive titre	2
At least one test high positive titre	3
Duration of Synovitis (0-1)	
<6 weeks	0
≥6 weeks	1
Acute Phase Reactants (0-1)	
Neither CRP or ESR abnormal	0
Abnormal CRP or abnormal ESR	1

Score ≥ 6 indicates 'Definite RA'

Low +: >1 & ≤3 × ULN
High +: >3 × ULN

Medium/Large joints
Knee, hip, shoulders, elbow and ankle

Small joints
PIPs, MCPs, wrists and MTPs

E-FIGURE 264-3. American College of Rheumatology/European League Against Rheumatism (ACR/EULAR) classification criteria for rheumatoid arthritis (RA). The classification criteria are shown as a flow diagram for initial decision making and also in tabular American College of Rheumatology/European League Against Rheumatism (ACR/EULAR) classification criteria for rheumatoid arthritis (RA). Form to calculate. ACPA = anti-citrullinated protein antibody; CRP = C-reactive protein; ESR = erythrocyte sedimentation rate; MCP = metacarpal phalangeal joint; MTP = metatarsal phalangeal joint; PIP = proximal interphalangeal joint; RA = rheumatoid arthritis; RF = rheumatoid factor; ULN = upper limit of normal. (From Aletaha D, Neogi T, Silman AJ, et al. 2010 Rheumatoid arthritis classification criteria. An American College of Rheumatology/European League Against Rheumatism collaborative initiative. *Arthritis Rheum.* 2010;62:2569-2581.

TABLE 264-5 GUIDELINES FOR USE OF GLUCOCORTICOIDS

Avoid use of glucocorticoids without DMARDs
Prednisone, >10 mg/day, is rarely indicated for articular disease
Taper to the lowest effective dose
Use as "bridge therapy" until DMARD therapy is effective
Remember prophylaxis against osteoporosis

DMARD = disease-modifying antirheumatic drug.

a disease of glucocorticoid deficiency (an issue that remains unresolved). As was the case with the first patient treated in 1948, glucocorticoids are dramatically and rapidly effective in patients with RA. Not only are glucocorticoids useful for symptomatic improvement but they also significantly decrease the radiographic progression of RA. However, the toxicities of long-term therapy are extensive and potentially devastating. Therefore, the optimal use of these drugs requires an understanding of several principles (Table 264-5).

Glucocorticoids remain among the most potent anti-inflammatory treatments available; for this reason, and because of their rapid onset of action, they are ideally suited to help control the inflammation in RA while the much slower-acting DMARDs are starting to work. Prednisone, the most commonly used glucocorticoid, should rarely be used in doses higher than 10 mg/day to treat the stiffness and articular manifestations of RA. At this dose at the start of methotrexate-based treatment, the addition of prednisone reduces erosive joint damage, disease activity, physical disability, and the use of biologic treatment at 2 years. The dose should be slowly tapered to the lowest effective dose, and the concomitant DMARD therapy should be adjusted to make this possible. Glucocorticoids should rarely, if ever, be used to treat RA without concomitant DMARD therapy. The paradigm is to shut off inflammation rapidly with glucocorticoids and then to taper them as the DMARD is taking effect ("bridge therapy"). In all patients receiving glucocorticoids, strong measures should be taken to prevent osteoporosis. Bisphosphonates have been shown to be particularly effective in this regard but are contraindicated in women of childbearing age. Higher doses of glucocorticoids may be necessary to treat extra-articular manifestations, especially vasculitis and scleritis.

Disease-Modifying Antirheumatic Drugs

DMARDs are a group of medications that have the ability to halt the disease process in the synovium and to modify or change the disabling potential of RA. These drugs have the ability to halt or slow the radiographic progression of RA.

Conventional Disease-Modifying Antirheumatic Drugs

Included in this group of medications are methotrexate, sulfasalazine (Azulfidine), gold, antimalarials (hydroxychloroquine [Plaquenil] and others), leflunomide (Arava), azathioprine (Imuran), minocycline, and the newly approved tofacitinib (Xeljanz). It is critically important that clinicians and patients understand that conventional DMARDs take 2 to 6 months to exert their maximal effect, and all require some monitoring (Table 264-6). Therefore, other measures, such as glucocorticoid therapy, may be needed to control the disease while these medications are starting to work.

These DMARDs have been shown to be effective in treating both early and more advanced RA. Until additional research elucidates factors that allow selection of the best initial therapy for each patient, the choice will depend on patient and physician concerns about toxicity and monitoring issues, as well as the activity of disease and presence of comorbid conditions. The critical issue is not which DMARD to start first but rather getting the DMARD therapy started early in the disease process.

Methotrexate

Methotrexate is the preferred initial DMARD of most rheumatologists, in part because patients have a more durable response, and because, with correct monitoring, serious toxicities are rare. Methotrexate is dramatically effective in slowing radiographic progression and is usually given orally in doses ranging from 5 to 30 mg/week as a single dose. This once-per-week administration is worthy of emphasis; prior experience with daily therapy in psoriasis has demonstrated the importance of allowing the liver time to recover between doses. Oral absorption of methotrexate is variable; subcutaneous injections of methotrexate may be effective if oral treatment is not. Side effects of methotrexate include oral ulcers, nausea, hepatotoxicity, bone marrow suppression, and pneumonitis. With the exception of pneumonitis, these toxicities respond to dose adjustments. Monitoring of blood counts and liver blood tests (albumin and aspartate aminotransaminase [SGOT] or alanine aminotransferase [SGPT]) should be done every 4 to 8 weeks initially and, when stable, every 3 months thereafter, with adjustments in the dose of methotrexate as needed. Renal function is critical for clearance of methotrexate; previously stable patients may experience severe toxicities if renal function deteriorates. Pneumonitis, although rare, is less predictable and can be fatal, particularly if the methotrexate is not stopped or is restarted. Folic acid, 1 to 4 mg/day, can significantly decrease most methotrexate toxicities without interfering with efficacy. If methotrexate alone does not sufficiently control

TABLE 264-6 CAVEATS FOR MONITORING DISEASE-MODIFYING ANTIRHEUMATIC DRUG THERAPIES*

MEDICATION	CAVEATS
Prednisone	Use as bridge to effective DMARD therapy. Prophylaxis for osteoporosis? (see Table 264-5)
Hydroxychloroquine	Keep dosage lower than 6.5 mg/kg/day. Yearly eye checkup by ophthalmologist
Sulfasalazine	CBC for neutropenia, initially every month, then every 6 mo
Methotrexate	CBC and SGOT/SGPT every 8-12 wk when dose is stable. Many toxicities respond to folic acid or small dose reduction. If pneumonitis, stop and do not restart. Decreasing renal function may precipitate toxicities. Absolute contraindication in pregnancy
Leflunomide	CBC and SGOT/SGPT every 4-8 wk; long half-life may require cholestyramine washout; absolute contraindication in pregnancy
TNF inhibitors	If fevers or infectious symptoms of any kind, stop until symptoms resolve; aggressively work up and treat possible infections. May precipitate congestive heart failure, demyelinating syndromes, or lupus-like syndromes

*Patients receiving DMARDs, both conventional and biologic, should be monitored by a rheumatologist.
CBC = compete blood count; DMARD = disease-modifying antirheumatic drug; SGOT = serum glutamate oxaloacetate transaminase (aspartate aminotransferase); SGPT = serum glutamate pyruvate transaminase (alanine aminotransferase); TNF = tumor necrosis factor.

disease, it is combined with other DMARDs. Methotrexate in combination with virtually any of the other DMARDs (conventional or biologic) has been shown to be more effective than either drug alone.

Leflunomide

Leflunomide, a pyrimidine antagonist, has a very long half-life and is most commonly started at 10 to 20 mg/day orally. Diarrhea is the most common toxicity and responds to dose reduction, and doses of leflunomide of 10 to 20 mg three to five times per week are frequently used. Also, because of the long half-life and teratogenic potential of leflunomide, women wishing to become pregnant who have previously received leflunomide, even if therapy was stopped years ago, should have blood levels drawn. If toxicity occurs or if pregnancy is being considered, leflunomide can be rapidly eliminated from the body by treatment with cholestyramine. Laboratory monitoring for hematologic and hepatic toxicity should be done during treatment with leflunomide, as recommended for methotrexate.

Antimalarial Drugs

The antimalarial drugs hydroxychloroquine (Plaquenil) and chloroquine are frequently used for the treatment of RA. They have the least toxicity of any of the DMARDs and do not require monitoring of blood tests. Yearly monitoring by an ophthalmologist after 5 years of therapy is recommended to detect any signs of retinal toxicity (rare). Hydroxychloroquine is the most commonly used preparation and is given orally at 200 to 400 mg/day. These drugs are frequently used in combination with other DMARDs, particularly methotrexate. Hydroxychloroquine decreases cholesterol levels and has recently been shown to decrease the incidence of diabetes in patients with RA.

Sulfasalazine

Sulfasalazine is an effective treatment when given in doses of 1 to 3 g/day. Monitoring of blood counts, particularly white blood cell counts, in the first 6 months is recommended. Sulfasalazine and hydroxychloroquine are often combined with methotrexate, a regimen referred to as triple therapy.

Minocycline

Minocycline 100 mg twice daily has been shown to be an effective treatment for RA, particularly when used in early, RF-positive disease. Chronic therapy (>2 years) with minocycline may lead to cutaneous hyperpigmentation. Minocycline has been associated with drug-induced lupus.

Gold

Gold, the oldest DMARD, is effective but cumbersome and is currently rarely used.

Tofacitinib

Tofacitinib (Xeljanz) has been recently approved for the treatment of RA in the United States. It is the first Jak kinase inhibitor to be approved for RA. It is given orally at a dose of 5 mg twice daily, and complete blood count and liver function tests should be monitored. Additional toxicity concerns include infections, including tuberculosis, and malignancies. Tofactinib has been

shown to be effective as initial DMARD therapy,[A] when combined with methotrexate in patients who have had incomplete responses to methotrexate, and in patients who have failed TNF inhibitors. Tofacitinib has not yet been approved in Europe.

Biologic Disease-Modifying Antirheumatic Drugs

Recent research has continued to elucidate the central role that cytokines, most notably TNF-α, IL-1 and IL-6, play in the pathophysiology of RA (Chapter 36). This led directly to the development and clinical use of biologic agents directed against TNF-α[11] (etanercept [Enbrel], infliximab [Remicade], adalimumab [Humira], golimumab [Simponi], and certolizumab [Cimzia]), IL-1 (anakinra [Kineret]), and IL-6 (tocilizumab [Actemra). Additionally, monoclonal antibodies that deplete B cells (anti-CD20, rituximab [Rituxan]) and that block the second signal for T cell activation (abatacept [Orencia]) are effective agents in the treatment of RA. All patients with RA receiving biologic therapies should be monitored by a rheumatologist, and their physicians should be aware of the risk for infections that are often atypical.[12] All the biologics, when combined with methotrexate, have been shown to decrease disease activity and slow radiographic progression in patients with RA with active disease despite methotrexate.[A] Early treatment with abatacept plus methotrexate was shown to result in greater sustainable clinical, functional, and radiographic benefits than methotrexate alone, with acceptable safety and tolerability, in early erosive RA. Currently, biologic agents should not be used in combination with each other because all studies to date have shown a significant increase in infections. See Chapter 36 for further details on the use of biologic agents in the treatment of RA.

The Order of Therapy in Rheumatoid Arthritis

Several randomized double-blind trials have elucidated the order of therapy in RA. The Treatment of Early Aggressive Rheumatoid Arthritis (TEAR) trial nicely showed that initial therapy with methotrexate in patients with poor-prognosis RA was not inferior at 2 years to initial combinations of either conventional DMARDs or the combination of methotrexate and etanercept.[A] The Rheumatoid Arthritis: Comparison of Active Therapies (RACAT) trial has also shown that in those patients who are not controlled on methotrexate alone, the strategy of initially adding sulfasalazine and hydroxychloroquine to methotrexate (triple therapy) was not inferior to the addition of etanercept to methotrexate.[A] Therefore, because of the huge economic advantages, the typical RA patient should be started on methotrexate monotherapy, and, if not controlled after 3 months on maximum methotrexate, advanced to triple therapy. If the patient does not achieve adequate control after 3 to 6 months on triple therapy, either a TNF inhibitor or abatacept should be added to methotrexate.

Treatment of Underlying Conditions

Optimal care of patients with RA requires recognition of the associated comorbid conditions, including an increased risk for cardiovascular death, osteoporosis, infections (especially pneumonia), and certain cancers.

Cardiovascular Disease

Increasingly, cardiovascular disease is being recognized as the cause of much of the excess mortality in RA. Various factors contribute to this mortality, including sedentary lifestyle and glucocorticoid therapy. However, a strong association between chronic inflammation and cardiovascular disease has been identified, and it is likely that this may be the most significant factor. Therapies that control RA earlier and better can be expected to decrease cardiovascular morbidity and mortality. Both methotrexate and TNF inhibitors have been shown to decrease cardiovascular mortality in RA. Clinicians should consider RA a risk factor for cardiovascular disease and should aggressively address other cardiovascular risk factors (Chapter 52) in their patients with RA.[13]

Other Associated Diseases

Osteoporosis is common in patients with RA, and early treatment results in long-term dividends. Patients with RA are at an increased risk for infections, and some forms of treatment further increase this risk. Patients should be cautioned to seek medical attention early for even minor symptoms suggestive of infection, especially if receiving biologic therapy. All patients with RA should receive a pneumococcal vaccine at appropriate intervals and yearly influenza vaccinations. Finally, patients with RA have an increased risk for lymphoma. Occasionally, B-cell lymphomas are associated with immunosuppression and regress after immunosuppression is discontinued. Patients with RA have significantly decreased risk of developing colon cancer. This is thought to be secondary to chronic inhibition of COX by NSAIDs.

PROGNOSIS

RA is not a benign disease and is not limited to the joints. Once established, RA is a lifelong progressive disease that produces significant morbidity in most patients and premature mortality in many. Long-term studies have found that 50% of patients with RA have had to stop working after 10 years (~10 times the average rate). Patients who are RF or ACPA positive and those who are positive for the shared epitope have a worse prognosis, with more erosions and more extra-articular disease (see Table 264-1). Once deformities are found on examination or erosions on radiography, the damage is largely irreversible. It has been clearly shown that erosions occur in most patients in the first 1 to 2 years and that the rate of radiographic damage can be affected by early therapy. A recent cohort study has shown that the aggressive use of disease-modifying agents and the introduction of biologic agents have been associated with substantial reductions in disability. Therefore, early DMARD therapy is critical. Although limited long-term data are available, the current information strongly suggests that patients have the opportunity to benefit greatly if the newer principles of therapy are practiced.

FUTURE DIRECTIONS

Significant advances in the effective treatment of RA have come from an understanding of the cytokine imbalance that accompanies this disease. Much research is focused on the further development of biologic products to modulate this balance. There remains a critical need for a cytokine thermostat that would allow titration of the desired cytokine balance to control disease without altering critical immune functions.

Even with existing therapies, there are many different effective options for patients with RA. The challenge for the clinician is to pick the right option for each patient. Few data are currently available to aid in this choice, and the establishment of parameters, genetic or otherwise, that would allow selection of the best initial option for each patient would be a major breakthrough. Finally, elucidation of the trigger or triggers for RA may allow the development of strategies to prevent the onset of clinical disease.

REVIEW QUESTIONS

1. A 32-year-old woman presents with 3 weeks of symmetrical swelling and stiffness in her PIPs and MCPs. The most helpful laboratory test result in establishing a diagnosis of RA in this patient would be:

A. ESR of 65 mm/hour.
B. RF of 120 IU (normal <40).
C. Anti-CCP of 87 (normal <20).
D. Positive ANA.

Answer: C The presence of anti-CCP antibodies in a patient with an inflammatory arthritis is 99% specific for the diagnosis of RA even when it is only of short duration as in this patient with only 3 weeks of disease. This is critically important because it allows very early institution of DMARD therapy. The presence of a positive ANA, an elevated RF, or elevated ESR would not be particularly helpful—all are nonspecific.

2. A 40-year-old attorney is diagnosed with RF- and CCP-positive rheumatoid arthritis. His mortality is increased, and he is most likely to die from which of the following?

A. Lymphoma
B. Pulmonary fibrosis from RA
C. Infections related to RA and its therapies
D. Coronary artery disease

Answer: D Heart disease is by far the biggest killer of patients with RA. Rheumatologists should do everything possible to get disease activity under control, and PCPs should do everything possible to control other risk factors, including ideal management of BP and cholesterol. RA patients have at least a two-fold increased risk for lymphoma, have increased risk for infections (particularly when treated with steroids or biologic agents), and can get pulmonary fibrosis, but these all have a small impact compared to that of heart disease.

3. A 28-year-old accountant with RA is considering another pregnancy. Reasons for concerns for conception and the health of her fetus during the first trimester include which of the following?

A. She is currently on 5 mg of prednisone.
B. She is currently taking sulfasalazine.
C. She has a history of treatment with leflunomide.
D. She is taking Naprosyn 500 mg.

Answer: C Leflunomide is a significant teratogen and has a half-life that is extremely prolonged. Any potential mother who has ever taken it needs blood levels drawn before conception. Leflunomide can be rapidly eliminated from the body by treatment with cholestyramine. Prednisone is considered safe in pregnancy; significant data suggest that sulfasalazine is well tolerated by both mother and child and NSAIDs are safe until the last trimester.

4. A 52-year-old woman with RA treated with methotrexate and adalimumab presents to the ER with fevers, cough, and increasing shortness of breath. A chest x-ray film shows diffuse patchy infiltrates. You would:

A. Admit, stop her adalimumab, and give her broad-spectrum antibiotics.
B. Admit, stop both her adalimumab and methotrexate, and aggressively pursue workup for infectious and inflammatory etiologies.
C. Treat her for community-acquired pneumonia.
D. Admit, stop adalimumab, and aggressively pursue workup for infectious etiology.

Answer: B All TNF inhibitors have a black box warning for fatal opportunistic infections. Tuberculosis, histoplasmosis, coccidioidomycosis, pneumocystis, legionellosis, and others have all been reported. The key to patient survival is aggressive diagnosis so appropriate treatment can be started rapidly. Methotrexate can be associated with unusual infections rarely, but the biggest concern here is that the patient may have methotrexate pneumonitis. This can be fatal if the methotrexate is not stopped. It usually presents with low-grade fevers, nonproductive cough, increasing dyspnea, and patchy infiltrates on chest x-ray films. Treatment of methotrexate pneumonitis after stopping methotrexate is usually supportive, but occasionally high-dose steroids may be indicated.

5. A 55-year-old carpenter is newly diagnosed with RA. His medical history includes type II diabetes for 15 years. CBC shows low-grade anemia with normal red cell indices, Hgb A_{1c} is 7, creatinine is 2.1, and urinalysis shows 3+ proteinuria. Laboratory studies are otherwise unremarkable. Appropriate initial DMARD therapy would be:

A. Cyclosporine.
B. Hydroxychloroquine.
C. Methotrexate.
D. Sulfasalazine.

Answer: B Although methotrexate at the doses used to treat RA rarely affects the kidney, well-functioning kidneys are important for the clearance of methotrexate. Methotrexate, if used, should be used with extreme caution and close monitoring in this situation. Cyclosporine, although effective in some cases of RA, also has renal toxicity and is not a good choice. Hydroxychloroquine is the best choice here—in addition to being effective against RA, it has been shown to lower blood sugar, particularly in type II diabetes. Additionally, patients with RA who are on hydroxychloroquine have a 60% reduction in their risk for incident diabetes. Finally, sulfasalazine would be a possible choice but not as good as hydroxychloroquine.

THE SPONDYLOARTHROPATHIES

ROBERT D. INMAN

COMMON FEATURES OF SPONDYLOARTHRITIS

DEFINITION

Spondyloarthritis (SpA) encompasses a group of clinical syndromes that are linked in terms of disease manifestations and genetic susceptibility. The

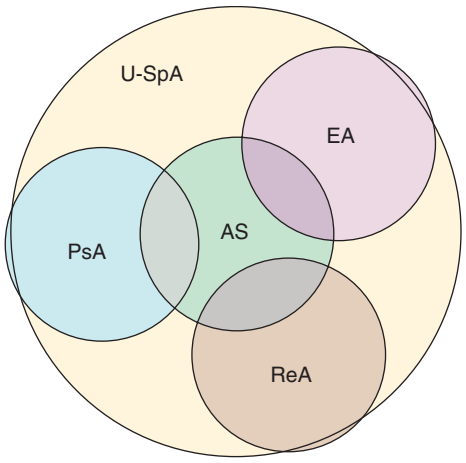

FIGURE 265-1. Schematic relationships among the different spondyloarthritis (SpA) subsets. Ankylosing spondylitis (AS), considered the classic SpA, encompasses the essential features of this family of diseases. AS may overlap with psoriatic arthritis (PsA), enteropathic arthritis (EA), or reactive arthritis (ReA). Many patients have clinical features of SpA that do not meet the diagnostic criteria for any of the four defined subsets. Such cases are termed *undifferentiated SpA* (U-SpA).

TABLE 265-1 ASAS CLASSIFICATION CRITERIA FOR AXIAL SPONDYLOARTHRITIS

Sacroiliitis* *Plus* ≥SpA feature†	OR	HLA-B27 *Plus* ≥2 other SpA features†
*Sacroiliitis (x-rays or MRI)		†SpA features:
• Definite radiographic sacroiliitis according to modified New York criteria (see Table 265-3) *Or* • Active (acute) inflammation on MRI highly suggestive of sacroiliitis associated with SpA		• IBP • Arthritis • Enthesitis (heel) • Dactylitis • Psoriasis • Crohn's disease/ulcerative colitis • Good response to NSAIDs • Family history of SpA • Elevated CRP • HLA-827

ASAS = Assessment in Spondyloarthritis International Society; CRP = C-reactive protein; IBP = inflammatory back pain; MRI = magnetic resonance imaging; NSAIDs = nonsteroidal anti-inflammatory drugs; SpA = spondyloarthritis.

clinical subsets most commonly recognized are ankylosing spondylitis (AS), reactive arthritis (ReA), psoriatic arthritis (PsA), and enteropathic arthritis (EA) (Fig. 265-1). In addition, a sizable number of patients do not fit into one of these distinct diagnostic categories but share some of the common clinical features described in this chapter. This syndrome is termed *undifferentiated spondyloarthritis* (USpA); it may evolve over time into a classic pattern such as AS, or it may retain an undifferentiated pattern in long-term follow-up studies.

PATHOBIOLOGY

Family studies involving multiple individuals with SpA have emphasized some of the common features among the four distinct subsets. The impression from such studies is that there is a shared common path of immunogenetic susceptibility, with further genetic and environmental influences that lead to characteristic clinical subsets. Thus, EA may occur in one such family, but in another family the disease may be PsA. In this sense, the subsets of SpA seem to "breed true." It should be recognized, however, that some distinct clinical features can be very similar in their manifestations (e.g., guttate psoriasis and keratoderma blennorrhagicum), making simple discrimination difficult.

CLINICAL MANIFESTATIONS

There are several common features in the clinical subsets of SpA that serve to both link them with and distinguish them from the other major contributor to chronic polyarthritis—rheumatoid arthritis (RA) (Chapter 264). SpA has a strong predilection for the spine, in particular the sacroiliac joints. There is a shared tendency for new bone formation at sites of chronic inflammation, with joint ankylosis as a consequence. When peripheral arthritis occurs, it is commonly in the lower extremity and asymmetrical. There is a predilection for involvement at sites of tendon insertion into bone (entheses), so enthesitis is one of the most specific clinical manifestations of SpA. Theories postulating the basis for this target organ involvement have invoked biomechanical factors, innervation, local vascularity, and bone marrow–derived inflammatory mediators, but the precise mechanism remains incompletely defined. Whatever the reason, inflammation in the enthesis and contiguous subchondral bone is a characteristic feature of this form of arthritis, and the appearance of this inflammation on magnetic resonance imaging (MRI) is distinct enough to be increasingly used for diagnostic purposes, particularly when the x-rays are not diagnostic.

A predilection for ocular inflammation, particularly acute anterior uveitis, is a common feature of SpA. Indeed, some investigators consider anterior uveitis to be a feature of SpA in its own right because it may occur in the same susceptible population of patients even in the absence of joint involvement, and it may have a unique genetic predisposition. Finally, all SpA subsets have an association with the class I human leukocyte antigen (HLA) allele B27, with the strength of the association varying somewhat among them. Newer genetic risk associations such as *IL23R*, which are shared between SpA, psoriatic arthritis, and inflammatory bowel disease (IBD), further link the clinical subsets of SpA.

DIAGNOSIS

Increasingly, diagnostic criteria (Table 265-1 [Assessment in Spondyloarthritis International Society criteria]) are emphasizing the common clinical features—namely, inflammatory spinal pain or asymmetrical lower extremity synovitis. Several distinct features differentiate SpA from RA, the other main contributor to the differential diagnosis of chronic polyarthritis (Table 265-2). These features include sex predilection, HLA association, pattern of joint involvement, and presence of rheumatoid factor, which becomes the serologic distinction between seropositive disease (RA) and seronegative disease (SpA).

At the level of joint histopathology, sites of chronic inflammation in RA are associated with erosions, but in SpA such sites are associated with new bone formation. This distinction suggests a fundamental difference in the cytokine profile in the microenvironment of the joint, but this issue has not been resolved, and the mediators of neo-ossification await identification. Dysregulation of the wnt/β-catenin pathway may play a key role in the ankylosing process. Synovial histopathology in SpA is characterized by abundant neutrophils, macrophages, and hypervascularity, whereas in RA the prominent features are lymphoid aggregates, dendritic cells, lining cell hyperplasia, and citrullinated proteins. These differences suggest that SpA reflects a fundamental alteration in innate immunity, whereas RA reflects dysregulation of adaptive immunity.

TREATMENT

General Measures

SpA necessitates a global approach to management in which education of patients is the cornerstone.[1-3] Because the typical onset is during young adulthood, these patients may experience significant frustration or depression if their acute arthritis evolves into a chronic disease that significantly impairs their functional capabilities and quality of life. A clinician managing patients with SpA should be aware that these psychosocial aspects are an important part of the burden of illness. Similarly, there may be important implications for the workplace, particularly if a job demands significant bending or twisting. It is important to include the mechanical demands of the workplace in the global assessment of patients with SpA.

Exercise is an important part of the treatment plan for patients with AS.[4] Generally, high-impact sports should be avoided, whereas swimming is an ideal exercise. Stretching to maintain mobility and maintenance of posture should be emphasized, and an experienced physiotherapist can greatly assist in instructing patients in daily exercises. Long car trips and air travel should include periodic stretching. Sleep position should emphasize a straight back position rather than one curled on the side. Deep breathing exercises and avoidance of smoking should be stressed.

One key area of concern for patients is prognosis, because SpAs, particularly ReA, often occur in young, active individuals for whom athletic activity is a

TABLE 265-2 DIFFERENTIAL DIAGNOSIS OF CHRONIC POLYARTHRITIS

FEATURE	RHEUMATOID ARTHRITIS	ANKYLOSING SPONDYLITIS	ENTEROPATHIC ARTHRITIS	PSORIATIC ARTHRITIS	REACTIVE ARTHRITIS
Male-female ratio	1 : 3	3 : 1	1 : 1	1 : 1	10 : 1

Rheumatoid factor	>80%	0	0	0	0

HLA = human leukocyte antigen.

priority. There is general recognition that ReA has a greater propensity for chronicity than was previously appreciated, and this should temper an overly optimistic projection of the disease's natural history. At the 5-year follow-up of a cohort of patients with *Salmonella*-induced ReA, two thirds continued to have subjective complaints, and one third demonstrated objective changes in their joints. The variability in prognosis for the large group of patients falling into the USpA group is perplexing. At present, there is a lack of reliable predictors of progression in patients with this heterogeneous cluster of articular and extra-articular features.

Medical Therapy

Nonsteroidal Anti-inflammatory Drugs

In general, joint inflammation in SpA improves significantly after the introduction of nonsteroidal anti-inflammatory drugs (NSAIDs). Indomethacin and diclofenac (up to 150 mg/day in divided doses) or naproxen (up to 1000 mg/day in divided doses) are generally well tolerated in this population. These agents have to be used with caution in EA because of concern about exacerbating possible underlying IBD. In the case of AS, the goal with anti-inflammatory treatment is to achieve sufficient relief of pain and stiffness to allow an active, sustained program of exercise and physical activity that maintains posture and improves quality of life. Some studies have suggested that NSAIDs have disease-modifying capability, but this effect appears to be restricted to those patients with elevated C-reactive protein (CRP) or erythrocyte sedimentation rate (ESR).

Corticosteroids

The response to the intra-articular injection of steroids in the peripheral joints of patients with SpA is often neither as dramatic nor as sustained as in those with RA. Corticosteroid injection into the sacroiliac joints is usually performed under imaging guidance (fluoroscopy or computed tomography [CT]). One study found that such injections resulted in a good response in 79% of patients and that the improvement could persist for many months. Systemic corticosteroids (either orally or via an intravenous bolus protocol) have been used for severe symptomatic flares, but there are few controlled trials to validate their effectiveness. The goal should be prompt tapering of the dose when symptomatic control is achieved. The recognition that osteoporosis (Chapter 243) is a significant problem in AS provides further impetus to use corticosteroids sparingly. Topical steroids are usually effective for the treatment of the mucous membrane and skin manifestations of ReA. For uveitis, topical corticosteroid eye drops are an integral component of management, and treatment should be monitored jointly with an ophthalmologist.

Sulfasalazine

Randomized placebo-controlled trials have provided some support for the use of sulfasalazine (SSZ), particularly in PsA. Three 36-week randomized double-blind multicenter studies of patients with AS, PsA, and ReA, respectively, were undertaken to compare SSZ (2 g/day) with placebo in each case. An analysis of these studies stratified the patients into those having axial disease and those having peripheral disease. In patients with only axial disease, response criteria were met equally in the SSZ group and the placebo group. In patients with peripheral arthritis, significantly superior responses were seen with SSZ: 59% of the SSZ group and 43% of the placebo group responded ($P < .0005$). These findings are useful in guiding the selection of patients for SSZ treatment. A recent study comparing SSZ with etanercept in AS demonstrated the superiority of tumor necrosis factor (TNF) inhibitor therapy with respect to symptomatic improvement as well as MRI evidence of inflammation.

Methotrexate

Concurrent with the widespread use of methotrexate (MTX) in patients with RA, there has been increasing use of MTX in patients with SpA, but responses have been good only for peripheral joint disease. There is no evidence that MTX is effective for the spinal inflammation characteristic of AS, nor is there evidence that MTX changes the course of axial involvement in AS. Experience with long-term MTX therapy in patients with PsA has increased, although there has been little in the way of randomized controlled trials. Long-term follow-up may be required to resolve whether MTX has a joint-sparing effect in PsA.

Disease-Modifying Agents

There have been additional therapeutic approaches to the control of PsA. The clinical impression of leflunomide therapy has been positive, in general, although there are few formal trials to validate this impression. The mechanism of action of disease-modifying antirheumatic drugs (DMARDs) in SpA has not been resolved. The response of SpA patients to SSZ may be attributable to the antibiotic moiety of this compound (sulfapyridine) or to the anti-inflammatory moiety (5-aminosalicylic acid).

Antibiotic Therapy

The current concept of the pathogenesis of ReA postulates that a bacterial infection, usually gastrointestinal (GI) or genitourinary (GU), is the triggering event in an immunogenetically susceptible host. For the other subsets of SpA, there is less compelling evidence that infection plays a causal role. It is sound clinical practice to treat any culture-proven chlamydial urethritis in conjunction with treatment of the sexual partner. For this indication, a single 1-g dose of azithromycin is as effective as doxycycline 100 mg twice a day for 7 days. The role of antibiotics in the management of ReA has been controversial. A meta-analysis concluded that there is little evidence for efficacy of antibiotic therapy in ReA. But a recent report compared rifampin/azithromycin, rifampin/doxycycline, and placebo for chronic *Chlamydia*-induced ReA and observed that tender and swollen joint counts responded more significantly to the combination antibiotics than to placebo. The precise role of antibiotics in chronic post-*Chlamydia* ReA has not yet been determined.

Anti–Tumor Necrosis Factor Therapy

The pathogenic role of immunomodulatory cytokines in the pathogenesis of SpA has remained unresolved, but the advent of biologic agents has changed the landscape for SpA.[5,6] Biologic agents such as monoclonal antibodies to TNF-α (infliximab, adalimumab, golimumab) or the soluble TNF receptor (etanercept) have been used in the treatment of SpA. So far, these four anti-TNF agents have been comparably effective in trials of AS and PsA. These studies have generally reported a prompt response in clinical outcome measures and in laboratory indicators of inflammation, and MRI evaluations have shown improvement in local inflammation in the sacroiliac joints and spine. The anti-TNF treatments have been well tolerated, with no significant incidence of serious adverse events, but patients appear to relapse when treatment is discontinued. Experience with longer-term treatment with anti-TNF agents has been encouraging with regard to the persistence of the therapeutic effect and the infrequency of late adverse events. These biologic agents have been shown to retard radiographic progression in PsA, and a recent report suggests a similar effect in AS.[7] Additional data using MRI may be helpful in assessing the capacity for these agents to alter the long-term outcomes of AS structurally as well as functionally.

GENETIC SUSCEPTIBILITY

Recent genome-wide association studies in AS have identified additional genetic markers of susceptibility for AS. Polymorphisms in the *IL-23R* gene are associated with AS, and these particular variants are the same as those seen in IBD and psoriasis.[8] Thus the clinical convergence of these different diseases, well known to clinicians, now appears to have a common genetic

The major histocompatibility complex (MHC), on the short arm of chromosome 6 in humans, is one of the most polymorphic regions of the human genome. This is particularly so for the B locus, which constitutes part of the class I MHC genes in this complex. More than 200 different alleles have been detected at this locus, of which B27 is just one. As with all HLA alleles, there is codominant expression of B locus genes, such that most individuals who are B27 positive are heterozygous for the B locus. There appears to be little clinical or prognostic significance associated with the less common homozygous B27 state. The conventional role of class I HLAs is to present a processed peptide to the T-cell receptor of a specific $CD8^+$ cytotoxic T cell, thereby initiating an immune response against the pathogen from which that peptide was derived by intracellular proteolysis and processing. This function gives the HLAs a critical role in host defense against pathogens, and the heterogeneity of cellular immune responses is alleged to be an advantage for a species (such as humans) with extensive polymorphism in a region of the genome. This idea has led to the concept that infectious diseases have driven allelic polymorphisms in the MHC. Such a hypothesis postulates a selective advantage in the extensive peptide-binding capabilities conferred by different alleles of the B locus, as appears to be the case for HLA-B27's association with a more robust immune response to hepatitis C virus infection.

element. Polymorphisms in the endoplasmic reticulum aminopeptidase (ERAP) gene constitute the strongest genetic risk factor for AS after HLA-B27,[9] and the association with AS is restricted to HLA-B27$^+$ AS patients, suggesting a gene-gene interaction. ERAP plays a key role in trimming peptides in the endoplasmic reticulum before loading these peptide complexes onto a nascent class I MHC molecule. This finding continues to attribute a central role to MHC class I peptide presentation in the pathogenesis of AS. With larger numbers studied, the list of candidate genes conferring susceptibility to AS has now extended to more than 20, but the odds ratio for any one gene is modest, with the notable exception of HLA-B27.

It is believed that the prevalence of AS in various parts of the world closely parallels the prevalence of B27 in that population, and in general, this pattern is valid. What introduces complexity into this concept is the recognition that there are more than 30 subtypes of B27. HLA-B2705 is regarded as the primordial subtype, with variability developing over time on the basis of alterations in genomic DNA. Some subtypes, notably B2706 and B2709, do not seem to confer increased susceptibility to the development of AS. This observation has led to a search for "arthritogenic peptides" that are presented by the disease-associated subtypes such as B2705 and B2704, but not by the non–disease-associated subtypes. To date, no simple peptide-susceptibility relationship has been demonstrated, but this is an important clue to the pathogenic role of B27, and studies are ongoing to explore this relationship. Recent studies have suggested that certain B27 subtypes have specific interactions with ERAP, which might fundamentally alter MHC structure and function.

Genome-wide screening studies of multiplex families with SpAs, particularly AS, are ongoing in several countries to identify other genes involved in the predisposition to these diseases. The strongest association of SpA to date remains with the HLA complex, so at least in familial AS, B27 may to a certain extent be necessary (but not sufficient) to confer disease susceptibility. MRI studies in asymptomatic B27-positive individuals indicate that there is a much higher prevalence of sacroiliitis than previously recognized, and studies are continuing to define that prevalence and indeed the prevalence of SpAs in the general population. Some investigators have concluded that SpA is as common as RA.

CLINICAL SUBSETS OF THE SPONDYLOARTHROPATHIES

Ankylosing Spondylitis

EPIDEMIOLOGY

AS is the most common inflammatory disorder of the axial skeleton.[10] The following is a useful rule of thumb: AS occurs in 0.2% of the general population, in 2% of the B27-positive population, and in 20% of B27-positive individuals with an affected family member. There is a male preponderance in the disease, with the male-to-female ratio ranging from 2.5 : 1 to 5 : 1; however, recent epidemiologic studies have found more female involvement than these earlier estimates indicate. The basis for the gender bias has not been resolved. It is held, however, that AS is underrecognized in women, perhaps because of milder axial disease and a more delayed disease onset, but alternative diagnoses of pelvic and low back pain in women may hinder clinician awareness of the disease in female patients.

CLINICAL MANIFESTATIONS

AS typically begins in young adulthood, but symptoms may arise in adolescence or earlier. Up to 15% of children with juvenile idiopathic arthritis are classified as having juvenile AS. Such children may have a pauciarticular pattern, with a predilection for the tarsal joints and frequently minimal spinal complaints. During the adolescent years there is an increasing prevalence of radiographic sacroiliitis, with a significant proportion of patients manifesting this feature by the end of the teenage years. At the other end of the age spectrum, a small number of patients with late-onset AS may have sacroiliitis and oligoarthritis. The axial involvement and asymmetrical lower extremity involvement may serve to differentiate such patients from those with late-onset RA, although there may be overlapping clinical features. Recent studies indicate that the rate of radiographic progression may be less in juvenile-onset AS than in adult-onset AS.

The classic manifestation of AS is the onset of low back pain that persists for more than 3 months, is accompanied by early-morning stiffness, and is typically improved by exercise but not by rest (Table 265-3). Some studies would include a response to NSAID therapy as an additional feature differentiating AS from mechanical low back pain. Back pain that awakens the patient from sleep is often a clue to inflammatory back pain that may have been misdiagnosed as the pain of degenerative disc disease, the latter being a much more common cause of low back pain in the population at large. The pain typically occurs in the region of the sacroiliac joints, with or without slight radiation to the buttock area. Midthoracic pain and cervical pain, particularly at night, are less common but strongly suggest inflammatory back pain when they occur. Fatigue is also a suggestive symptom and is often a major concern for the typical young male patient who has a high functional target in terms of sports and recreation. If the inflammation is inadequately controlled, there is increasing stiffness that may persist most of the day, as well as progressive loss of mobility and flexibility.

TABLE 265-3 MODIFIED NEW YORK CRITERIA FOR ANKYLOSING SPONDYLITIS (1984)

CLINICAL CRITERIA
Low back pain and stiffness for > 3 mo that improve with exercise but are not relieved by rest
Limitation of motion of the lumbar spine in both sagittal and frontal planes
Limitation of chest expansion
RADIOLOGIC CRITERIA
Sacroiliitis: grade ≥ 2 bilateral or grade 3 or 4 unilateral
GRADING
Definite AS if the radiologic criterion is associated with at least one clinical variable
Probable AS if:
The three clinical criteria are present
The radiologic criterion is present without the clinical criteria

AS = ankylosing spondylitis.

Peripheral oligoarthritis is seen in up to 30% of patients with AS. Typically, it is an asymmetrical oligoarthritis with a predilection for the lower extremities. It is important to ask about concurrent or previous tendinitis (e.g., Achilles tendinitis) or heel pain (e.g., plantar fasciitis), because either may reflect an enthesitis that is part of the clinical picture. Involvement of the hip can occur at any point in the course of AS and can follow a course to joint destruction. A hip flexion contracture on this basis may contribute to increasing stoop on standing and walking, which may otherwise be attributed to spinal involvement in the disease.

Extra-articular features most commonly involve the eye. Ocular involvement may occur in up to 40% of AS patients, most typically acute anterior uveitis (iritis). The uveitis often manifests as a slight impairment in visual acuity, with accompanying photophobia and eye pain. Typically, it is unilateral and recurrent. IBD and psoriasis occur in approximately 10% of AS cohorts. Less common manifestations include aortic insufficiency, cardiac conduction defects, and pulmonary fibrosis.

DIAGNOSIS

Physical Examination

Physical examination of the spine characteristically indicates restricted movement, which in the early stages may reflect paraspinal muscle spasm in part; late in the course it reflects ankylosis of the zygapophyseal joints and syndesmophyte bridging of the vertebral bodies. Forward flexion is restricted and can be monitored by Schober's test. This test is used to measure mobility in the lower part of the back: with the patient standing upright, a 10-cm span is marked from the fifth lumbar vertebra upward. On maximal forward flexion, the distance between the marks is remeasured. With normal spinal mobility, the flexed distance should register as 15 cm or an increment of 5 cm. Thoracic involvement is measured in chest expansion, with the chest circumference at maximal inspiration being more than 5 cm greater than the circumference at maximal expiration. Changes in cervical mobility can be measured as the occiput-to-wall distance, with the patient's heels against the wall as the patient attempts to touch the back of the head to the wall. Restricted spinal mobility early in the course of the disease may best be detected by lateral spinal flexion, measured as the difference in the finger-to-floor distance when standing erect compared with maximal bending to the side. Inflammation in the sacroiliac joint may be reflected by joint line tenderness to direct pressure or by the FABERE test (for Flexion, ABduction, External Rotation, and Extension) or Gaenslen maneuver. In the former, the patient lies supine while the examiner flexes and externally rotates the hip. In the latter, the examiner extends the hip by letting the leg dangle off the side of the examining table. In both cases,

It is clear that HLA is strongly associated with SpA, yet the prevalence of HLA-B27 varies widely in different racial and ethnic clusters around the world. It is virtually absent in aboriginal populations in Australia, occurs in 1% of the population in Japan, in 7% in northern European countries, and in 50% in some of the native tribes in western Canada. The environmental-genetic interaction that may account for the expansion or restriction of this gene in human populations is unknown, but some evidence indicates that B27 may confer a more effective host response to some viruses, such as hepatitis C. This variability has a practical impact for the clinician. Because the relative risk conferred by a gene reflects the prevalence of the gene in affected individuals versus its prevalence in the normal population, the relative risk for SpA is higher in a population in which the gene is uncommon (e.g., Japan) than in a population in which B27 is more common (e.g., Scandinavia). In the North American white population, the prevalence of the gene is approximately 7%. Thus, there is a 7% "false-positive" rate if one is attempting to use the gene as a diagnostic marker to decipher the cause of chronic back pain in an unselected population of patients. In contrast, 90% of patients with AS are B27 positive, so there is a 10% "false-negative" rate when using the test diagnostically. The key factor is pretest probability. In a patient with chronic back pain that is clearly inflammatory in character, the addition of B27 positivity combines to strengthen the likelihood of AS accounting for the back problem. The presence of distinctive extra-articular features (e.g., uveitis) further increases this likelihood.

Other steps have also been taken to define the mechanism whereby B27 confers disease susceptibility, in addition to that of uniquely presenting an arthritogenic peptide to T cells. According to the theory of molecular mimicry, an autoimmune response can ensue after an infection if the immune response against the pathogen cross-reacts with host antigens. There is a degree of sequence homology between B27 and several candidate gram-negative enteric bacteria, and there is evidence for cross-reacting monoclonal antibodies, but the significance of such homology for disease pathogenesis remains unresolved. It has also been argued that B27 is distinctive in its propensity to misfold in the endoplasmic reticulum, which may induce a pro-inflammatory cascade called the unfolded protein response. Furthermore, B27 may have a distinct tendency to form heavy-chain homodimers at the cell surface, and the possible consequences of this change for the immune response are under investigation. There has also been investigation into the alteration of primary host-pathogen interactions, such as modulation of pathogen invasion, intracellular replication, and clearance. However, no definitive allele-specific relationships have been demonstrated in these studies.

In B27 transgenic rats, the spontaneous development of pathology that is strikingly similar to human SpAs has supported the notion that B27 itself is the critical genetic factor in disease pathogenesis. These animals demonstrate pathology similar to that of Crohn's disease in the GI tract, spondylitis, peripheral arthritis, uveitis, and psoriasiform skin and nail changes. Of interest, if such animals are raised in a germ-free environment, there is a marked reduction in joint and gut disease, implying a dynamic interrelationship between microbial triggers and background host genes that seems to recapitulate the situation seen clinically.

stress is placed on the sacroiliac joint and may reproduce the back pain if it derives from this site.

Laboratory Findings

Laboratory tests in the evaluation of inflammatory back pain are relatively nonspecific. The ESR and CRP are typically elevated, but normal levels do not exclude inflammatory back pain, and the degree of elevation is typically less than would be seen in acute RA. Anemia of chronic disease may be observed if the condition is long-standing. HLA-B27 is rarely the definitive factor for diagnosis, and the false-positive and false-negative rates have already been discussed; however, in the setting of characteristic back symptoms, the test has reasonably high sensitivity and specificity.

Imaging

Radiographic assessment is important for confirmation of disease, but early in the course there may be no radiographic changes in the sacroiliac joints. If the clinician has a high index of suspicion in such cases, MRI may improve the sensitivity of the plain radiograph because inflammatory changes on MRI predate radiographic changes.[11,12] When ordering x-rays, specific views of the sacroiliac joints can be requested. A routine anteroposterior pelvic radiograph is generally the standard diagnostic x-ray. The classic findings are bilateral changes in the sacroiliac joints (Fig. 265-2). Abnormalities include erosions in the joint line, pseudowidening, subchondral sclerosis, and, finally, ankylosis, reflecting complete bony replacement of the sacroiliac joints.

Radiographs of the spine may reveal squaring of the vertebral bodies (loss of the normal anterior concavity of the lumbar vertebra) and "shiny corners" (subchondral sclerosis at the upper edge of the vertebral body), both of which are manifestations of enthesitis. Syndesmophytes, which represent marginal bridging of the vertebrae (Figs. 265-3 and 265-4), eventually develop and make the diagnosis clear. Because ankylosis of the apophyseal joints may occur without syndesmophyte formation, it is important to assess the posterior joints on the lateral lumbosacral spine views, as well as the anterior margin of the vertebrae. Eventually, the changes may result in a "bamboo spine," so called because the bridging syndesmophytes can mimic the appearance of bamboo. It is now appreciated that osteoporosis (Chapter 243) is a significant feature of AS, probably reflecting both the local chronic inflammation and the abnormal biomechanical loading of the vertebrae as the disease progresses.

Differential Diagnosis

The differential diagnosis of AS includes the following: osteitis condensans ilii; diffuse idiopathic skeletal hyperostosis (DISH); the syndrome of synovitis, acne, pustulosis, hyperostosis, and osteomyelitis (SAPHO); and some induced hyperostotic states (vitamin A intoxication, fluorosis). New bone formation occurs in degenerative disc disease, but the bulky horizontal appearance of osteophytes is usually easily distinguished from that of syndesmophytes, and narrowing of the disc space is not a feature of AS. Osteoarthritis of the sacroiliac joint has recently been recognized as having a higher prevalence than previously appreciated.

The clinical course and severity of AS are highly variable. Inflammatory back pain and stiffness dominate the picture in the early stages, whereas chronic pain and deformity may develop over time. In both early and late phases of the disease, there may be a significant impact on work disability and quality of life. In only a minority of patients does the full-blown picture of a bamboo spine eventually develop, but there are few variables that can reliably aid in prognosticating the course. At present, the strongest predictor of new syndesmophyte formation is the presence of syndesmophytes at baseline. In AS patients in whom new, refractory spinal pain develops, an intervertebral fracture should be considered, which can occur after only minimal trauma.

Additional late complications may include cauda equina syndrome, osteoporotic compression fractures, spondylodiscitis, and restrictive lung disease.

FIGURE 265-2. Bilaterally symmetrical sacroiliitis in ankylosing spondylitis.

Reactive Arthritis

DEFINITION

ReA is an aseptic arthritis that occurs subsequent to an extra-articular infection, most typically of the GI or GU tract. In the GI tract, the key pathogens

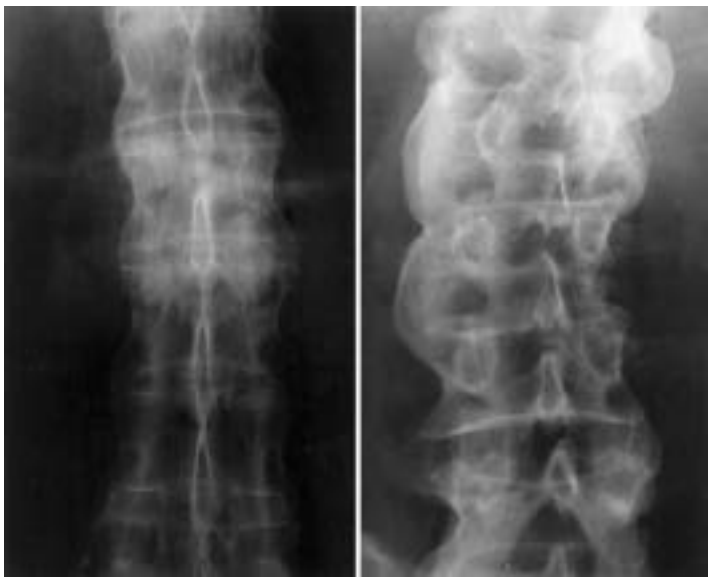

FIGURE 265-3. *Left,* Lumbar spondylitis in ankylosing spondylitis, with symmetrical marginal bridging syndesmophytes and calcification of the spinal ligament. *Right,* The bulky, nonmarginal, asymmetrical syndesmophytes of reactive arthritis with lumbar spondylitis.

FIGURE 265-4. A 34-year-old man who has had ankylosing spondylitis for 9 years and neck pain. Radiographs demonstrate narrowing of the C2-C3 apophyseal joints posteriorly and anterior bridging marginal syndesmophytes extending from C2 to C5.

are *Salmonella typhimurium*, *Yersinia enterocolitica*, *Shigella flexneri*, and *Campylobacter jejuni*. In the GU tract, *Chlamydia trachomatis* is the most common offender.

EPIDEMIOLOGY

The true incidence and prevalence of ReA are not well defined. In epidemics involving *Salmonella* (Chapter 308) or *Yersinia* (Chapter 312), it is estimated that ReA develops in 2 to 7% of infected individuals but in as many as 20% of B27-positive infected individuals. In such epidemic studies, B27 confers risk not only for the onset of arthritis but also for axial involvement and chronicity. Genetic variants in toll-like receptor 2 (TLR-2) are associated with acute ReA, thus implicating host innate immunity as central in ReA. The variability in the rate of ReA is determined by the heterogeneity of the cohorts reported, which introduces confounding variables of different genetic backgrounds in the population and different species of pathogens. Even in the setting of an epidemic point source outbreak, the inoculum varies widely among the exposed individuals, and the genetic makeup of the population at risk (e.g., the prevalence of B27) may differ greatly among different studies. Case ascertainment and relative risk are even more difficult to determine for post-*Chlamydia* ReA. Young adults in the United States have a high prevalence of asymptomatic *Chlamydia* carriage in the GU tract, and establishing a causal link between *Chlamydia* and synovitis can be difficult. Nevertheless, it is with *Chlamydia* that ReA has been most intensively studied.

PATHOBIOLOGY

Although immunofluorescence studies have identified bacterial antigens in the joints of patients with ReA after both GI and GU infections, it is primarily in post-*Chlamydia* ReA that results of polymerase chain reaction studies on synovial tissues have most consistently been positive, suggesting that viable *Chlamydia* may persist in the joints of such patients, albeit in a metabolically altered state.

Typically, the onset of arthritis occurs 1 to 3 weeks after the GI or GU infection, but the temporal details are often difficult to define precisely.

Although the definition of aseptic arthritis after an extra-articular infection may include a broader range of pathogens (e.g., *Chlamydia pneumoniae*), sites of infection (e.g., streptococcal pharyngitis), and types of infections (e.g., *Giardia* infections of the GI tract), these clinical scenarios have not generally been included in the category of ReA. They lack the other associated clinical features of the SpA group of diseases, and they lack an association with B27.

DIAGNOSIS

The pattern of joint involvement in ReA is one of asymmetrical oligoarthritis with a predilection for the lower extremity, a pattern shared by most SpA syndromes. Enthesitis may present as Achilles tendinitis or plantar fasciitis. Dactylitis, appearing as a sausage digit, may also be seen. Dactylitis is the net result of inflammatory changes affecting the joint capsule, entheses, periarticular structures, and periosteal bone. Sacroiliitis may be seen in the acute phase, but radiographic changes are seen largely in patients with a more chronic course.[13]

When ReA is accompanied by certain extra-articular features such as urethritis, conjunctivitis, or mucocutaneous lesions, the term *Reiter's syndrome* has been applied historically, but it is no longer in common use. The urethritis may manifest as dysuria or discharge, and the rash as circinate balanitis, which appears as vesicles or shallow ulcerations on the glans penis. Painless lingual or oral ulcerations may also be seen. The fact that the cervicitis may be less symptomatic could partially account for the underdiagnosis in women. The classic skin manifestation of ReA is keratoderma blennorrhagicum, a painless papulosquamous eruption on the palms or soles (Fig. 265-5). Occasionally, nail dystrophy with pitting and onycholysis or subungual keratosis can be seen. The conjunctivitis can be bilateral and painful; in contrast, the acute anterior uveitis that can also be seen in this setting tends to be less painful and unilateral.

Radiographic changes of ReA can be seen in the involved peripheral joints, with early findings consisting of soft tissue swelling and juxta-articular osteopenia. Areas of periostitis and new bone formation may develop in peripheral joints. When changes in the sacroiliac joints are seen, they are typically asymmetrical (Fig. 265-6), in contrast to the symmetrical pattern seen in AS. In the chronic phase, syndesmophytes may develop, but they are described as bulky, nonmarginal, often asymmetrical formations that differ from the classic syndesmophytes of AS. The frequency with which ReA evolves into bona fide AS has not been determined definitively.

FIGURE 265-5. Keratoderma blennorrhagicum of the feet in reactive arthritis.

FIGURE 265-6. Bilaterally asymmetrical sacroiliitis in reactive arthritis. Erosions, pseudowidening, and ileal sclerosis are present.

Differential Diagnosis

The most important differential diagnosis for such reactive arthropathies is septic arthritis. Both *Yersinia* and *Salmonella* can cause septic arthritis, so an appropriate culture of synovial fluid should precede the diagnosis of ReA whenever possible. The course of ReA is variable, and few prognostic markers are available for the clinician to predict the course in an individual case. The majority of patients have an initial episode lasting 2 to 3 months, but synovitis may persist for a year or longer. In one 5-year follow-up of a point source cohort of post-*Salmonella* ReA, 20% of patients had ongoing inflammatory joint disease, and some degree of functional disability was observed in 30% of patients 5 years after the onset of disease.

REACTIVE ARTHRITIS AND HUMAN IMMUNODEFICIENCY VIRUS

An aggressive form of SpA may be seen in patients who are concomitantly infected with HIV.[14] There is no increased frequency of ReA in patients with HIV, but HIV may alter the course of these arthropathies, with a tendency for a more aggressive and more refractory joint disease. Aggressive skin and joint disease may be seen in patients in whom PsA develops in the setting of HIV infection. Most North American patients with the HIV-ReA constellation are B27 positive, but studies of comparable patients in Africa have found a sizable B27-negative component in such patients. The arthritis in these patients falls into two clinical patterns: (1) an additive, asymmetrical polyarthritis or (2) an intermittent oligoarthritis that most commonly affects the lower extremities. Enthesitis, fasciitis, conjunctivitis, and urethritis can all be

seen in such patients. Sacroiliitis can occur, although extensive spinal syndesmophyte formation is not common.

Psoriatic Arthritis

EPIDEMIOLOGY

PsA develops in 5 to 7% of patients with psoriasis. Although most cases arise in patients with established cutaneous disease, some patients (particularly children) have arthritis that antedates the appearance of the skin lesions.[15] Although the extent of psoriatic skin disease correlates poorly with the development of arthritis, the risk for PsA increases with a family history of SpA. The age at onset can range from 30 to 55 years, with an equal predilection for PsA in women and men. Psoriatic spondylitis has a slight male preponderance. Two large prospective studies suggest that obesity is a significant risk factor for psoriatic arthritis.[16,17]

PATHOBIOLOGY

The genetic associations with PsA are complex. Psoriasis itself is associated with several HLA loci; some B alleles have been reported, but the dominant element is HLA-Cw6. HLA-B39 and HLA-B27 have been associated with sacroiliitis and axial involvement. No etiologic agent has been proved in PsA, although some investigators have proposed that the disease process represents ReA in response to cutaneous bacteria. The histopathology of the synovitis of PsA is comparable to that of the other forms of SpA, with the absence of the local production of immunoglobulin and rheumatoid factor differentiating this disease from RA. There is the potential for aggressive osteolysis, fibrous ankylosis, and heterotopic new bone formation to occur in PsA. As mentioned earlier, the coexistence of HIV and PsA seems to set the stage for an aggressive course of joint destruction in some patients.

DIAGNOSIS

PsA has a variable manifestation and disease course, but several clinical patterns have been identified in prospectively monitored cohorts of patients. The clinical subsets are not mutually exclusive, nor are they static over time. The most common form, which affects 30 to 50% of patients, is an asymmetrical oligoarthritis that may involve both large and small joints. Dactylitis, arising as sausage digits, can be seen in fingers and toes and actually represents an enthesitis. In the second subset there is selective targeting of the distal interphalangeal joints, seen in 10 to 15% of patients. These changes are strongly associated with nail dystrophy, of which the features are onycholysis, subungual keratosis, pitting, and oil drop–like staining (Fig. 265-7). The third subset (15 to 30% of patients) has a symmetrical polyarthritis that mimics RA in many ways, except for the absence of rheumatoid nodules and rheumatoid factor. The fourth clinical variant is psoriatic spondylitis, which occurs in 20% of patients; 50% of such patients are B27 positive. Finally, arthritis mutilans (5% of patients) is a destructive, erosive arthritis that affects large and small joints and can be associated with marked deformities and significant disability.

Radiographic changes in PsA involve soft tissue swelling (particularly in the case of dactylitis), erosions, and periostitis. Axial involvement may lead to the appearance of asymmetrical sacroiliitis with syndesmophytes that are bulky, asymmetrical, and nonmarginal. The classic "pencil-in-cup" deformity may be seen in patients with distal interphalangeal joint disease or arthritis mutilans. Acro-osteolysis is noted in a minority of patients and reflects an aggressive erosive process.

FIGURE 265-7 Nail pitting in psoriasis. The pits are more discrete and regular compared with pits affecting the nail plate in dermatitis.

Differential Diagnosis

The diagnosis of PsA depends on finding the typical skin or nail changes in association with one of the articular variants described previously. The differential diagnosis for the skin lesions can include seborrheic dermatitis, dyshidrotic eczema, fungal infection, keratoderma blennorrhagicum, and palmoplantar pustulosis.

TREATMENT Rx

Patients typically receive aggressive treatment for psoriasis (Chapter 438). The advent of biologic agents has had a major impact on the treatment of PsA. The anti-TNF agents have been studied most extensively, indicating the efficacy of infliximab, etanercept, adalimumab, and golimumab. In a phase III randomized placebo-controlled trial, treatment of psoriatic arthritis with subcutaneous golimumab (50 mg to 100 mg every 4 weeks) inhibited the progression of structural damage and demonstrated continued clinical efficacy and safety through 1 year.[■] In a study of patients with PsA, ustekinumab, a monoclonal antibody against interleukin-12/23, was well tolerated, reduced the extent and severity of psoriasis, and was safe.[■] Brodalumab, a human monoclonal antibody against interleukin-17 receptor A (IL17RA), significantly improved response rates among patients with PsA in a phase 2 randomized, double-blind, placebo-controlled study.[■] The European League Against Rheumatism in 2012 published recommendations for the management of PsA with systemic and local (nontopical) symptomatic and disease-modifying antirheumatic drugs. They suggest nonsteroidal anti-inflammatory drugs to relieve musculoskeletal signs and symptoms; treatment with disease-modifying drugs such as methotrexate, sulfasalazine, or leflunomide in patients with swollen joints, structural damage in the presence of inflammation, or clinically relevant extraarticular manifestations; and anti-TNF agents in patients with active enthesitis and/or dactylitis and insufficient response to other medications. Patients should be switched to another anti-TNF agent if the first is not successful.

Enteropathic Arthritis

DEFINITION

EA refers to the arthritis associated with Crohn's disease (CD) or ulcerative colitis (UC) (Chapter 141; Table 265-4).

PATHOBIOLOGY

All extraenteric manifestations, including arthritis, occur more commonly in CD than in UC. Peripheral arthritis occurs in 10 to 20% of CD patients and in 2 to 7% of UC patients. This pattern of arthritis occurs more commonly in patients with other extraenteric features (e.g., erythema nodosum, iritis). It is typically an inflammatory nonerosive polyarthritis, predominantly of large joints. In general, the clinical activity of the peripheral arthritis parallels the

TABLE 265-4 ENTEROPATHIC ARTHRITIS

FEATURE	PERIPHERAL ARTHRITIS	SACROILIITIS, SPONDYLITIS
CROHN'S DISEASE (CD)		
Frequency in CD	10-20%	2-7%
HLA-B27 associated	No	Yes
Pattern	Transient, symmetrical	Chronic
Course	Related to activity of CD	Unrelated to activity of CD
Effect of surgery	Remission of arthritis uncommon	No effect
Effect of anti-TNF therapy	Effective	Effective
ULCERATIVE COLITIS (UC)		
Frequency in UC	5-10%	2-7%
HLA-B27 associated	No	Yes
Pattern	Transient	Chronic
Course	More common in pancolitis than proctitis; related to activity of UC	Unrelated
Effect of surgery	Remission of arthritis	No effect

HLA = human leukocyte antigen; TNF = tumor necrosis factor.

activity of the gut inflammation, and measures that control the GI disease usually control the joint disease as well. The peripheral arthritis of EA is not associated with B27. As mentioned earlier, IBD and AS share genetic susceptibility associated with numerous genes.

In contrast, the sacroiliitis or spondylitis of EA follows a pattern in which the joint inflammation waxes and wanes independently of the bowel inflammation. Axial disease occurs in 2 to 7% of both CD and UC patients. HLA-B27 is found in 50% of patients with axial arthritis. The course tends to be chronic, as opposed to the transient course of peripheral arthritis.

The association of bowel inflammation and arthritis is supported by ileocolonoscopic studies in which subclinical inflammation of the bowel has been demonstrated in diseases covering the entire spectrum of SpAs. Histologic evaluation demonstrates that changes of acute ileitis are seen in postdysenteric ReA, whereas chronic inflammatory changes are more likely to be seen in patients with AS. As mentioned earlier, the abnormalities in the bowel of B27 transgenic rats have strong similarity to the lesions of CD, and a germ-free environment minimizes inflammatory changes in both the gut and the joints. This finding argues that altered bowel permeability, with enhanced bacteremia or antigenemia, may provide the link in both cases.

DIAGNOSIS

It is important to recognize that the musculoskeletal features of EA may precede any GI symptoms or signs. Conversely, the diarrhea preceding the onset of peripheral or axial arthritis in a young patient could just as likely represent a food-borne pathogen (e.g., *Salmonella*, *Yersinia*), with secondary ReA as IBD and accompanying EA. In the initial assessment of such a patient, it is important to carry out careful and complete stool cultures. If the GI symptoms persist, diagnostic colonoscopy is often required to resolve the issue.

Undifferentiated Spondyloarthritis

Despite careful clinical and radiographic assessment, there are still a substantial number of patients who do not fall into one of the classic diagnostic subsets of SpA outlined previously. These patients are often defined as having USpA with peripheral enthesitis, asymmetrical arthritis or sacroiliitis, or iritis in the absence of identifiable antecedent infection or concurrent IBD or psoriasis. The natural history of USpA has not been well defined, and case heterogeneity and diagnostic dilemmas plague a systematic or multicenter approach to the problem. When the clinical course is examined, a number of patients may finally meet the diagnostic criteria for AS, but many retain a distinct USpA pattern for prolonged periods.[18]

REVIEW QUESTIONS

1. A 28-year-old man presents with a 2-year history of low back pain and intermittent arthritis in the lower extremity. Physical examination demonstrates bilateral Achilles tendonitis and tenderness to direct pressure over the sacroiliac joints. Which of the following would ***not*** support the diagnosis of spondyloarthritis (SpA)?

A. Presence of HLA-B27
B. History of anterior uveitis
C. Positive rheumatoid factor
D. Elevated CRP
E. History of inflammatory bowel disease

Answer: C The history and the other optional features would be entirely consistent with a diagnosis of SpA. HLA-B27 is strongly associated with SpA in general, and its strongest association is with ankylosing spondylitis (AS). Anterior uveitis occurs in approximately 30% of AS cases, and is itself associated with HLA-B27 even when AS is not present. Positive rheumatoid factor is characteristic of rheumatoid arthritis but not of SpA, so it would not be expected to be positive in such patients. Elevated C-reactive protein (CRP) is a nonspecific marker of inflammation and would be commonly seen in patients with active SpA. Inflammatory bowel disease occurs in approximately 10% of AS cases, and its presence strongly suggests that concurrent musculoskeletal inflammation that the underlying arthritis is part of the SpA spectrum.

2. A 32-year-old man presents with pain and swelling of one ankle and one knee. The history reveals that he had just returned from a trip to South America and developed diarrhea that was now subsiding. He denied any eye inflammation or skin lesions. Physical examination confirmed tenderness and swelling of an ankle and a knee. The next appropriate diagnostic test would be which of the following?

A. Aspiration of the knee swelling and culture of the synovial fluid
B. Initiate a course of broad-spectrum antibiotics.
C. X-rays of the lumbar and cervical spine
D. Check a blood test for the presence of antinuclear antibodies.
E. Initiate an empirical trial of methotrexate.

Answer: A A patient with new-onset swelling in the joints, particularly when one or two joints are affected, should always raise the possibility of septic arthritis. When there has been a recent infection elsewhere in the body, it is possible the inciting infection could spread by a hematogenous route to seed the joint. Although the history is suggestive of reactive arthritis (ReA), it is important to rule out septic arthritis with certainty before entertaining that diagnosis. Culture of synovial fluid is the definitive test to rule out septic arthritis.

Empirical use of broad-spectrum antibiotics rarely has a place in the management of new-onset arthritis. The first step is to make a diagnosis. X-rays of the spine are important in the evaluation of inflammatory back pain, but in this case there is only peripheral joint involvement. If the course of the arthritis becomes chronic or back pain develops over time, x-rays at that point would be appropriate. Antinuclear antibodies in the serum are the hallmark of many autoimmune rheumatic diseases—in particular, lupus. But with the clinical presentation in this case, there are no features to implicate lupus or related conditions, and it would not be appropriate to search for antinuclear antibodies. The immediate priority is to rule out septic arthritis. It would be inappropriate to institute methotrexate before that is resolved.

3. A 30-year-old man presents with worsening back pain. The history reveals that this has been present for the past 3 years and is increasing in severity. It is characterized by early-morning stiffness, nocturnal pain, and modest improvement with exercise. He initially noted an improvement with an NSAID, but subsequently that effect was lost, and he has tried two other NSAIDs without effect. Physical examination reveals limitation in forward flexion of the lumbar spine. An AP x-ray of the pelvis reveals bilateral erosive changes in the sacroiliac joints. A lateral x-ray of the lumbar spine reveals squaring of several vertebral bodies. The next step in pharmacologic treatment of this condition is which of the following?

A. Methotrexate
B. Leflunomide
C. Sulfasalazine
D. TNF inhibitor biologic agents
E. Azathioprine

Answer: D The patient meets the diagnostic criteria for ankylosing spondylitis (AS). He has long-standing back pain that has features of inflammatory back pain and has limitation in spinal mobility. The presence of bilateral erosive sacroiliitis provides imaging support for the diagnosis of AS. He has had an adequate trial of NSAIDs, and his back pain has not responded adequately to these agents. The classical DMARDs used in rheumatoid arthritis—methotrexate, leflunomide, sulfasalazine, and azathioprine—have proved ineffective in controlling the spinal inflammation seen in AS. On the other hand, the TNF inhibitors (infliximab, etanercept, adalimumab, golimumab) have established efficacy in controlling the signs and symptoms of AS.

4. A 35-year-old woman is under your care for ankylosing spondylitis (AS). She is HLA-B27 positive and has no extra-articular features accompanying her back pain. Her symptoms have been controlled with NSAIDs in combination with physiotherapy and exercises. She has an 8-year-old son, and she is inquiring about his current and future health prospects. Which of the following would be advisable in this circumstance?

A. The son should be checked for HLA-B27 status.
B. The mother should be advised that the likelihood of her son developing AS is less than 10%.
C. The son should be advised to avoid sports and physical activities.
D. Preventive low-dose NSAIDs should be instituted for the son.
E. The son should be advised to avoid foreign travel in order to avoid food-borne pathogens.

Answer: B There is a 50% chance that any particular child of a B27-positive patient will be B27 positive, but there is only a 20% chance of a B27-positive individual with a positive family history developing AS. So the likelihood of a child developing AS when he has a B27-positive parent with AS is maximally 10%. It would not be advisable to test an asymptomatic child for HLA-B27, because it has low predictive value (as discussed earlier) and could introduce chronic anxiety about future disease, which is unwarranted. There is no reason to limit the sports and recreation of the child. Maintaining general fitness and muscle strength and posture is sound advice even if there is a greater chance of later arthritis than in the general population. There is no evidence that sports-related injuries trigger AS. There is no evidence that NSAIDs prevent the subsequent development of SpA in individuals who are genetically predisposed to SpA. Chronic NSAID therapy carries its own risks and would not be justified in an asymptomatic individual. There is a theoretical concern that being B27 positive could increase the risk of reactive arthritis after a food-borne pathogen illness. This might lead to advising a patient with ***prior*** diagnosis of ReA to minimize exposure to food-borne pathogens, but it would be inappropriate to restrict travel for anyone who has never had an episode of ReA.

5. A 19-year-old female patient has developed a painful swollen knee over the course of 7 days. There is no history of trauma and no associated skin lesions or ocular complaints. The patient relates a history that she has just returned from a trip abroad with the family and had a transient diarrheal episode while traveling. Further questioning reveals that she has had two prior episodes of diarrhea in the past year, each associated with crampy abdominal pain, but on each occasion the diarrhea was self-limited and she did not seek medical attention. Which of the following would ***not*** be an appropriate next step in the management of this patient?

A. Referral to a gastroenterologist for ileocolonoscopy
B. Culture of a stool sample
C. Aspiration of the knee and culture of synovial fluid
D. Check hemoglobin and ESR.
E. Institute a 2-week course of ciprofloxacin.

Answer: E The patient has developed arthritis in the setting of a recurrent diarrheal course. The key differential is between reactive arthritis (ReA) and enteropathic arthritis (EA) as part of inflammatory bowel disease (IBD). In either case, it would be inappropriate to institute an empirical course of antibiotics before a diagnosis is made. In neither postdysenteric ReA nor in IBD-associated arthritis is there evidence that antibiotics alter the course of the arthritis. It would be appropriate in this case to determine whether the recurrent diarrhea could be a manifestation of Crohn's disease or ulcerative colitis, and ileocolonoscopy would be indicated to address that question. Recurrent diarrhea might reflect a infectious agent such as *Salmonella*. Stool cultures would be an appropriate test to address that. Culture of synovial fluid is the definitive test to rule out septic arthritis. Both *Salmonella* and *Yersinia* can cause a septic arthritis, so it is appropriate to exclude an infection in the joint before proceeding to other management decisions. Anemia of chronic disease might raise the suspicion that a chronic process, such as IBD, has been present for some time. Elevation in CRP or ESR is appropriate in the work-up of this patient, although this would not differentiate ReA from IBD-related arthritis. These acute phase reactants can serve as useful surrogate markers to monitor response to treatment.

SYSTEMIC LUPUS ERYTHEMATOSUS

MARY K. CROW

DEFINITION

Systemic lupus erythematosus (SLE) is a multisystemic autoimmune disease that results from immune system–mediated tissue damage. Manifestations of SLE can involve the skin, joints, kidney, central nervous system (CNS), cardiovascular system, serosal membranes, and the hematologic and immune systems. The disease is highly heterogeneous, with individual patients manifesting variable combinations of clinical features. In most patients with SLE, the disease is characterized by a waxing and waning clinical course, although some demonstrate a pattern of chronic activity. The molecular triggers of the disease are not known, but the pathogenesis is understood to involve the production of autoantibodies exhibiting multiple specificities, with reactivity with nucleic acid–binding proteins being a common feature. Immune complexes, along with immune system cells and soluble mediators, generate inflammation and tissue damage. Therapeutic approaches generally involve immunosuppression.

EPIDEMIOLOGY

A notable feature of SLE is that it occurs much more frequently in females than in males. Like Hashimoto's thyroiditis and Sjögren's syndrome, the female-to-male ratio is approximately 8 : 1 to 10 : 1 in adults, and most cases are diagnosed between the ages of 15 and 44 years. In children and women older than 55, the ratio is closer to 2 : 1. The prevalence of SLE in the United States is estimated to be approximately 73 per 100,000, and the incidence of new cases is 5.5 per 100,000 per year. The prevalence, severity, and characteristics of disease differ in different ethnic groups, with SLE being 2.3-fold more frequent in African Americans than in the white population. The severity of disease is also greater in Hispanic individuals than in whites, although data for Hispanic populations are less abundant. Asians may also have a higher prevalence of disease than whites. Recent studies of lupus in minority populations indicate that socioeconomic factors are major contributors to the increased prevalence and severity of disease in African Americans and Hispanic Americans.

PATHOBIOLOGY

Current understanding of lupus pathogenesis incorporates roles for genetic susceptibility based on a threshold model involving multiple genes[1]; environmental triggers, including microbial infection, sunlight, and certain drugs; and altered immune system function. Recent advances in immunology have focused attention on the mechanisms that account for innate immune system activation.[2] At least some of the genetic and environmental contributions to lupus are likely to promote innate immune system activation and subsequent autoimmunity. Others may contribute to inflammation and tissue damage. Induction of cellular stress responses, including oxidative modification of cell proteins, is of current interest as a mechanism that links environmental triggers to altered immune function.

Murine models have proved useful in identifying genes that could contribute to lupus susceptibility or define patterns of disease. Production of autoantibodies characteristic of SLE and development of nephritis and accelerated death have been demonstrated in numerous murine strains in which immune system genes have been modified. In most cases, no alterations have been noted in the homologous human genes. The ease of induction of lupus-like disease in murine models suggests that there are numerous possible pathogenic paths that might lead to the clinical manifestations of lupus. It is not known which of these molecular pathways is responsible for human SLE, although mediators of the immune response to viral infection, particularly components of the type I interferon response, are associated with lupus in both murine and human systems and are likely to be important in disease pathogenesis.[3]

Genetics

An important role for a genetic contribution to lupus susceptibility is suggested by the high concordance of disease in monozygotic twins (14 to 57%).

Genes that might account for increased lupus susceptibility or severity include those encoding components of the complement pathway, including C1q, C2, and C4A (E-Table 266-1). Impaired production of these early complement components may decrease the clearance of apoptotic cells, thereby augmenting the pool of available autoantigens, or decrease the solubility of immune complexes. Polymorphic variants in components of the toll-like receptor (TLR) pathways that regulate type I interferon production, including interferon regulatory factor 5 *(IRF5)*, have been associated with a diagnosis of SLE and increased plasma interferon activity in some populations. Association of SLE with the major histocompatibility complex (MHC) class II alleles human leukocyte antigen (HLA)-DR2 and HLA-DR3 has been documented in many studies and is most striking in patients expressing particular autoantibody specificities. Polymorphisms in the Fc receptor genes *FCGR2A* and *FCGR3A* have been associated with SLE nephritis, possibly based on altered clearance of immune complexes. Variants of the *PTPN22* gene, which encodes a phosphatase that regulates T-cell activation, are also associated with SLE. Genome-wide association studies have expanded the list of lupus-associated gene variants to include regulators of innate immune system activation *(TNFAIP3, ITGAM, IRAK1)* and signaling molecules important in lymphocyte activation *(STAT4, BANK1, BLK,* and *LYN)*. Rare mutations in genes encoding proteins that regulate nucleic acid integrity and degradation, including *TREX1*, encoding a DNase; *SAMHD1*, a triphosphohydrolase; *RNASEH2A, B* and *C*; and *ADAR*, an RNA-specific adenosine deaminase, have been documented in some patients with a lupus-like syndrome called Aicardi-Goutieres syndrome, characterized by skin lesions, CNS disease, autoantibodies, and high levels of interferon. Mutations in these genes have also been documented in rare patients with SLE and have provided new insights into the likely contribution of endogenous nucleic acids to innate immune system activation and lupus pathogenesis.[4] The available data suggest a common theme: the genes that have been associated with lupus confer either increased activation or impaired regulation of the innate or adaptive immune responses, with increased type I interferon often observed in association with the risk genotype.

Environmental Triggers

Several classes of potential environmental triggers for lupus have been studied.[5] Although the female preponderance of SLE implies a role for hormonal factors in the disease, recent concepts describe a possible contribution of epigenetic modification or dosage effects of the X chromosome as accounting for at least some of the sex skewing. A role for microbial triggers—particularly viral infection—has been postulated, consistent with the constitutional symptoms that often characterize the earliest stage of the disease. Epstein-Barr virus has garnered particular interest among investigators, because the frequency of previous infection in SLE patients is significantly higher than in the general population (99 vs. 94%). Evidence of exposure to other viruses, including cytomegalovirus, is equivalent between SLE patients and healthy control subjects. Ultraviolet light exposure is a well-described trigger of lupus flares. Possible mechanisms include DNA damage, induction of cellular stress responses, and induction of apoptosis of skin cells, which result in concentration of nucleic acids and associated proteins in cell membrane blebs and increased processing by antigen-presenting cells. Data also support an association between current tobacco use and anti–double-stranded DNA antibodies and lupus disease activity. Certain drugs, including procainamide and hydralazine, can induce a lupus-like syndrome, but the symptoms usually abate after discontinuing use of the drug. These agents may promote demethylation of DNA, thereby altering gene expression and potentially increasing the availability of immunostimulatory DNA. Sulfa antibiotics have been reported to induce lupus flare in some patients. Administration of recombinant interferon-α to patients with hematologic malignancies or hepatitis C infection has been associated with induction of a lupus-like syndrome. In addition, anti–tumor necrosis factor agents have induced lupus autoantibodies and occasionally clinical lupus in patients with rheumatoid arthritis.

Immunologic Triggers

Genetic and environmental factors that increase the probability of development of SLE are likely to act on the immune system to induce autoimmunity and consequent tissue inflammation and damage. In addition to mechanisms that increase the availability of self-antigens (such as ultraviolet light), altered expression of gene products that mediate or regulate apoptosis, or impaired clearance of apoptotic debris, results in generalized activation of the immune system and contributes to autoimmunity in lupus. In parallel with the events that account for effective immune responses directed at exogenous microbes, the autoimmunity that occurs in SLE patients is likely to require activation of both innate and adaptive immune responses. The innate immune response is first activated by common molecular patterns expressed on the microbe and results in augmented antigen-presenting cell capacity and successful generation of an antigen-specific adaptive immune response. The characterization of the TLR family of pattern recognition receptors has provided new understanding of the mechanisms through which the innate immune system is activated by exogenous and endogenous stimuli, including nucleic acid–containing immune complexes, and promotes induction of a self-directed adaptive immune response.[6]

Type I Interferon

Recent studies of gene expression in peripheral blood mononuclear cells of SLE patients using microarray technology have demonstrated that activation of genes regulated by type I interferon is a common feature in patients with active disease and may represent innate immune system activation. Interferon (IFN)-α may be responsible for many of the immunologic alterations that have been observed in SLE and is identified as a potential therapeutic target. Immune complexes containing DNA or RNA are postulated to contribute to the production of type I interferon in SLE. Demethylated CpG-rich DNA or RNA associated with nucleic acid–binding proteins can activate plasmacytoid dendritic cells and other immune system cells through TLRs and thereby result in the production of type I interferon (IFN-α or IFN-β) and other proinflammatory cytokines (E-Fig. 266-1). Diverse effects of type I interferon on immune system function are consistent with the altered immune responses observed in SLE patients, including maturation of dendritic cells, increased immunoglobulin class switching to mature immunoglobulin isotypes (immunoglobulin [Ig]G and IgA), and induction of soluble mediators that increase B-cell differentiation and inflammatory responses, such as B-lymphocyte stimulator (BLyS) and IFN-γ.[7] Induction of an immunostimulatory microenvironment by IFN-α may support the development of a humoral immune response directed at self-antigens, particularly intracellular particles that contain nucleic acids and nucleic acid–binding proteins. It is not known why some individuals initiate immune system activation directed at self-antigens and others do not. In addition to its effects on immune system function, type I interferon has been associated with altered endothelial cell function and may contribute to the development of atherosclerotic vascular pathology in patients with lupus.[8]

Autoantibodies

The most characteristic lupus autoantibodies target intracellular particles containing both nucleic acid and nucleic acid–binding proteins. Understanding the significance of induction of these particular autoantibody specificities may provide clues to the etiology of SLE. A recent analysis of the spectrum of autoantibodies present in the sera of individuals in whom SLE is later diagnosed has suggested that autoantibodies reactive with certain RNA-binding proteins, including the Ro protein, occur early in the preclinical stage of the disease, along with a positive antinuclear antibody (ANA) test. These are often followed by anti-DNA antibodies and, finally, by the development of antibodies specific for the spliceosomal proteins Smith (Sm) and ribonucleoprotein (RNP) at approximately the time of diagnosis (Fig. 266-1). These observations suggest that individuals who demonstrate progression from humoral immunity targeting proteins associated with RNA to antibodies that bind DNA and other specificities are those in whom sufficient autoimmunity develops to manifest clinical symptoms. Approximately one third of SLE patients have autoantibodies reactive with phospholipids or the proteins associated with them, particularly β_2-glycoprotein I (β_2GPI). These autoantibody specificities can also be present independently of SLE in primary antiphospholipid antibody syndrome (Chapter 174).

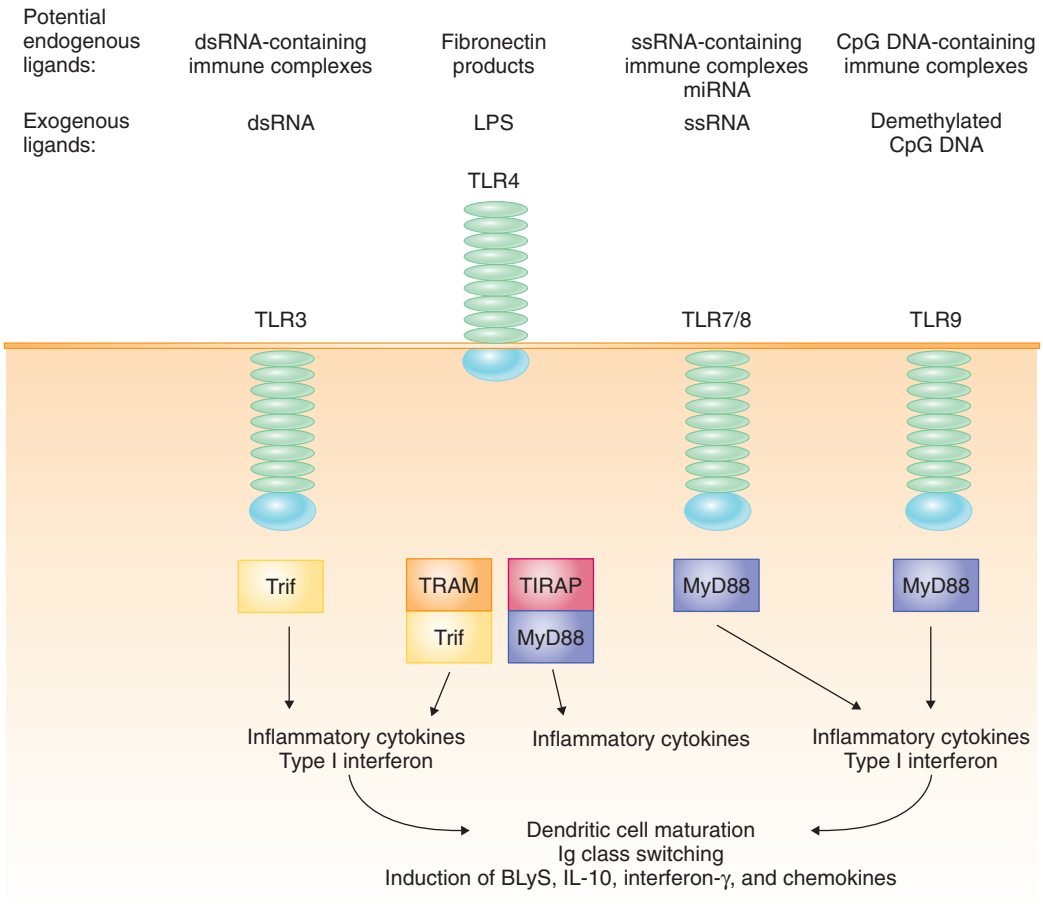
Immune Complexes and Complement

Tissue and organ damage in SLE is mediated by the deposition or in situ formation of immune complexes and subsequent complement activation and inflammation. The complement system (Chapter 50), composed of more than 30 proteins that act in concert to protect the host against invading organisms, initiates inflammation and tissue injury. Complement activation promotes chemotaxis of inflammatory cells and generates proteolytic fragments that enhance phagocytosis by neutrophils and monocytes. The classic pathway is activated when antibodies bind to antigen and generate potent effectors. Alternative pathway activation mechanisms differ in that they are initiated by the binding of spontaneously activated complement components

E-TABLE 266-1 GENES ASSOCIATED WITH SYSTEMIC LUPUS ERYTHEMATOSUS

GENE*	PROTEIN
BANK1	B-cell scaffold protein with ankyrin repeats 1
BLK	B-lymphocyte–specific tyrosine kinase
C1QA, *B*, and *C*	Complement component C1q
C2	Complement component 2
C4A and *C4B*	Complement component C4
CRP	C-reactive protein
DRB11501	MHC class II (DR2)
DRB10301	MHC class II (DR3)
FCGR2A	Activating FcγRIIA
FCGR3A	Activating FcγRIIIA
IRF5	Interferon regulatory factor 5
ITGAM	Mac1/complement receptor 3
IRAK1	Interleukin-1 receptor–associated kinase 1
LYN	Lyn tyrosine kinase
PTPN22	Protein tyrosine phosphatase nonreceptor type 22
STAT4	Signal transducer and activator of transcription 4
TNFAIP3	A20
TNFSF4	Ox40 ligand
TREX1	DNase III

*Genes listed have an odds ratio of ≥ 1.3.
MHC = major histocompatibility complex.



E-FIGURE 266-1. Model for induction of innate immune system activation in systemic lupus erythematosus. Both exogenous and endogenous stimuli can induce toll-like receptor (TLR) activation and thereby result in new gene transcription. Among potential endogenous ligands are immune complexes containing DNA or RNA or matrix-derived components. TLR ligands trigger the activation of intracellular adaptors, including TIR domain-containing adapter-inducing interferon-β (Trif), Trif-related adaptor molecule (TRAM), TIR domain-containing adapter protein (TIRAP), or myeloid differentiation primary response protein 88 (MyD88), and induce transcription of type I interferons or inflammatory cytokines. Type I interferons mediate diverse effects on immune system cells, including maturation of dendritic cells, increased immunoglobulin (Ig) class switching, and induction of cytokines that promote autoimmunity and inflammation, including B-lymphocyte stimulator (BLyS), interleukin-10 (IL-10), interferon-γ, and chemokines. LPS = lipopolysaccharide.

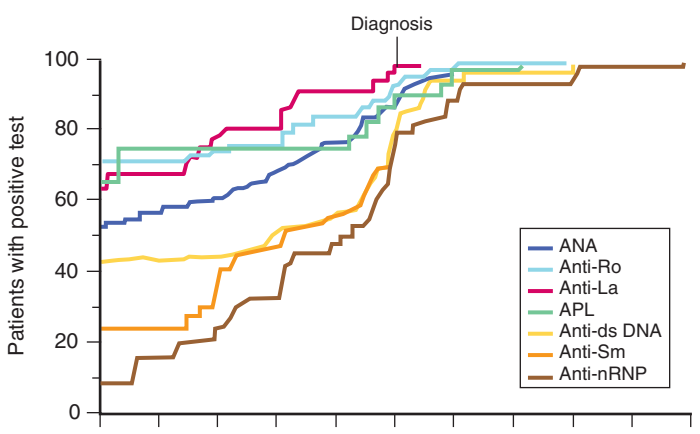


FIGURE 266-1. Proportion of patients with positive antibody tests relative to the time of diagnosis or appearance of the first clinical manifestation of systemic lupus erythematosus (SLE). For each autoantibody, the proportion of patients testing positive relative to the time of diagnosis or to the time of appearance of the first clinical criterion was assessed. In analyses of the time from antibody development to the diagnosis of SLE, antinuclear antibodies (ANAs) appeared significantly earlier than anti-Sm antibodies and antinuclear ribonucleoprotein (anti-nRNP) antibodies, but not significantly earlier than anti-Ro, anti-La, antiphospholipid (APL), or anti–double-stranded DNA antibodies (anti-dsDNA). (From Arbuckle MR, McClain MT, Rubertone MV, et al. Development of autoantibodies before the clinical onset of systemic lupus erythematosus. *N Engl J Med.* 2003;349:16.)

to the surfaces of pathogens or self-tissues. C3a, an anaphylatoxin that binds to receptors on leukocytes and other cells, causes activation and release of inflammatory mediators. C5a is a potent soluble inflammatory, anaphylatoxic, and chemotactic molecule that promotes recruitment and activation of neutrophils and monocytes and mediates endothelial cell activation through its receptor. The release of reactive oxygen and nitrogen intermediates is an additional mechanism that contributes to tissue damage.

Tissues targeted by immune system activity in lupus include the skin, where immune complexes and complement are deposited in a linear pattern (as demonstrated in the lupus band test, in which deposited antibodies are identified by a fluorescent tag), the glomeruli, and heart valves. Antibodies reactive with hippocampal neurons in the brain can mediate excitotoxic death. Immune and inflammatory mechanisms responsible for the vasculopathy of lupus are multifactorial and not clearly defined. Microvascular damage is observed in splenic arteries and is characterized by the typical onion-skin pattern of concentric connective tissue deposition. In addition to vascular damage mediated by inflammation, thrombosis, including microthrombi, contributes to ischemia and cell necrosis in the brain and other organs.

CLINICAL MANIFESTATIONS

Symptoms and Signs

Constitutional Symptoms

SLE is a disease that involves virtually all components of the immune system and can be accompanied by constitutional symptoms similar to those seen in the setting of microbial infection. Fatigue, headaches, weight loss, and fevers are common, along with generalized arthralgias, myalgias, and lymphadenopathy. The level of activity of lupus typically follows a pattern of flares and remissions, although some patients sustain active disease for prolonged periods. Careful monitoring for the development of major organ system disease is important to ensure timely adjustments in medical therapy.

Cutaneous and Mucous Membranes

The skin and mucous membranes are affected in most lupus patients (Table 266-1). The erythematous facial rash with a butterfly distribution across the malar and nasal prominences and sparing of the nasolabial folds is the classic rash of SLE and is seen in 30 to 60% of patients (Fig. 266-2). The butterfly rash is often triggered by sun exposure, but photosensitivity can also be demonstrated diffusely in other areas of the body.

The discoid skin lesions are erythematous plaques with central scarring and may be covered with scale. These lesions are seen in about 25% of patients, involve the scalp or the face and ears, and may be associated with alopecia. Discoid lesions can be present in the absence of systemic manifestations of SLE (discoid lupus). In addition to the scarring alopecia of discoid lupus, more transient alopecia may be a clinical sign of increased disease activity and is associated with apoptosis of cells in the hair follicle.

Inflammation of the deep dermis and subcutaneous fat can result in lupus panniculitis, with firm painful nodules that sometimes adhere to the epidermis, causing irregularities in the superficial skin. Subacute cutaneous lupus erythematosus is seen in sun-exposed areas and can involve erythematous plaques or psoriasiform lesions. It is associated with autoantibodies to the Ro (SSA) RNA-binding protein. Mucosal ulcerations, especially of the buccal mucosa and upper palate, result from mucositis and are typical of SLE. Manifestations of vasculopathy are also common in SLE, including arteriolar spasm or infarcts in the nail folds, a diffuse lacey pattern over the skin described as livedo reticularis, and petechial-purpuric or urticarial lesions on the extremities. Vasculopathy in SLE is often associated with the presence of antiphospholipid antibodies.

Musculoskeletal System

Arthralgias and nonerosive arthritis are among the most common clinical features of SLE and are experienced by more than 85% of patients. The

proximal interphalangeal and metacarpophalangeal joints of the hand are most commonly symptomatic, along with the knees and wrists. In some patients (≈10%), deformities resulting from damage to periarticular tissue can occur, a condition termed *Jaccoud arthropathy*. The heavy use of corticosteroids in many lupus patients can be accompanied by the development of osteoporosis, including osteoporotic fractures or osteonecrosis, most commonly of the hips, although the underlying vasculopathy can also contribute to joint damage.

Inflammation of the muscles with elevated creatine phosphokinase can occur rarely in SLE, and myopathy may be observed as a consequence of corticosteroid therapy. Fibromyalgia, characterized by painful trigger points at characteristic locations, commonly accompanies SLE and can contribute to fatigue and depression.

Renal System

Kidney involvement in SLE is common, with 74% of patients being affected at some time in the course of disease, and is a poor prognostic indicator. Renal pathology is generally attributed to the deposition of circulating immune complexes or in situ formation of these complexes in glomeruli and results in the activation of complement and subsequent recruitment of inflammatory cells. In addition to glomerular inflammation, necrosis, and scarring, renal pathology is characterized by vascular lesions, including thrombotic microangiopathy and extraglomerular vasculitis. Tubulointerstitial disease, including infiltration of the interstitium with mononuclear cells, tubular atrophy, and interstitial fibrosis, is increasingly recognized as associated with a poor prognosis for persistent nephritis and renal survival. Hypertension may be a consequence of significant renal involvement.

Most cases of lupus nephritis present a complex immunopathologic picture, but in general, the pattern of renal disease reflects the site of deposition of immunoglobulins and the quality of the effector mechanisms they induce. Mesangial deposition of immunoglobulin induces mesangial cell proliferation and is associated with microscopic hematuria and mild proteinuria (Fig. 266-3). Subendothelial deposition of immune complexes results in proliferative and exudative inflammation, together with hematuria, mild to moderate proteinuria, and reduced glomerular filtration rate. Subepithelial deposition of immune complexes adjacent to podocytes and along the glomerular basement membrane can result in membranous nephritis with nephrotic-range proteinuria. In addition, antiphospholipid antibodies may support the development of thrombotic or inflammatory vascular lesions within or external to glomeruli.

A World Health Organization classification of lupus nephritis lesions was first published in 1975, with subsequent revisions. These classifications were reviewed and rigorously reexamined in the revised International Society of Nephrology and Renal Pathology Society classification criteria for lupus glomerulonephritis (GN) (Table 121-7 in Chapter 121, and also E-Table 266-2). Class I and II GN involves mesangial deposition of immune complexes (class I without and class II with mesangial hypercellularity); class III describes focal GN involving less than 50% of total glomeruli; class IV includes diffuse GN involving 50% or more of glomeruli; class V designates membranous lupus nephritis; and class VI is characterized by advanced sclerotic lesions. Classes III and IV have subdivisions for active and sclerotic lesions, and class IV also has subdivisions for segmental and global involvement. Pathologic diagnosis should include descriptions of tubulointerstitial and vascular disease as well as glomerular involvement.

The prognosis of class I and class II disease is usually good, whereas class IV, the most common form of lupus nephritis, has the worst prognosis, particularly when the serum creatinine level is elevated at the time of diagnosis. Class V nephritis occurs in 10 to 20% of patients, and the implication for long-term outcome depends on the degree of proteinuria, with mild proteinuria having a good prognosis and nephrotic syndrome with chronic edema having a more negative prognosis. It should be noted that renal veins can occasionally become involved with thrombosis, which then also contributes to nephrotic syndrome. This complication can be evaluated by renal ultrasound (Chapter 121).

Cardiovascular System

Pericarditis and valve nodules were among the first clinical manifestations described in SLE. It is only recently that the extent of premature atherosclerotic disease has been well documented. Pericarditis (Chapter 77) is the most common cardiac manifestation, but it is sometimes recognized only on imaging studies or at autopsy. It is a component of the generalized serositis that is often a feature of SLE and is associated with local autoantibodies and

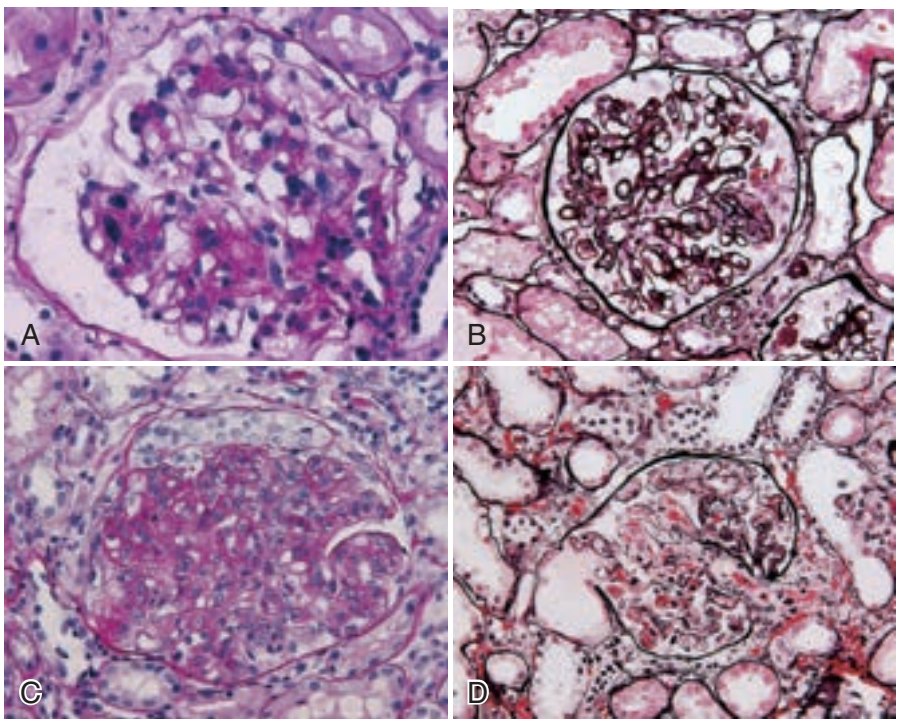

FIGURE 266-3. Histopathology of lupus nephritis. A, Lupus nephritis class II. A light micrograph of a glomerulus shows mild mesangial hypercellularity (periodic acid–Schiff). **B**, Lupus nephritis class III (A). Light micrograph showing a glomerulus with segmental endocapillary hypercellularity, mesangial hypercellularity, capillary wall thickening, and early segmental capillary necrosis (methenamine silver). **C**, Lupus nephritis class IV-G (A/C). A glomerulus manifests global endocapillary proliferation, leukocyte influx and apoptotic bodies, double contours, crescent formation with tubular transformation, early sclerosis, and disruption of Bowman's capsule (periodic acid–Schiff). **D**, Thrombotic microangiopathy in a patient with systemic lupus erythematosus and circulating anticoagulant. A glomerulus shows severe capillary and arteriolar thrombosis, endothelial cell swelling and necrosis, neutrophil influx, and stasis of erythrocytes. No signs of immune deposits were found (methenamine silver). (From Wenning JJ, D'Agati VD, Schwartz MM, et al. The classification of glomerulonephritis in systemic lupus erythematosus revisited. *J Am Soc Nephrol.* 2004;15:241.)

E-TABLE 266-2 INTERNATIONAL SOCIETY OF NEPHROLOGY/RENAL PATHOLOGY SOCIETY 2003 CLASSIFICATION OF LUPUS NEPHRITIS

Class I	**Minimal mesangial lupus nephritis** Normal glomeruli by light microscopy, but mesangial immune deposits by immunofluorescence
Class II	**Mesangial proliferative lupus nephritis** Purely mesangial hypercellularity of any degree or mesangial matrix expansion by light microscopy, with mesangial immune deposits. May be a few isolated subepithelial or subendothelial deposits visible by immunofluorescence or electron microscopy, but not by light microscopy
Class III	**Focal lupus nephritis*** Active or inactive focal, segmental, or global endocapillary or extracapillary glomerulonephritis involving < 50% of all glomeruli, typically with focal subendothelial immune deposits, with or without mesangial alterations
Class III (A)	Active lesions: focal proliferative lupus nephritis
Class III (A/C)	Active and chronic lesions: focal proliferative and sclerosing lupus nephritis
Class III (C)	Chronic inactive lesions with glomerular scars: focal sclerosing lupus nephritis
Class IV	**Diffuse lupus nephritis**† Active or inactive diffuse, segmental or global endocapillary or extracapillary glomerulonephritis Involving ≥ 50% of all glomeruli, typically with diffuse subendothelial immune deposits, with or without mesangial alterations. This class is divided into diffuse segmental (IV-S) lupus nephritis when ≥ 50% of the involved glomeruli have segmental lesions, and into diffuse global (IV-G) lupus nephritis when ≥ 50% of the involved glomeruli have global lesions. Segmental is defined as a glomerular lesion that involves less than half of the glomerular tuft. This class includes cases with diffuse wire loop deposits but with little or no glomerular proliferation.
Class IV-S (A)	Active lesions: diffuse segmental proliferative lupus nephritis
Class IV-G (A)	Active lesions: diffuse global proliferative lupus nephritis
Class IV-S (A/C)	Active and chronic lesions: diffuse segmental proliferative and sclerosing lupus nephritis Active and chronic lesions: diffuse global proliferative and sclerosing lupus nephritis
Class IV-S (C)	Chronic inactive lesions with scars: diffuse segmental sclerosing lupus nephritis
Class IV-G (C)	Chronic inactive lesions with scars: diffuse global sclerosing lupus nephritis
Class V	**Membranous lupus nephritis** Global or segmental subepithelial immune deposits or their morphologic sequelae by light microscopy and by immunofluorescence or electron microscopy, with or without mesangial alterations Class V lupus nephritis may occur in combination with class III or IV, in which case both will be diagnosed Class V lupus nephritis shows advanced sclerosis
Class VI	**Advanced sclerosis lupus nephritis** ≥90% of glomeruli globally sclerosed without residual activity

*Indicate the proportion of glomeruli with active and with sclerotic lesions.
†Indicate the proportion of glomeruli with fibrinoid necrosis and/or cellular crescents.
From Weening JJ, D'Agati VD, Schwartz MM, et al. The classification of glomerulonephritis in systemic lupus erythematosus revisited. *J Am Soc Nephrol.* 2004;15:241.

immune complexes. Pericarditis is usually manifested as substernal chest pain that is improved by bending forward and can be exacerbated by inspiration or coughing. The symptoms and effusions associated with pericarditis are quite responsive to moderate-dose (20 to 30 mg/day of prednisone) corticosteroid treatment.

Structural valve abnormalities in SLE range from sterile nodules (originally described by Libman and Sacks) to nonspecific valve thickening (Chapter 75). The nodules are immobile and usually located on the atrial side of the mitral valve and sometimes on the arterial side of the aortic valve. Right-sided lesions are rare. These structural changes may in some cases result in valvular regurgitation. Although valve nodules are detected in most patients with SLE at autopsy, clinically significant valvular heart disease is much less common (1 to 18%). The verrucous valvular lesions of Libman and Sacks are most likely inflammatory in nature and may be associated with the presence of antiphospholipid antibodies.

Premature and accelerated atherosclerosis is prevalent in lupus patients, and preclinical atherosclerotic carotid plaque has been documented in 37% of SLE patients as opposed to 15% of age- and sex-matched controls. Traditional cardiovascular risk factors apply, but the diagnosis of SLE is itself a significant risk factor for premature atherosclerosis (Chapter 70). Among the lupus-related mechanisms that confer additional risk for atherosclerosis, IFN-α and oxidative modification of lipid-associated proteins contribute to the accumulation of vascular damage.[9] Mortality from atherosclerosis may be up to 10 times greater in patients with SLE than in age- and sex-matched controls.

Although not specific to SLE, Raynaud's phenomenon (Chapter 80), characterized by episodic vasospasm and occlusion of the digital arteries in response to cold and emotional stress, is a feature in up to 60% of SLE patients and contributes to pain and sometimes necrosis of the distal ends of extremities. The character of the digits classically changes from pallor to cyanosis and then to rubor as vascular perfusion becomes impaired and then reperfusion ensues. In addition, small arteries, arterioles, and capillaries can be affected by vasculitis and fibrinoid necrosis, with clinical manifestations that include periungual telangiectases, abdominal pain, and neuropsychiatric symptoms.

Pulmonary System

Pleuritis is the most frequent manifestation of pulmonary involvement in SLE and occurs in about 30% of patients at some point in their disease course. Pleuritis is characterized by pain on respiration and exudative effusions (Chapter 99). Parenchymal disease is less common but may be based on several distinct mechanisms, including pneumonitis in the absence of documented infection and sometimes involving alveolar hemorrhage (in up to 12% of patients), pulmonary embolism secondary to venous thrombosis, or pulmonary hypertension with increased pulmonary resistance and impaired diffusing capacity.

Neuropsychiatric Involvement

Clinical features of SLE that involve the nervous system include both neurologic and psychiatric manifestations. The central and peripheral nervous systems can be affected by the disease. The American College of Rheumatology has identified 19 neuropsychiatric syndromes that can be associated with SLE, and validation of these neuropsychiatric findings has been substantiated in several independent studies. The most common manifestations that are probably attributable to SLE cerebritis include cognitive dysfunction, present in 17 to 66% of SLE patients; psychosis or mood disorder, the former reported in up to 8% of patients; cerebrovascular disease in 5 to 18% of patients; and seizures, present in 6 to 51% of patients. Headaches are also common. Because none of these CNS manifestations is found exclusively in SLE, it can be difficult to be certain that a neuropsychiatric complaint or symptom should be attributed to SLE.

Evaluation of neuropsychiatric lupus depends on a careful clinical history and physical and laboratory examinations and, in some cases, imaging studies and analysis of cerebrospinal fluid to rule out infection. Magnetic resonance imaging is useful for detecting intracranial abnormalities, which are seen in 19 to 70% of patients and include white matter lesions, cerebral infarction, venous sinus thrombosis, and sometimes atrophy. More sophisticated imaging techniques such as magnetic resonance angiography and magnetic resonance spectroscopy can be used to assess cerebral blood flow or neuronal metabolism.

Cranial nerve and ocular involvement, most likely based on vasculopathy and focal ischemia, can sometimes affect vision. Ocular examination of the retina can reveal cotton-wool spots as a result of retinal ischemia or necrosis. Although rare, transverse myelopathy, frequently associated with antiphospholipid antibodies, can have devastating consequences, including paraplegia. Sensorimotor neuropathies, often asymmetrical, are more common (up to 28%) and are based on damage to small nerve fibers with vasculopathy in the small arteries that supply the nerve fibers.

As is the case with lupus nephritis, the pathophysiologic mechanisms that account for the neuropsychiatric manifestations of SLE are diverse and complex. Recent data suggest that autoantibodies cross-reactive with neuronal cell surface glutamate receptors and DNA may mediate excitotoxic death of neurons and are proposed to contribute to cognitive dysfunction. Antibodies directed against ribosomal P protein have also been associated with neuropsychiatric lupus, and antiphospholipid antibodies can contribute to a procoagulant state, vascular thrombosis, and cerebral ischemia. Cerebral vasculopathy has been clearly demonstrated by angiographic and pathologic studies. Noninflammatory small vessel vasculopathy is the most common lesion and can be associated with microinfarcts. Inflammatory mediators, including the cytokines interleukin (IL)-6 and IFN-α, and matrix metalloproteinases may also contribute to the neuropsychiatric manifestations of SLE.

Gastrointestinal System

Although uncommon, vasculitis of the gastrointestinal tract or mesentery can result in pain and bowel necrosis. Less common than pleuritis and pericarditis, peritonitis can manifest as peritoneal effusion and abdominal pain. Pancreatitis occurs in less than 10% of patients but may also be due to vascular pathology. Lupoid hepatitis, a syndrome that was named for the presence of positive ANAs in patients with chronic active hepatitis, is a misnomer because elevated transaminases are only rarely seen in lupus patients.

Lymphadenopathy

About one third of SLE patients demonstrate diffuse lymphadenopathy at some time during the course of their disease. The nodes are often nontender, and lymphoma is sometimes considered in the differential diagnosis. Biopsy usually reveals follicular hyperplasia, although some histopathologic findings appear similar to the histiocytic necrotizing lymphadenitis that is a feature of Kikuchi's disease, a self-limited syndrome characterized by fever and lymphadenopathy. Recent multicenter studies have determined the frequency of malignancies in patients with SLE and have found a significant increase in hematologic malignancies, particularly non-Hodgkin's lymphoma. Splenomegaly is sometimes seen in SLE, and spleen pathology is characterized by a classic onion-skin histology that appears as concentric circles of collagen matrix surrounding splenic arteries and arterioles.

Hematologic System

In addition to autoantibody specificities that are fairly specific for SLE (anti-DNA, anti-Sm), antibodies that target each of the cellular blood elements are also common. Anemia is present in about 50% of patients and is multifactorial. It can be associated with a positive Coombs test or microangiopathic hemolysis (Chapter 160) or reflect chronic disease (normochromic, normocytic) (Chapter 158). Leukopenia, particularly lymphopenia, is observed, with the lymphocyte count decreasing in the setting of increased disease activity. Antibodies that bind to lymphocytes and neutrophils have been described, and an increased tendency for lymphocytes to undergo spontaneous apoptosis may contribute to lymphopenia. Idiopathic thrombocytopenic purpura (Chapter 172) can be an early manifestation of SLE, and thrombocytopenia induced by antiplatelet autoantibodies can sometimes lead to a life-threatening risk for hemorrhage. Autoantibodies to clotting factors can also occur and contribute to impaired clot formation and hemorrhage.

Lupus Pregnancy and Neonatal Lupus

Whether pregnancy increases the likelihood of lupus exacerbation has been debated, with differences on this point presented by different investigators. However, abundant data indicate that patients with SLE have worse fetal outcomes than healthy individuals.[10] Gestational hypertension, fetal growth restriction, and fetal distress are increased in patients with SLE and may lead to fetal loss or premature delivery. Preeclampsia can contribute to a poor outcome in both the mother and fetus and can be difficult to distinguish from a lupus flare associated with lupus nephritis.

Neonatal lupus is a distinct entity that can occur in infants of mothers with or without a diagnosis of SLE.[11] The syndrome is characterized by cutaneous lesions and congenital heart block in the infant and the presence of antibodies

TABLE 266-2 UPDATE OF THE 1982 REVISED CRITERIA FOR CLASSIFICATION OF SYSTEMIC LUPUS ERYTHEMATOSUS

CRITERION*	DEFINITION
1. Malar rash	Fixed erythema, flat or raised, over the malar eminences that tends to spare the nasolabial folds
2. Discoid rash	Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions
3. Photosensitivity	Rash as a result of unusual reaction to sunlight, by history or physician observation
4. Oral ulcers	Oral or nasopharyngeal ulceration, usually painless, observed by a physician
5. Arthritis	Nonerosive arthritis involving 2 or more peripheral joints and characterized by tenderness, swelling, or effusion
6. Serositis	A. Pleuritis—convincing history of pleuritic pain or rubbing heard by a physician or evidence of pleural effusion *or* B. Pericarditis—documented by electrocardiography, a rub, or evidence of pericardial effusion
7. Renal disorder	A. Persistent proteinuria > 0.5 g/day or > 3+ if quantitation is not performed *or* B. Cellular casts—may be red cell, hemoglobin, granular, tubular, or mixed
8. Neurologic disorder	A. Seizures—in the absence of offending drugs or known metabolic derangements (e.g., uremia, ketoacidosis, electrolyte imbalance) *or* B. Psychosis—in the absence of offending drugs or known metabolic derangements (e.g., uremia, ketoacidosis, electrolyte imbalance)
9. Hematologic disorder	A. Hemolytic anemia—with reticulocytosis *or* B. Leukopenia—<4000/mm^3 total on 2 or more occasions *or* C. Lymphopenia—<1500/mm^3 on 2 or more occasions *or* D. Thrombocytopenia—<100,000/mm^3 in the absence of offending drugs
10. Immunologic disorder	A. Deleted in 1997 update B. Anti-DNA: antibody to native DNA in abnormal titer *or* C. Anti-Sm: presence of antibody to Sm nuclear antigen *or* D. Positive finding of antiphospholipid antibodies based on (1) an abnormal serum level of immunoglobulin (Ig)G or IgM anticardiolipin antibodies, (2) a positive test for lupus anticoagulant using a standard method, or (3) a false-positive serologic test for syphilis known to be positive for at least 6 months and confirmed by *Treponema pallidum* immobilization or the fluorescent treponemal antibody absorption test (modified in the 1997 update)
11. Antinuclear antibody	An abnormal titer of antinuclear antibody by immunofluorescence or an equivalent assay at any point in time and in the absence of drugs known to be associated with "drug-induced lupus" syndrome

***The proposed classification is based on 11 criteria. For the purpose of identifying patients in clinical studies, a person shall be said to have systemic lupus erythematosus if any 4 or more of the 11 criteria are present, serially or simultaneously, during any interval of observation.**

Modified from Tan EM, Cohen AS, Fries JF, et al. The 1982 revised criteria for the classification of systemic lupus erythematosus. *Arthritis Rheum.* 1982;25:1271.

to the Ro (SSA) or La (SSB) RNA-binding proteins (or both) in the mother. Mortality in babies with a congenital heart block is 15 to 31%. Deposition of anti-Ro IgG in the fetal heart, indicative of transplacental transfer of maternal autoantibody, and dense connective tissue encompassing the conduction system have been demonstrated in autopsy specimens. Prenatal testing of lupus mothers for the presence of anti-Ro and anti-La antibodies is appropriate, and careful monitoring with fetal echocardiography starting at week 16 of pregnancy can detect conduction defects. Fluorinated corticosteroids such as dexamethasone have been effective in reversing heart block in some cases. The role of hydroxychloroquine in prevention of neonatal lupus manifestations is under investigation.

Antiphospholipid Antibody Syndrome

Antiphospholipid antibodies represent a distinct class of autoantibodies that are seen in about one third of SLE patients but can also be present in individuals who do not carry a diagnosis of SLE (Chapter 171). Although these antibodies were initially thought to be specific for phospholipids exposed in cell membranes, particularly after "flipping" of the membranes of apoptotic cells, extensive data support their primary reactivity with phospholipid-binding proteins, particularly β_2GPI. Whether in primary antiphospholipid syndrome or in SLE, antiphospholipid antibodies have been associated with venous and arterial thromboses.[12] In addition to vascular thromboses, clinical manifestations of antiphospholipid syndrome include thrombotic microangiopathic glomerular disease, cardiac valve lesions, livedo reticularis, thrombocytopenia, hemolytic anemia, and CNS disease. Recent data indicate that these autoantibodies can contribute to fetal loss and growth restriction by binding to the placenta, activating the complement system, and inducing inflammation. Catastrophic antiphospholipid syndrome, triggered by the acute onset of multisystemic (three or more organs) thrombosis, is resistant to anticoagulation treatment and is fatal in approximately 50% of cases.[13]

DIAGNOSIS

Classification

Criteria for the classification of patients with SLE for the purpose of clinical studies were developed by the American College of Rheumatology, with the most recent full revision published in 1982 and an update published in 1997 (Table 266-2). The criteria include 11 features that encompass manifestations of skin and mucosal involvement, arthritis, serositis, renal disorder, neurologic disorder, hematologic disorder, immunologic disorder, and an abnormal titer in the ANA test, with at least four criteria required for classification as SLE. ANA has low specificity but strengthens the sensitivity of the criteria because it is positive in virtually all lupus patients. These criteria are not intended for use as diagnostic criteria, because more than 50% of patients with SLE do not meet four criteria at any point in time, although all do meet these criteria at some point during the course of the disease. The criteria are useful in reminding the clinician of the most characteristic features of SLE, but a careful history with detailed review of systems and triggering factors, as well as a family history, is essential in raising suspicion for a diagnosis of SLE. Because drugs can trigger a lupus-like syndrome, a careful drug history should be taken. Procainamide and hydralazine present the greatest risk for development of lupus, with quinidine, isoniazid, minocycline, and recombinant interferon-α presenting a lower risk. At the onset of clinical symptoms, the diagnosis of SLE can be uncertain because many of the systemic manifestations of lupus can mimic other conditions, particularly viral infections or malignancy, and only some of the typical clinical symptoms may be expressed at any one point in time. Important features of SLE are its multisystemic nature and characteristic serology. The differential diagnosis of SLE includes other rheumatic disorders, such as rheumatoid arthritis and vasculitis; infections, including gonococcal arthritis, parvovirus B19, and mononucleosis; inflammatory bowel disease; thrombotic thrombocytopenic purpura; drug reactions; and malignancies, particularly lymphoma. It should be recognized that the clinical manifestations of lupus can demonstrate overlap with those of other autoimmune rheumatic diseases and can evolve over time. Many genetic, environmental, and immunologic factors associated with lupus are also associated with other systemic autoimmune diseases, often contributing to a complex clinical picture.

Laboratory Findings

Laboratory tests can be very helpful in supporting the diagnosis of SLE. All cellular elements of blood can be affected in lupus, so the complete blood

count is an essential test that aids in diagnosis and management. A prolonged activated partial thromboplastin time (aPTT) can indicate the presence of pathogenic antiphospholipid antibodies (Chapter 171). These antibodies are also associated with a false-positive result in the serologic test for syphilis, an observation that is mainly of historical interest.

Evaluation of renal disease in SLE includes urinalysis with microscopic analysis of urine sediment, serum blood urea nitrogen and creatinine, and 24-hour urine collection (or alternatively, spot urine protein-to-creatinine ratio) for estimation of protein and creatinine clearance. Low serum albumin would be consistent with persistent proteinuria and membranous GN, whereas red and white blood cell casts in the urinary sediment suggest proliferative GN. Although a renal biopsy is usually performed only when the result may influence therapeutic decisions, pathologic classification of the features of renal disease can provide prognostic information.

The erythrocyte sedimentation rate (ESR), although a very nonspecific indicator of systemic inflammation, is often monitored and in many patients can provide an indication of disease activity. Interestingly, C-reactive protein, an acute phase reactant, is relatively uninformative in SLE because it is often low in comparison to an ESR performed on the same occasion.

Assaying and monitoring characteristic lupus serologic tests can strongly support the diagnosis of SLE and, in some cases, can assist in the assessment of disease activity. The ANA test is positive in virtually all patients and does not need to be repeated once it has been documented to be positive (Table 266-3). Anti–double-stranded DNA antibodies are common in SLE, and some studies have found that monitoring their titer can be useful in assessing the activity of lupus nephritis. Autoantibodies specific for proteins that associate with nucleic acids in intracellular particles are present in many patients and can provide support for a diagnosis of SLE. Anti-Sm antibodies are highly specific for SLE and, along with anti-RNP antibodies, react with the spliceosome particle. Anti-Ro (SSA) and anti-La (SSB) antibodies are specific for proteins in an RNA-containing particle and are common in patients with Sjögren's syndrome and in mothers of babies with neonatal lupus, as well as being a feature of SLE. It is useful to document the presence of anti-Sm, anti-RNP, anti-Ro, and anti-La antibodies when the diagnosis of SLE is being made, but the titers of these autoantibodies are not helpful in monitoring disease activity.

Proteins of the complement system are activated by immune complexes, such as those that form in patients with SLE. The activation products that result from enzymatic cleavage of the complement components promote inflammation directly by binding to cell surface receptors on mononuclear phagocytes, and indirectly by acting as chemotactic agents to recruit inflammatory cells. Decreased levels of two of the more stable complement components, C3 and C4, are typically measured in serum, and decreased C3 and C4 levels are often indicators of enhanced consumption and increased disease activity. Some laboratories also use a functional measure of total hemolytic complement activity (CH_{50}).

It is the global picture provided by a careful history, physical examination, and blood, urine, and serologic data that supports a diagnosis of SLE. It should be recognized that there is considerable heterogeneity among patients and that different combinations of clinical features will characterize any one individual. As is the case with many systemic diseases, infection and some malignancies may have a similar picture and should be included in the differential until the diagnosis of SLE is secure.

TABLE 266-3 AUTOANTIBODIES ASSOCIATED WITH SYSTEMIC LUPUS ERYTHEMATOSUS

TARGET ANTIGEN	APPROXIMATE FREQUENCY
Nuclear antigens	99
dsDNA	70
Sm	38
RNP (U1-RNP)	33
Ro (SSA)	49
La (SSB)	35
Phospholipids	21
Ribosomal P	10

TREATMENT

Although current knowledge of genetic risk factors for SLE is not sufficient to predict those in whom the disease will develop, once the diagnosis has been made, regular counseling and education are fundamental to the treatment of SLE patients. Patients should be advised to avoid known triggers of disease exacerbation, such as ultraviolet light, and should be instructed regarding the need for adequate rest. Pregnancy should be undertaken with caution and with careful monitoring. Lupus patients can be informed that data indicate that oral contraceptive agents and estrogen replacement therapy do not contribute to disease exacerbations.

Conventional Medical Therapy

Clinical manifestations of lupus that do not involve major organ systems can often be managed with nonsteroidal anti-inflammatory drugs, low-dose corticosteroids, and antimalarials. Corticosteroids (Chapter 35) are immunosuppressive agents that modulate many functions of lymphocytes and monocytes, including the production of proinflammatory cytokines. Oral prednisone in doses ranging from 5 to 30 mg daily is effective in treating constitutional symptoms, arthralgias, pericarditis and pleuritis, and skin disease. Topical corticosteroids are sometimes applied to cutaneous lesions. Although effective, corticosteroids also have toxicities that add to the morbidity associated with lupus. The broad immunosuppression mediated by these drugs contributes to the susceptibility to infection that is an inherent feature of SLE. Osteonecrosis, osteoporotic fractures, posterior subcapsular cataracts, diabetes, myopathy, hypertension, hypoadrenalism, and emotional disturbance are additional deleterious effects of corticosteroids.

Antimalarial agents, most commonly hydroxychloroquine administered at 200 to 400 mg/day, have long been used to control skin involvement and arthralgias and are now routinely used in most lupus patients. An important Canadian study demonstrating an increased frequency of disease flare in patients who discontinued hydroxychloroquine contributed to its recent use in lupus for a broader range of clinical manifestations. Hydroxychloroquine has been associated with a decreased incidence of thrombosis, a mechanism that could affect vasculopathy and end-organ damage. An additional potential mechanism of action implicates the TLR pathway, which is responsible for activation of the innate immune response.[14] The effects of antimalarial agents on acidification of the intracellular vesicles where TLRs associate with their ligands may inhibit immune cell activation mediated by stimulatory nucleic acids. Antimalarials are well tolerated. Because they can rarely cause eye toxicity, ophthalmologic examinations should precede initiation of therapy and take place every 6 to 12 months.

Management of Serious Organ-System Disease

For more serious disease, particularly active nephritis, CNS disease, or systemic vasculitis, prednisone at 60 mg daily or 1 g of intravenous methylprednisolone administered daily for 3 days can sometimes gain control of disease activity. In many situations, additional immunosuppressive, cytotoxic, or biologic therapies are required. Because lupus nephritis is the most common severe clinical organ-system manifestation of SLE, an algorithm describing guidelines for medical management of lupus nephritis developed by a Task Force Panel assembled by the American College of Rheumatology is useful (Fig. 266-4).[15] A similar approach can be applied to other serious clinical disease flares. Lupus flares involving rapid decompensation of renal function, CNS disease (including seizures, strokes, or psychosis), or widespread vasculitis or vasculopathy can be life-threatening and must be recognized and treated early and aggressively.[16] Careful attention to monitoring for concurrent or superimposed infection is an important priority during management of a severe lupus flare, and distinguishing sepsis from active lupus or catastrophic antiphospholipid syndrome can be a particular challenge. In general, cyclophosphamide is added to high-dose corticosteroid therapy in the setting of severe flare, although mycophenolate mofetil has gained increased use in situations where the physician or patient wishes to avoid the potential toxicities associated with cyclophosphamide. Randomized controlled studies have investigated options for maintaining improvement in those patients who respond to induction therapy in the setting of lupus nephritis flare, with current data favoring mycophenolate mofetil over azathioprine. One biologic agent, belimumab, a monoclonal antibody reactive with BLyS, has been approved by the U.S. Food and Drug Administration (FDA) for treatment of active autoantibody-positive SLE in conjunction with standard therapies, but belimumab has not yet been tested in patients with lupus nephritis or other severe manifestations of lupus. Agents used in management of lupus are reviewed below.

Immunosuppressive Agents

Alkylating Agents

Approximately 33% of lupus patients receive cytotoxic therapy during the course of their disease. Cyclophosphamide is a cytotoxic agent that has been one of the more reliable and studied treatments for severe organ system manifestations of lupus, particularly lupus nephritis and CNS involvement.

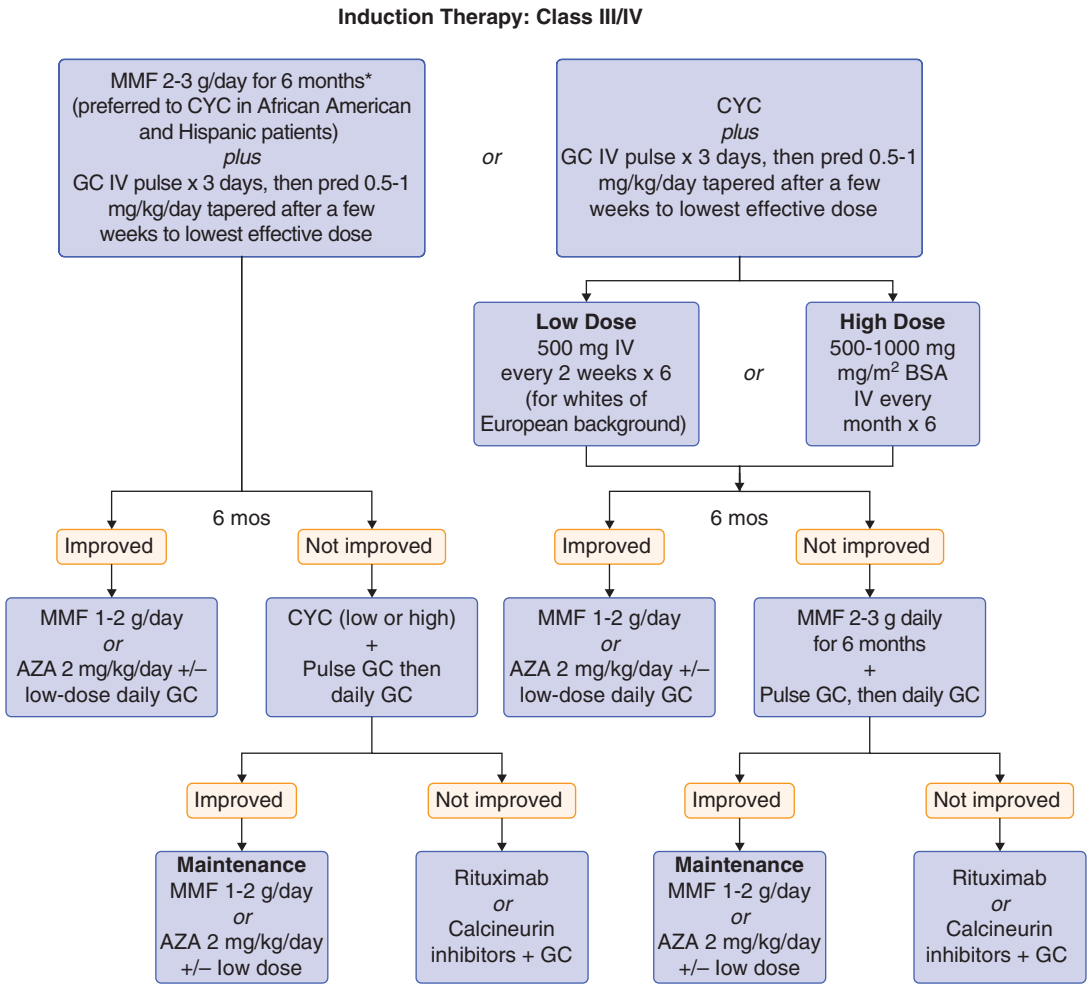

FIGURE 266-4. Algorithm for induction therapy for lupus nephritis. Guidelines developed by the Task Force Panel of the American College of Rheumatology for management of class III/IV lupus nephritis. Refer to reference 15 for guidelines for management of class III/IV lupus nephritis with crescents and class V membranous lupus nephritis without proliferative changes and nephrotic range proteinuria. *The Task Force Panel preferred MMF over CYC in patients who desire to preserve fertility. AZA = azathioprine; BSA = body surface area; CYC = cyclophosphamide; GC = glucocorticoid; IV = intravenous; MMF = mycophenolate mofetil; pred = prednisone. (From Hahn BH, McMahon MA, Wilkinson A, et al. American College of Rheumatology guidelines for screening, treatment, and management of lupus nephritis. *Arthritis Care Res (Hoboken)*. 2012;64:797-808.)

Studies performed at the National Institutes of Health in the 1980s led to recommendations of a standard regimen of cyclophosphamide, 0.5 to 1 g/m^2 body surface area administered intravenously monthly for 6 months, followed by quarterly doses through 2 years. Cyclophosphamide is usually given with oral prednisone in tapering doses or sometimes with pulse methylprednisolone. Although this regimen is often effective in controlling GN, overall patient survival has not been demonstrated to be increased, and cyclophosphamide is associated with significant toxicity, including cytopenia, infection, gonadal failure, and malignancy. Recent clinical studies have included modified immunosuppressive regimens, such as a 6-month induction followed by maintenance with less toxic immunosuppressive agents, including azathioprine or, even better, mycophenolate mofetil (MMF). Cyclophosphamide is relatively contraindicated in pregnant women.

Purine Synthesis Inhibitors

Azathioprine has been used for the treatment of lupus nephritis and as a steroid-sparing agent in SLE for many years. Azathioprine inhibits DNA synthesis and inhibits key signaling pathways in T lymphocytes. Azathioprine is commonly dosed at 2 to 3 mg/kg/day administered as a tablet. Toxicities of azathioprine target the bone marrow (and result in cytopenias) as well as the liver, occasionally resulting in transaminitis. Its use is rarely associated with non-Hodgkin's lymphoma (Chapter 185). It has been used safely in pregnant women.

MMF is an inhibitor that binds to the isoform of inosine monophosphate dehydrogenase that mediates purine synthesis in activated lymphocytes. It has a good track record of utility in inhibiting allograft rejection. Recent clinical trials have compared MMF with intravenous cyclophosphamide for induction therapy in lupus nephritis; the results demonstrated equivalence of MMF and cyclophosphamide in patients with lupus nephritis.[■] In a randomized trial, MMF (1 g twice daily) was more effective than azathioprine for the maintenance treatment of lupus nephritis, with treatment failure rates reduced from 32 to 16%.[■]

Methotrexate

Methotrexate is a folate antagonist that is commonly used in rheumatoid arthritis. A double-blind randomized placebo-controlled trial of oral methotrexate (15 to 25 mg/week for 6 months) in SLE controlled disease and allowed tapering of prednisone. The most responsive clinical manifestations were cutaneous and articular.

Ancillary and Other Therapies

Intravenous Gamma Globulin

Although positive data from controlled trials of intravenous gamma globulin are not available, case reports and clinical experience indicate that administration of pooled IgG fractions can sometimes be efficacious in gaining control of lupus disease activity that is refractory to other therapies. A common regimen is 2 g/kg in divided doses over a 3- to 5-day period. Several mechanisms have been proposed for this therapy, including blockade of Fc receptors, modulation of lymphocyte function through Fc receptors, increased catabolism of pathogenic immunoglobulin, and actions of the anti-idiotype antibody that is a component of the administered IgG.

Plasmapheresis

Removal of pathogenic antibodies and immune complexes is the goal of plasmapheresis, but there are scant data supporting the utility of this therapy. Nonetheless, plasmapheresis has been occasionally useful in lupus patients with life-threatening complications in which the clinical manifestations can be clearly attributed to pathogenic autoantibodies. In particular, plasmapheresis has been effective in cases of thrombotic thrombocytopenic purpura associated with SLE (Chapter 172).

Biologic Therapies

Biologic therapies (Chapter 36) are being actively investigated in clinical trials, but only one agent has been successful as yet in phase III studies. Belimumab, a monoclonal antibody, blocks a B-cell survival and differentiation

signal. At a dose of 1 mg/kg or 10 mg/kg intravenously on days 1 and 28 and then every 28 days for 48 weeks, belimumab reduced disease activity by both validated measures and physician global assessment and decreased autoantibody levels.[A9] In a second study, belimumab at a dose of 10 mg/kg administered intravenously on days 0, 14, and 28 and then every 28 days, the currently recommended regimen, for 72 weeks, added to standard therapy, significantly improved response rate, disease activity, and severe flares, and was generally well tolerated in SLE.[A10] The clinical settings that are most appropriate for the use of belimumab, which was approved by the FDA, will be determined by future clinical trials and clinical experience. Additional agents under investigation target B cells, T-cell activation, and cytokines.[17] Rituximab, a monoclonal antibody specific for the cell surface B-cell molecule CD20, is approved for use in B-cell lymphomas and has been used in some patients with SLE who are poorly responsive to other therapies. Rituximab depletes B cells, often for many months, and may limit T-cell activation by eliminating activated B cells that can serve as antigen-presenting cells. However, controlled clinical trials of rituximab in lupus have not shown efficacy. In a randomized double-blind placebo-controlled phase III trial in patients with active proliferative lupus nephritis, rituximab therapy led to more responders and greater reductions in anti-dsDNA and C3/C4 levels, but did not improve clinical outcomes after 1 year of treatment.[A11] Other agents that block B-cell survival and differentiation factors or target B-cell surface molecules are under study. T-cell targets include CD28 and inducible costimulator (ICOS), a T-cell surface molecule in the same molecular family as CD28 and CTLA4. Blockade of T-cell activation by CTLA4-Ig, a soluble inhibitor of CD28 ligation, or inhibition of ICOS-ICOS ligand interaction might inhibit B-cell differentiation in the germinal center. Monoclonal antibodies specific for most isoforms of IFN-α are under study and represent a rational approach in view of the strong genetic and immunologic role of type I interferon in many SLE patients.[18] IL-6 and IFN-γ represent additional cytokine targets under study.

Adjunctive Therapies

In addition to controlling autoimmunity and inflammation in SLE, it is essential to control hypertension adequately when it occurs. In those with lupus nephritis, treatment with an angiotensin inhibitor or an angiotensin receptor blocker reduces intraglomerular pressure, thus reducing proteinuria. In patients with a history of thrombosis, who will usually have antiphospholipid antibodies, long-term warfarin is recommended. The potential use of statins in lupus is of interest because those agents have anti-inflammatory as well as lipid lowering effects, but statins have not yet been shown efficacious in controlling lupus disease activity in controlled trials. The role of vitamin D supplementation in lupus is under study.

Future Directions

Recent advances in basic immunology, together with detailed molecular and clinical characterization of cohorts of SLE patients, have directed attention to the role adjuvant-like factors play in activating the innate immune response through TLRs. The primary triggers of that response are not known, but abundant data support production of type I interferon as an important consequence of immune activation that has an impact on many aspects of lymphocyte function, probably including induction of self-antigen–specific immune responses. In addition to the biologic therapies currently under study that target T and B lymphocytes, future therapies may be designed that can inhibit TLR activation, signaling components downstream from TLRs, cytoplasmic sensors of stimulatory nucleic acids, or type I interferon itself. Recognition that the complement system is an essential contributor to inflammation triggered by antiphospholipid antibodies, as well as by immune complexes, provides additional targets that might be inhibited therapeutically and limit tissue damage. Continued investigation of the genetic and environmental factors that contribute to disease susceptibility may permit identification of individuals at risk for the development of SLE and may elucidate the primary stimuli that lead to autoimmunity. Identification of informative biomarkers that reflect or even predict disease flares would improve medical management of lupus patients.

PROGNOSIS

Although survival of patients with a diagnosis of SLE is good, lupus remains a disease that is potentially fatal. SLE demonstrates a bimodal pattern of death, with deaths within the first year attributable to active lupus and infection and late deaths attributable to atherosclerotic cardiovascular disease. Recent cohort studies have estimated 5-year survival rates greater than 90%, with improvement in medical management probably contributing to improved outcomes, as opposed to earlier studies, and 85% survival rates at 10 years. However, once a diagnosis of SLE has been made, prolonged remission is rare. Of 702 patients registered in a lupus clinic in Canada, 6.5% achieved complete remission (score of 0 on the SLE Disease Activity Index), and only 1.7% maintained remission for at least 5 years with no treatment. The presence of any permanent organ damage within the first year after a diagnosis of SLE is associated with poorer survival at 10 years (a 75 vs. 95% rate in those without permanent organ damage). Regarding renal outcome, an elevated level of serum creatinine at the time of diagnosis has been correlated with an adverse outcome.

Recent studies of minority populations in the United States have indicated that predictors of high lupus disease activity include Hispanic Texan and African American ethnicities, lack of health insurance, and poor social support. African admixture and anti–double-stranded DNA antibodies also predicted high levels of disease activity, as did previous disease activity.

Data from a multicenter study of nearly 10,000 patients has supported an increased risk for hematologic malignancies in SLE patients, particularly non-Hodgkin's lymphoma. Prognostic factors for an adverse fetal outcome in pregnant lupus mothers are maternal renal disease and hypertension.

REVIEW QUESTIONS

1. Data from genome-wide association studies identify gene variants encoding the following proteins as associated with a diagnosis of systemic lupus erythematosus (SLE):

A. Major histocompatibility complex class I
B. Interferon regulatory factor 5 (IRF5)
C. Interferon-γ
D. Interleukin-17
E. Adiponectin

Answer: B Polymorphisms in IRF5 are associated with SLE. IRF5 is a transcription factor that is activated following cell triggering through endosomal toll-like receptors and induces transcription of type I interferon and other proinflammatory mediators. Although MHC class II alleles are associated with a diagnosis of SLE, associations with class I alleles have not been reported. Interferon-γ and interleukin-17 are T-cell products that may be implicated in lupus pathogenesis, but significant genetic polymorphisms in their genes have not been associated with SLE. Adiponectin is a product of adipocytes and has not been described as having a role in lupus susceptibility.

2. Environmental factors can trigger initiation or exacerbation of SLE. One mechanism by which drug-induced lupus can be triggered is through:

A. Induction of T regulatory cells
B. Damage to renal podocytes
C. DNA demethylation
D. Increased proteinuria
E. Hemolysis

Answer: C Procainamide is an antihypertensive agent that has been associated with induction of lupus. This drug impacts gene expression and cell function through demethylation of DNA, resulting in self-reactive T cells. T regulatory cells contribute to protection from autoimmune disease rather than induction of autoimmune disease. Damage to podocytes might be one mechanism of renal damage but has not been associated with drug-induced lupus. Increased proteinuria and hemolysis are clinical manifestations of lupus but do not represent mechanisms that account for drug induced lupus.

3. Clinical manifestations of lupus can include:

A. Seizures
B. Renal failure
C. Myocardial infarction
D. Pericarditis
E. All of the above

Answer: E The clinical manifestations of lupus are protean and can effect any organ system. It should be noted that premature atherosclerotic cardiovascular disease is frequent among lupus patients and can contribute to increased mortality.

4. Autoantibodies specific for the following antigen are specific for SLE:

A. Ro
B. Centromere
C. RNP
D. Scl70
E. Sm

Answer: E Autoantibodies associated with a diagnosis of SLE include those targeting protein components of ribonucleoprotein particles, such as Ro, which is also associated with Sjögren's syndrome and rheumatoid arthritis. Anti-RNP antibodies can be seen in patients with SLE or mixed connective tissue disease. Anti-centromere and anti-Scl70 antibodies are associated with systemic sclerosis. Anti-Smith (Sm) antibodies are nearly exclusive to patients with SLE.

5. Which therapeutic agent is appropriate for both induction and maintenance therapy for class III or IV lupus nephritis?

A. Intravenous pulse glucocorticoid therapy
B. Azathioprine
C. Cyclophosphamide
D. Mycophenolate mofetil
E. Rituximab

Answer: D Induction therapy for lupus nephritis is often conducted with cyclophosphamide, along with IV pulse glucocorticoid therapy. However, recent data indicate that mycophenolate mofetil (MMF) can be as effective as cyclophosphamide. In addition, MMF has shown efficacy as a maintenance therapy. IV pulse glucocorticoid therapy and cyclophosphamide are appropriate for induction therapy but should not be used as a chronic maintenance therapy for lupus nephritis. Azathioprine is appropriate as a maintenance therapy but is inferior to other options as induction therapy. Rituximab has not shown efficacy in randomized controlled clinical trials for lupus nephritis, but nonetheless is sometimes used in that clinical setting if other therapies are not successful.

267 SYSTEMIC SCLEROSIS (SCLERODERMA)

JOHN VARGA

DEFINITION

Systemic sclerosis (SSc) is a chronic autoimmune connective tissue disease of unknown cause. Although middle-aged women are most commonly affected, SSc can occur at any age and is associated with considerable morbidity and increased mortality. The disease shows marked clinical heterogeneity, has protean clinical manifestations, and commonly follows a progressive course.[1] The hallmark of SSc is thickening and hardening of the skin (scleroderma), but in most patients the lungs, gastrointestinal (GI) tract, kidneys, and heart are also affected. In its earliest stages, SSc is associated with prominent inflammation and autoimmunity and altered microvascular function. Over time, progressive structural alterations in small blood vessels and fibrosis in multiple organs cause organ failure. Although there is no approved disease-modifying therapy for SSc, current treatment strategies can control symptoms, slow disease progression, improve quality of life, and prolong

survival. The presence of scleroderma (hard skin) distinguishes SSc from other autoimmune and rheumatic diseases, but skin induration also features prominently in localized forms of scleroderma and multiple unrelated conditions (Table 267-1).

Classification

Systemic Sclerosis

SSc is clinically classified into two subsets: diffuse cutaneous SSc (dcSSc) and limited cutaneous SSc (lcSSc), defined by the pattern of skin involvement and associated with distinct clinical and laboratory manifestations and natural history (Table 267-2). In lcSSc, skin involvement is restricted to the fingers, toes, distal extremities, and face; proximal extremities and the trunk are spared. Diffuse cutaneous SSc is characterized by involvement of the skin proximal to the elbows and knees, including the trunk, along with the distal extremities. In patients with lcSSc, Raynaud phenomenon commonly precedes other disease manifestations. In contrast to lcSSc, dcSSc is generally rapidly progressive and may be complicated by early pulmonary fibrosis, accelerated hypertension, and acute renal failure. The constellation of calcinosis cutis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly (scleroderma of the fingers), and telangiectasia in a subset of patients with lcSSc is termed *CREST syndrome*. Patients with CREST generally follow an indolent course and have a relatively good prognosis. Raynaud phenomenon and other characteristic clinical and laboratory findings of SSc in the absence of obvious skin thickening is the hallmark of SSc sine scleroderma.

TABLE 267-1 CONDITIONS WITH SCLERODERMA-LIKE SKIN INDURATION

Systemic sclerosis (SSc)
- Limited cutaneous SSc
- Diffuse cutaneous SSc

Localized scleroderma
- Morphea (plaque, guttate, generalized)
- Pansclerotic morphea
- Linear scleroderma, "coup de sabre"

Scleredema and diabetic scleredema
Scleromyxedema (papular mucinosis)
Nephrogenic fibrosing syndrome (nephrogenic systemic fibrosis)
Chronic graft-versus-host disease
Diffuse fasciitis with eosinophilia (Shulman disease, eosinophilic fasciitis)
Eosinophilia-myalgia syndrome
Chemically induced scleroderma-like conditions
- Vinyl chloride–induced disease, other solvents
- Pentazocine-induced skin fibrosis
- Other drug associations

Paraneoplastic syndrome

TABLE 267-2 CLASSIFICATION OF SYSTEMIC SCLEROSIS

CHARACTERISTIC FEATURES	LIMITED CUTANEOUS SYSTEMIC SCLEROSIS	DIFFUSE CUTANEOUS SYSTEMIC SCLEROSIS
Skin induration	Limited to fingers, distal to elbows, face; progression slow	Diffuse: fingers, extremities, face, trunk; progression rapid; tendon friction rubs
Raynaud phenomenon	Precedes skin involvement; often severe; associated with critical ischemia	Onset occurs coincident with or subsequent to skin involvement
Pulmonary fibrosis	Occasional, moderately severe	Frequent, early, can be progressive and severe
Pulmonary arterial hypertension	Frequent, late, may be isolated	Occasional, commonly in association with pulmonary fibrosis
Scleroderma renal crisis	Very rare	Occurs in up to 15%; early
Calcinosis cutis	Frequent, prominent	Infrequent
Characteristic autoantibodies	Anticentromere	Antitopoisomerase I (Scl-70), anti-RNA polymerase III

Mixed Connective Tissue Disorder

Mixed connective tissue disorder (MCTD) is an overlap syndrome first described in 1971 that is characterized by features of systemic lupus erythematosus (SLE), SSc, and myositis, all occurring in the same patient. In the early phase, most patients have Raynaud phenomenon in association with edema of the hands and evidence of inflammatory muscle disease. Over time, these patients sequentially manifest other features of connective tissue diseases, including pericarditis, esophageal dysmotility, sclerodactyly, neuropathy, and pulmonary arterial hypertension (PAH). Erosive arthritis does not occur. On the other hand, some patients develop acute renal involvement similar to scleroderma renal crisis. In the early stage of this disorder, it is often difficult to predict whether the patient will progress to develop a distinct connective tissue disease such as SSc or SLE or will be ultimately diagnosed with MCTD. A diagnostic hallmark of MCTD is the presence in the serum of a highly characteristic autoantibody specificity against U1-ribonuclear protein (U1-RNP). Most MCTD patients have a very high titer (often > 1 : 1000) of anti-U1-RNP autoantibody. Some of the features of MCTD might respond to corticosteroid therapy. Overall, patients with MCTD generally have a better prognosis than those with SSc.

Localized Scleroderma

Localized scleroderma refers to a family of generally benign skin conditions primarily affecting children. These conditions are characterized by discreet areas of skin induration in the absence of Raynaud phenomenon or systemic involvement. Lesional skin is discolored and indurated and histologically may be indistinguishable from SSc. Localized scleroderma has multiple distinct forms. When it occurs as single or multiple solitary patches of induration, it is called morphea. When these patches coalesce, the condition is called generalized morphea. The lesions are generally asymmetrical in distribution and spare the digits. Some individuals have extensive and disabling induration (pansclerotic morphea). Induration may follow in a linear distribution, most commonly on the lower extremities (linear scleroderma). In children, linear scleroderma can be complicated by growth retardation and joint contractures.

EPIDEMIOLOGY

SSc is a sporadic disease with a worldwide distribution. The incidence is 9 to 19 cases per million per year, with an estimated 100,000 cases in the United States. Studies from several countries suggest that the incidence of SSc may be increasing. Like other connective tissue diseases, SSc shows a marked female predominance, particularly in the childbearing years. The peak age of onset is 30 to 50 years for both the limited and diffuse cutaneous forms. African Americans have a higher incidence and an earlier age of disease onset compared to whites, and are more likely to have the diffuse cutaneous form of SSc associated with interstitial lung involvement and a worse prognosis.

Etiology and Environmental and Occupational Exposures

Although the cause of SSc is unknown, the onset is commonly ascribed to an interplay between environmental factors and genetic susceptibility. Suspected environmental triggers include occupational, dietary, medical, and lifestyle exposures, and possibly certain infectious agents. Because some SSc autoantibodies cross-react with certain virus-associated epitopes, molecular mimicry has been proposed as a possible pathogenetic link between viral infection and SSc.

Epidemic outbreaks of SSc-like syndromes have been linked with toxic exposures. A Spanish outbreak of toxic oil syndrome in the 1980s affected more than 20,000 individuals. The syndrome was characterized by chronic skin induration and neuropathy, and the outbreak was linked to ingestion of contaminated rapeseed oils used for cooking. An outbreak of eosinophilia-myalgia syndrome (EMS) a decade later was linked to ingestion of over-the-counter L-tryptophan dietary supplements used for insomnia, weight loss, and other indications. The syndrome was characterized by peripheral blood eosinophilia and severe myalgia in the acute stage, followed by intractable scleroderma-like diffuse skin induration. Neither toxic oil syndrome nor EMS was associated with Raynaud phenomenon or SSc-specific autoantibodies.

Occupational exposures tentatively linked with SSc include silica (in miners), polyvinyl chloride, epoxy resins, and aromatic hydrocarbons including toluene and trichloroethylene. Certain drugs, including bleomycin, pentazocine, hormone replacement therapy, cocaine, and appetite suppressants, have been linked with SSc or PAH. Although earlier studies implied a

possible association of SSc with silicone breast implants, large-scale epidemiologic investigations failed to establish an increased risk.

Genetic Factors

A genetic contribution to SSc susceptibility is indicated by the fact that 1.6% of patients have a first-degree relative with SSc, a prevalence rate substantially higher than in the general population (0.026). Indeed, a family history is the strongest identified risk factor for SSc. Moreover, patients with SSc are more likely to have first-degree relatives with Raynaud phenomenon and interstitial lung disease, as well as other autoimmune diseases including multiple sclerosis, rheumatoid arthritis, and thyroiditis. Genomewide association and candidate-gene studies in SSc have identified association with multiple HLA loci, as well as non-HLA loci including *STAT4*, *IRF4*, *PTPN22*, *TNIP-1*, *IRAK1*, *CD247*, and *BANK1*, each of which encodes genes involved in immune regulation or autoimmunity. Moreover, most of these SSc-associated risk alleles are also linked with other autoimmune diseases, especially SLE.

PATHOBIOLOGY

The protean clinical and pathologic manifestations of SSc reflect a complex underlying pathobiology encompassing three interrelated cardinal processes: autoimmunity and inflammation, vascular injury and obliteration, and fibrosis and excessive matrix accumulation in multiple tissues and organs (Fig. 267-1).[2] This canonical triad is operative to a greater or lesser extent in all patients with SSc, and their variable relative contribution of each process to the individual phenotype account for the observed disease heterogeneity.

Pathology

The distinguishing pathologic hallmark of SSc is the constellation of capillary loss (rarefaction) and obliterative vasculopathy coexisting with fibrosis in the skin and internal organs. In early-stage disease, perivascular inflammation can be detected in multiple organs before the appearance of fibrosis. The vascular lesion is characterized by intimal proliferation in the small and medium-sized arteries, resulting in luminal narrowing and obliteration.[3] In later-stage SSc, fibrosis is prominent in the skin, lungs, GI tract, heart, tendon sheath, perifascicular tissue surrounding skeletal muscle, and some endocrine organs.[4] Accumulation of connective tissue rich in collagens, fibronectin, cartilage oligomeric matrix protein (COMP), and proteoglycans disrupts normal architecture, resulting in functional impairment of affected organs.

In the skin, dermal collagen deposition causes obliteration of the hair follicles, sweat glands, and other adnexae, as well as invasion of the subjacent adipose layer with entrapment of fat cells. The epidermis is atrophic, and the rete pegs are effaced. In late-stage disease, there is a paucity of vascular and lymphatic endothelium. In the lungs, the interstitium and alveolar spaces are infiltrated with inflammatory cells in early disease. With progression, interstitial fibrosis and vascular damage, often coexisting within the same lesions, dominate the pathologic picture. The most common histologic pattern in SSc-associated lung disease is nonspecific interstitial pneumonitis (NSIP). Progressive thickening of the alveolar septae results in obliteration of the air spaces, honeycombing, and loss of pulmonary blood vessels.

Intimal thickening of the pulmonary arteries (Fig. 267-2), best seen with elastin stain, underlies PAH (Chapter 68). These vascular lesions resemble those of, but are distinct from, idiopathic PAH, but the hallmark plexiform lesions are uncommon in SSc. In the GI tract, pathologic changes can be found at any level from the mouth to the rectum. Fibrosis of the lamina propria and submucosa with atrophy of the muscular layers are prominent in the lower esophagus, whereas striated muscle in the upper third of the esophagus is generally spared (Chapter 138). Replacement of the normal gut architecture leads to disordered peristaltic activity with gastroesophageal reflux and dysmotility, gastroparesis, and small bowel obstruction. Chronic reflux

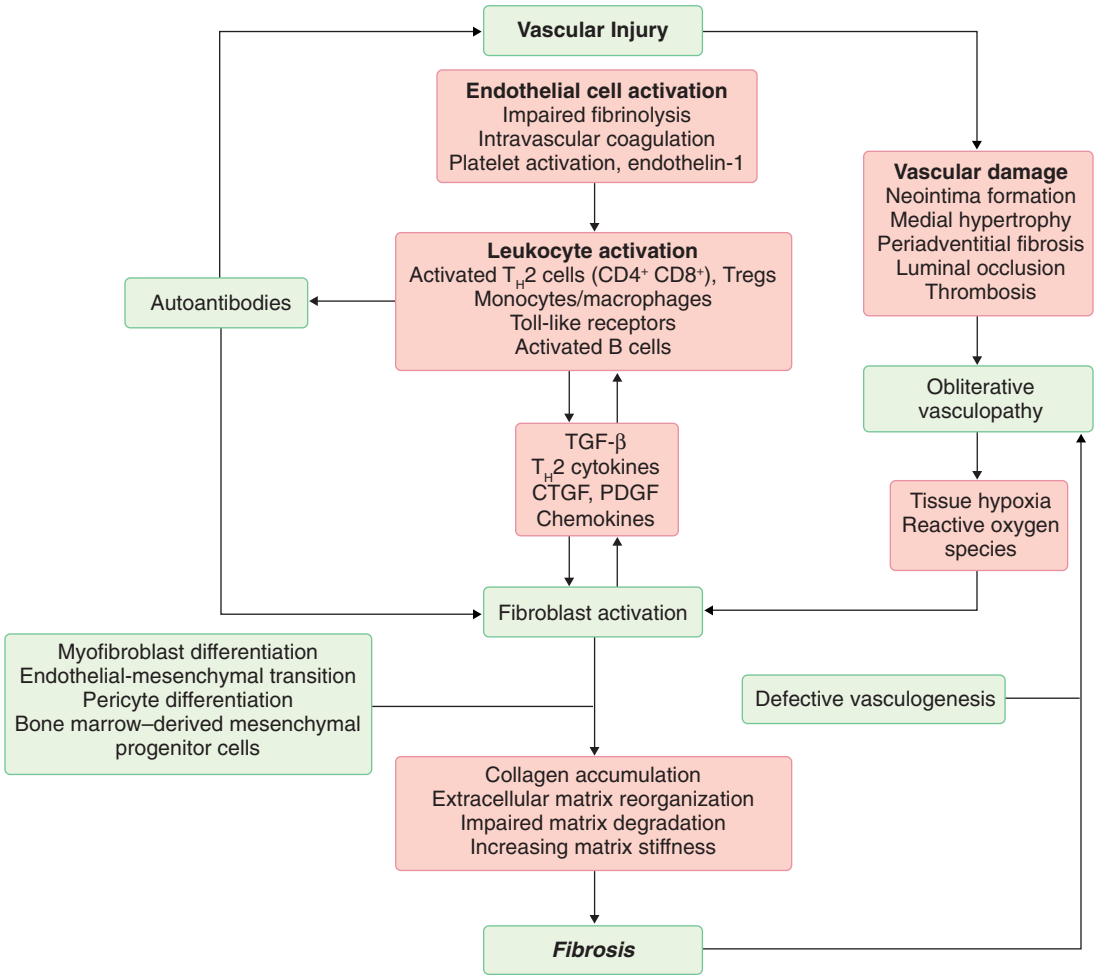

FIGURE 267-1. The pathogenetic triad of systemic sclerosis: vasculopathy, autoimmunity, fibrosis. Initial endothelial injury in a genetically susceptible individual leads to vascular damage, inflammation, and autoimmunity. The inflammatory and immune responses initiate fibroblast activation, resulting in intractable fibrosis. Vasculopathy, loss of microvasculature, and reduced blood flow result in ischemia and generation of reactive oxygen species that contribute to and further aggravate vascular damage, tissue fibrosis, and atrophy. CTGF = connective tissue growth factor; PDGF = platelet-derived growth factor; TGF-β = transforming growth factor-β.

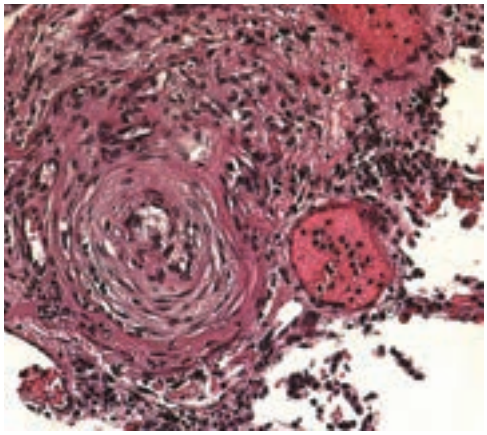

FIGURE 267-2. Pulmonary artery obliterative vasculopathy. Striking intimal hyperplasia and narrowing of the lumen of a small pulmonary artery, coexisting with interstitial pulmonary fibrosis, in a patient with diffuse cutaneous systemic sclerosis.

is associated with esophageal inflammation, ulcerations, stricture formation, and Barrett metaplasia.

Pathologic changes in the heart are common in SSc, with involvement of the myocardium and pericardium. Characteristic microvascular lesions include concentric intimal hypertrophy and luminal narrowing. Contraction band necrosis reflecting ischemia-reperfusion injury in the myocardium is prominent and may be accompanied by patchy myocardial fibrosis. In the kidneys, noninflammatory lesions occur in the interlobular arteries. Scleroderma renal crisis (Chapter 125) is associated with striking changes in small renal arteries, with reduplication of elastic lamina, marked intimal proliferation, and concentric narrowing of the lumen giving rise to the onion-skin appearance, frequently accompanied by thrombosis and microangiopathic hemolysis.[5]

Pathophysiologic Triad: Vasculopathy, Immune Dysregulation, and Fibrosis

Vasculopathy

Vascular injury is an early and presumably primary event in pathogenesis of SSc. It effects primarily the small and medium-sized arteries and arterioles in multiple vascular beds and accounts for major clinical complications. The initial vascular endothelial injury might be caused by viruses and other infectious agents, oxygen radicals, circulating cytotoxic factors, complement activation, or autoantibodies. Endothelial cell injury and apoptosis result in altered production of endothelium-derived vasodilatory (nitric oxide and prostacyclin) and vasoconstricting (endothelin-1) molecules. Endothelial dysfunction causes increased vascular permeability associated with upregulation of adhesion molecules with transendothelial leukocyte diapedesis, as well as platelet aggregation, activation of intravascular coagulation, defective fibrinolysis, and thrombosis. Small blood vessels show intimal hyperplasia with thickening and reduplication of the basement membrane. In the vascular media, myointimal cells proliferate, whereas the adventitial layers develop fibrosis; the net result is progressive narrowing and obliteration of capillaries, arterioles, and even large vessels. Impaired blood flow results in widespread tissue ischemia, which is a potent stimulus for fibrogenesis. Recurrent ischemia-reperfusion is associated with the generation of reactive oxygen species that further damage the endothelium. Paradoxically, despite the presence of tissue hypoxia and sometimes dramatically elevated levels of angiogenic factors, compensatory vasculogenesis is impaired owing to reduced production, mobilization, or maturation of endothelial progenitor cells. The combination of widespread capillary loss, obliterative vasculopathy of small and medium-sized arteries, and failure to regenerate damaged blood vessels are hallmarks of SSc that underlie Raynaud phenomenon, ischemic digital ulcers, cutaneous telangiectasia, PAH, and other major vascular manifestations.

Raynaud Phenomenon

The earliest and most common vascular complication of SSc, Raynaud phenomenon, reflects abnormal thermal regulation of blood flow and can precede other disease manifestations by years.[6] Raynaud phenomenon in SSc is characterized by autonomic and peripheral nervous system changes leading to impaired production of calcitonin gene–related peptide from sensory afferent nerves and heightened sensitivity of α_2-adrenergic receptors on vascular smooth muscle cells. In contrast to primary Raynaud phenomenon, a common and relatively benign condition, Raynaud phenomenon in SSc is generally progressive and complicated by vascular remodeling with irreversible structural changes that result in tissue damage.

TABLE 267-3 CHARACTERISTIC AUTOANTIBODIES IN SYSTEMIC SCLEROSIS

AUTOANTIBODY (FREQUENCY IN SSc)	SYSTEMIC SCLEROSIS SUBSET	CLINICAL ASSOCIATION
Topoisomerase-I (10-40%)	Diffuse cutaneous (less commonly limited)	Tendon friction rubs, ILD, cardiac involvement, scleroderma renal crisis; isolated PAH rare
Centromere (15-40%)	Limited cutaneous	Digital ischemia, calcinosis cutis, isolated PAH, PBC; severe ILD and scleroderma renal crisis rare
RNA polymerase III (4-25%)	Diffuse cutaneous	Extensive skin involvement; tendon friction rubs, scleroderma renal crisis, increased cancer risk
U3-RNP/fibrillarin (1-5%)	Diffuse cutaneous	PAH, ILD, myositis
Th/To (1-7%)	Limited cutaneous	ILD, isolated PAH
PM/Scl (0-6%)	Limited cutaneous	Calcinosis, myositis, arthritis
U1-RNP (5-35%)	MCTD	Severe PAH, myositis

ILD = interstitial lung disease; MCTD = mixed connective tissue disease; PAH = pulmonary arterial hypertension, PBC = primary biliary cirrhosis.

Inflammation and Autoimmunity

Cellular Immunity

Immune dysregulation is a hallmark SSc shares with other autoimmune diseases. In early SSc, activated T cells, B cells, and monocyte-macrophages accumulate in lesional tissues. Recent studies employing genomewide transcriptional profiling indicate that a subset of SSc patients demonstrate a strong inflammatory gene signature in their lesional skin, with evidence of activated innate and adaptive immune signaling and elevated expression of many inflammatory chemokines and cytokines.

Infiltrating $CD4^+$ T cells display restricted TcR receptor signatures indicative of their oligoclonal expansion in response to unknown antigens. Moreover, these T cells show T_H2 polarization with secretion of interleukin (IL)-4, IL-13, and IL-21, and low levels of interferon (IFN)-γ. T_H2 cytokines induce TGF-β and promote the synthesis of collagen and other extracellular matrix molecules. Increased levels of IL-17 detected in the serum suggest a role for T_H17 cells in SSc. The frequency of circulating regulatory T cells is elevated, but their immunosuppressive function appears to be defective. Myeloid dendritic cells show abnormally high secretion of inflammatory cytokines and chemokines such as CXCL.[7] Moreover, in response to thymic stromal lymphopoietin (TSLP), which is elevated in SSc, dendritic cells contribute to the persistence of the T_H2-polarized profibrotic immune response. Macrophages show evidence of alternative activation associated with pathologic fibrogenesis. In SSc, aberrant innate immune responses in dendritic cells and tissue fibroblasts might be triggered by damage-associated nucleic acids and matrix macromolecules. These responses are mediated through toll-like receptors (TLRs) and are likely to contribute to autoimmunity and progressive fibrosis.[8] The elevated expression of type I interferon-regulated genes (IFN signature) in SSc is consistent with innate immune activation and may contribute to vascular injury.

Autoantibodies and B Cells

Although circulating autoantibodies have well-established clinical utility in SSc as diagnostic and prognostic markers, their role in driving pathogenesis and tissue damage remains speculative. In addition to antinuclear antibodies (ANAs) that are detected in virtually all patients with SSc, a number of highly disease-specific and mutually exclusive autoantibodies occur (Table 267-3).

Animal Models of Disease

Although no single animal model fully recapitulates the tripartite immune-vascular-fibrotic pathobiology of SSc, certain genetically engineered mice and mice subjected to chemical or immunologic challenges exhibit particular disease features and are useful in investigating pathogenesis and therapy. Tight skin mice (Tsk1) spontaneously develop diffuse skin induration and fibrosis, with prominent thickening of the hypodermis. The Tsk1 phenotype is due to a duplication mutation in the gene for fibrillin-1, a component of extracellular microfibrils. Microfibrils provide a scaffold for elastin fibers but also control the storage and activity of transforming growth factor (TGF)-β and other regulatory molecules. Mutations in the fibrillin-1 gene also underlie Marfan syndrome. Scleroderma-like skin changes and organ fibrosis can be induced in mice by subcutaneous injection of bleomycin, TGF-β angiotensin II, or HOCl, or by transplantation of HLA-mismatched bone marrow or spleen cells. Increasingly, targeted genetic modifications such as deletion or transgenesis are used to create novel animal models for dissecting the molecular and cellular pathways in fibrosis and for the discovery and preclinical evaluation of novel therapies. For instance, transgenic mice with constitutive TGF-β, connective tissue growth factor [CTGF], platelet-derived growth factor [PDGF], Fra-2 or Wnt10 signaling spontaneously develop scleroderma-like changes in multiple organs and serve as valuable experimental tools.

Most SSc-specific autoantibodies are directed against intracellular proteins, such as topoisomerase-I, centromere, and RNA polymerases I and III. Recent studies identified autoantibodies in SSc that are directed against endothelial cell or myenteric neuron epitopes, or recognize cell surface receptors (platelet-derived growth factor receptor [PDGFR], angiotensin II receptor, and muscarinic-3-acetylcholine receptor), and appear to directly contribute to vascular injury, intestinal wall atrophy and dysmotility, or tissue fibrosis. B cells are implicated in mediating both the autoimmune and fibrotic components of SSc. In addition to their role in antibody production, B cells also present antigen, produce IL-6 and other profibrotic cytokines, and modulate the function of T cells and dendritic cells. Gene expression profiling of SSc skin biopsies has identified messenger RNA expression signatures characteristic of B-cell activation.

Fibrosis

Fibrosis of the skin and multiple internal organs is the distinguishing feature of SSc. It characteristically follows, and is thought to be a consequence of, inflammation and vascular injury. Fibrosis is characterized by replacement of normal tissue architecture with a collagen-rich extracellular matrix that is secreted by resident fibroblasts and myofibroblasts.[9] Under physiologic conditions, these mesenchymal cells undergo controlled activation triggered by TGF-β, IL-6, PDGF, hypoxia, oxygen radicals, and other factors. Fibroblasts proliferate, migrate, synthesize and secrete collagens and extracellular matrix, and transdifferentiate into contractile myofibroblasts, enabling them to repair damaged tissue with full regeneration. When this tightly regulated wound healing program becomes sustained and amplified, excessive scar tissue formation ensues, leading to intractable fibrosis.

Effector Cells in Fibrosis

Myofibroblasts are mesenchymal cells with both smooth muscle cell–like contractile and biosynthetic properties. Myofibroblasts appear transiently in wounds, where they contribute to healing through production of collagen and TGF-β and contraction of the surrounding extracellular matrix. In SSc, activated myofibroblasts accumulate in lesional tissue and persist there because of one of three pathways: (1) in situ activation of quiescent resident fibroblasts, (2) through transdifferentiation from damaged epithelial cells, endothelial cells, or pericytes, or (3) by migration and terminal differentiation of bone marrow–derived mesenchymal progenitor cells.

CLINICAL MANIFESTATIONS

Overview

Multiple organs are affected in SSc, but the frequency, tempo, and severity of their involvement show substantial patient-to-patient variability. Patients with dcSSc characteristically develop extensive skin induration associated with early and progressive internal organ involvement. In contrast, patients with lcSSc commonly present with long-standing Raynaud phenomenon, skin changes limited to the distal extremities and face, and indolent progression of internal organ disease. However, patients with SSc frequently defy easy subclassification, or show an overlap of typical SSc features coexisting with clinical and laboratory evidence of another autoimmune disease such as polymyositis, Sjögren syndrome, polyarthritis, or SLE.

Initial Clinical Presentation

Diffuse Cutaneous Systemic Sclerosis

Patients with dcSSc typically present with soft tissue swelling, erythema, and pruritus, often accompanied by fatigue, stiffness, and malaise. Although arthralgia, muscle weakness, and carpal tunnel syndrome are common, Raynaud phenomenon may not be present until later in the disease. In the ensuing weeks to months, the inflammatory edematous phase evolves into a chronic "fibrotic" phase with skin induration accompanied by hyperpigmentation, loss of body hair, and impaired sweating. The wrists, elbows, shoulders, knees, and ankles become stiff owing to fibrosis of the joint structures. Advancing skin changes are commonly accompanied by onset of internal organ involvement that is most rapidly progressive during the initial 4 years from disease onset. The risk for new organ involvement declines thereafter.

Limited Cutaneous Systemic Sclerosis

In lcSSc, the diagnosis is generally made at a more advanced stage of the disease. These patients give a history of long-standing Raynaud phenomenon, sometimes complicated by ischemic ulcerations at the fingertips. The course of disease is indolent, with delayed onset and slow progression of gastroesophageal reflux, telangiectasia, or cutaneous calcinosis. Vascular manifestations of lcSSc tend to be more pronounced compared with dcSSc, and digital ischemia, cutaneous telangiectasia, and progressive PAH are frequent late manifestations. In contrast, scleroderma renal crisis is uncommon in lcSSc.

Organ Involvement

Skin

Skin thickening, the distinguishing hallmark of SSc, typically starts in the fingers and advances in a centripetal pattern from distal to proximal extremities. The skin becomes hyperpigmented, but dark-skinned individuals may develop vitiligo-like hypopigmentation or "salt-and-pepper" changes, most prominently on the upper back and chest. Obliteration of eccrine sweat glands and sebaceous glands results in decreased sweating and oil secretion, causing dry and itchy skin. The face may assume a characteristic appearance with a beaklike nose, thinning and retraction of the lips, fine wrinkles (radial furrowing) around the mouth, and occasionally a masklike facies due to reduced mobility of the eyelids, cheeks, and mouth (Fig. 267-3). Decreased oral aperture (microstomia) interferes with eating and oral hygiene.

In patients with long-standing SSc, the skin is atrophic and tethered to the subcutaneous tissue. Telangiectasias are prominent on the face, hands, lips, and oral mucosa. They resemble the skin lesions of hereditary hemorrhagic telangiectasia and are due to dilatation of postcapillary venules in the upper dermis. Breakdown of atrophic skin leads to painful ulcerations at the extensor surfaces of the interphalangeal joints, fingertips, and bony prominences such as the elbows and malleoli. Ulcers may become secondarily infected, resulting in osteomyelitis. Ischemic fingertip ulcerations heal slowly and give rise to characteristic digital tip "pits." Ischemic soft tissue loss at the fingertips is associated with resorption of the terminal phalanges (acro-osteolysis) (Fig. 267-4).

Calcium deposits composed of calcium hydroxyapatite crystals develop in the skin and soft tissues. These deposits, varying in size from tiny punctate lesions to large conglomerate masses, can be readily visualized on plain radiographs. Frequent locations include the finger pads, extensor surfaces of the forearms, and olecranon and prepatellar bursae. Calcific deposits can ulcerate through the overlying skin, producing drainage of chalky white material, pain, and local inflammation.

Raynaud Phenomenon

Raynaud phenomenon (Chapter 80) is an episodic vasoconstriction in the digits that occurs in virtually all patients with SSc.[8] Typical attacks start with

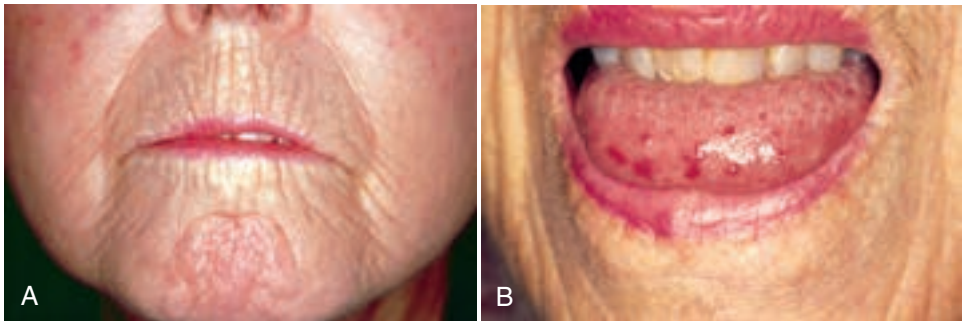

FIGURE 267-3. Facial features in systemic sclerosis. A, Perioral furrowing. Note vertical lines of furrowing around the mouth in a patient with diffuse cutaneous systemic sclerosis. **B,** Telangiectasia on the lips and tongue in a patient with long-standing limited cutaneous systemic sclerosis.

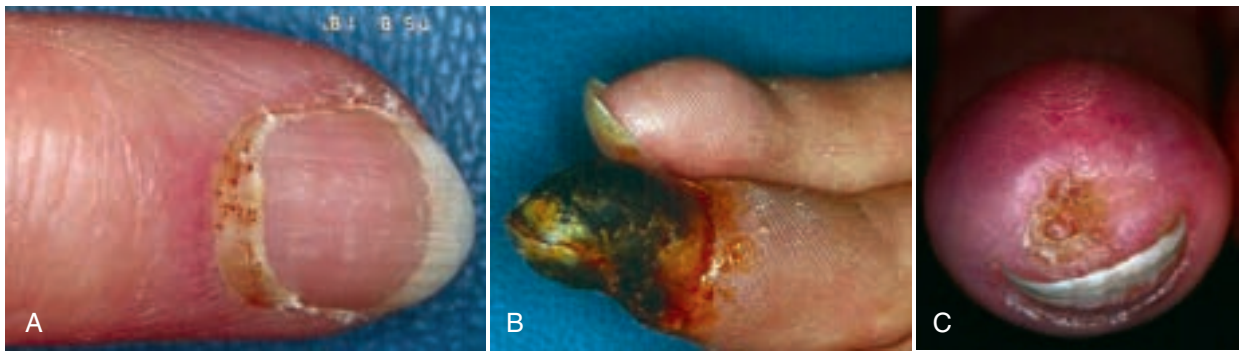

FIGURE 267-4. Vascular complications of systemic sclerosis in the fingers. **A,** Nailfold microvascular changes. **B,** Digital infarction. Sharply demarcated necrosis of the fingertip in a patient with limited cutaneous systemic sclerosis associated with severe Raynaud phenomenon. **C,** Digital tip ulceration and pitting.

pallor (vasoconstriction) followed by cyanosis (ischemia) and erythema (reperfusion), commonly triggered by exposure to cold or emotional stress. Primary Raynaud phenomenon, a benign condition representing an exaggerated physiologic response to cold, occurs in 3 to 5% of the population and is more frequent in women. Secondary Raynaud phenomenon occurs in SSc but also other connective tissue diseases, hematologic and endocrine conditions, and occupational disorders, and with the use of β-blockers and anticancer drugs such as cisplatin and bleomycin.

Distinguishing primary from secondary Raynaud phenomenon can present a challenge. Secondary Raynaud phenomenon typically develops at an older age (>30 years), tends to be more severe, and is frequently complicated by critical ischemia. Nailfold capillaroscopy allows cutaneous capillaries to be viewed under a drop of immersion oil using an ophthalmoscope. Patients with primary Raynaud phenomenon have normal nailfold capillaries that appear as regularly spaced parallel vascular loops, whereas in SSc, capillaries are distorted with widened and irregular loops, dilated lumen, and areas of vascular "dropout."

Gastrointestinal Involvement

GI tract involvement is very common in both lcSSc and dcSSc and may be the presenting manifestation of the disease. A pathologic picture of smooth muscle atrophy and obliterative small vessel vasculopathy with or without fibrosis is seen throughout the length of the GI tract, causing altered peristaltic activity and consequent complications. Severe intestinal involvement and malnutrition are associated with high mortality.

Upper Gastrointestinal Tract

Oropharyngeal manifestations of SSc include xerostomia, reduced oral aperture, periodontal disease, and resorption of the mandibular condyles. The frenulum of the tongue may be shortened. The most frequently affected GI organ is the esophagus. Gastroesophageal reflux is associated with heartburn, regurgitation, and dysphagia but can also be asymptomatic (Chapter 138). Reduced lower esophageal sphincter pressure resulting in gastroesophageal reflux frequently coexists with impaired esophageal clearance of refluxed gastric contents due to diminished motility in the distal two thirds of the esophagus. Delayed gastric emptying further aggravates the problem. On high-resolution computed tomography (HRCT) of the chest, the esophagus is dilated and shows intraluminal air. Endoscopy may show severe erosive esophagitis in patients with minimal reflux symptoms. Esophageal strictures and Barrett esophagus (Chapter 138) can complicate long-standing reflux. Because Barrett esophagus is associated with an increased risk for adenocarcinoma, SSc patients require periodic endoscopy with mucosal biopsy. Hoarseness and chronic cough may be extraesophageal manifestations of gastroesophageal reflux disease (GERD). Chronic microaspiration of gastric contents may aggravate underlying interstitial lung disease. A distinct pattern of interstitial lung disease called centrilobular fibrosis, associated with esophageal dilatation and chronic gastroesophageal reflux, is occasionally seen in SSc.

Stomach

Gastroparesis contributes to delayed gastric emptying with early satiety, abdominal distention, and aggravated reflux symptoms. Gastric vascular ectasia (GAVE) develops in 5% of patients and is equally prevalent in limited and diffuse cutaneous disease. On endoscopy, parallel longitudinal mucosal folds resembling the stripes of a watermelon are seen in the antrum. The histologic features of dilated thrombosed mucosal capillaries and fibromuscular dysplasia of the lamina propria reflect the diffuse small vessel vasculopathy of SSc. Patients with GAVE may develop recurrent GI bleeding and typically present with unexplained iron deficiency anemia.

Lower Gastrointestinal Tract

Impaired small bowel motility in SSc can cause chronic diarrhea due to bacterial overgrowth. Fat and protein malabsorption, vitamin B_{12} and D deficiency, and malnutrition may ensue and are associated with high mortality. Malabsorption is diagnosed by hydrogen breath test or 14C-D-xylose test, and serum prealbumin (transthyretin) is useful to monitor malnutrition (Chapter 140). Disturbed intestinal motor function can also cause recurrent episodes of intestinal pseudo-obstruction with acute abdominal pain, nausea, and vomiting. Differentiating pseudo-obstruction, which responds to supportive care and intravenous nutritional supplementation, from mechanical bowel obstruction is a difficult diagnostic challenge. Colonic and anorectal involvement causing constipation, rectal prolapse, and fecal incontinence is frequent and is the source of much distress. In late-stage SSc, wide-mouth colonic sacculations can occur and cause perforation and bleeding. An occasional radiologic finding is pneumatosis cystoides intestinalis due to air trapping in the bowel wall. These lesions can rupture and cause pneumoperitoneum. The liver is rarely affected in SSc. However, primary biliary cirrhosis associated with antimitochondrial antibodies may occur.

Lung Involvement

The two major forms of lung involvement in SSc are interstitial lung disease and PAH, with many patients developing both. Less frequent pulmonary manifestations include aspiration pneumonitis complicating gastroesophageal reflux, pulmonary hemorrhage, obliterative bronchiolitis, pleural reactions, restrictive ventilatory disease due to chest wall fibrosis, spontaneous pneumothorax, and drug-induced lung toxicity. The incidence of lung cancer, particularly bronchoalveolar carcinoma (Chapter 191), is increased.

Interstitial Lung Disease

Interstitial lung disease (Chapter 92) in SSc can remain asymptomatic until quite advanced.[10] The most frequent presenting symptoms are exertional dyspnea, fatigue, and reduced exercise tolerance. A chronic dry cough may be present. Physical examination may reveal "Velcro" crackles at the lung bases. Pulmonary function testing (Chapter 85) is a sensitive method for detecting early interstitial lung disease. The most common abnormalities are reductions in forced vital capacity (FVC) or single breath diffusing capacity (D_{LCO}). However, a reduction in D_{LCO} that is significantly out of proportion to the reduction in FVC (FVC/D_{LCO} ratio > 1.6) suggests pulmonary vascular disease.

Evidence of interstitial lung disease can be found in almost all patients with SSc and is clinically significant in up to 50%. Risk factors include male sex, African American race, diffuse skin involvement, severe gastroesophageal reflux, and the presence of topoisomerase-I autoantibodies. The most rapid progression in interstitial lung disease occurs within the first 3 years of the disease.

Chest radiography is useful for ruling out infection and other causes of pulmonary involvement but is relatively insensitive for detection of early interstitial lung disease. In contrast, HRCT is highly sensitive (Chapter 84). Prominent HRCT findings include reticular linear interstitial opacities,

predominantly in the lower lobe periphery, occurring in isolation or in combination with ground-glass opacification. Additional findings include mediastinal lymphadenopathy and, rarely, honeycombing. The extent of lung disease on initial HRCT correlates with progression and prognosis of interstitial lung disease and may provide useful information regarding the need for initiating therapy. Bronchoalveolar lavage (Chapter 85) may be indicated for ruling out occult infection. Lung biopsy is rarely useful.

Pulmonary Arterial Hypertension

Approximately 15% of SSc patients develop PAH, defined as a mean pulmonary arterial pressure of 25 mm Hg or greater, with a pulmonary capillary wedge pressure of 15 mm Hg or less (Chapter 68). In the setting of SSc, PAH can occur as an isolated abnormality (World Health Organization [WHO] group I), or coexist with interstitial lung disease (WHO group III). Although the natural history of SSc-associated PAH is variable, patients generally follow a progressive downhill course, with development of right heart failure and increased mortality. Risk factors for SSc-associated PAH include limited cutaneous disease, older age of disease onset, severe Raynaud phenomenon, large number of cutaneous telangiectasias, and anticentromere, U1-RNP, U3-RNP (fibrillarin), Th/To, B23, and β_2-glycoprotein I autoantibodies.

The initial symptoms of PAH are exertional dyspnea and reduced exercise capacity, but early-stage disease is often clinically silent. With progression, angina, syncope, and symptoms and signs of right-sided heart failure develop. Physical examination shows tachypnea, a prominent pulmonic S_2 heart sound, palpable right ventricular heave, elevated jugular venous pressure, and dependent edema. Pulmonary arterial systolic pressures above 40 mm Hg (determined by Doppler echocardiography) suggest PAH, as does an isolated low D_{LCO} or a FVC/D_{LCO} ratio over 1.6. Right heart catheterization is required for confirming the diagnosis of PAH, assessing its severity, and evaluating ventricular function. The serum levels of N-terminal brain natriuretic peptide (NT-pro-BNP) are elevated in PAH and correlate with severity and survival.

Kidney Involvement

Scleroderma renal crisis is an uncommon but life-threatening acute complication of SSc, but chronic and indolent kidney disease also occurs.

Scleroderma Renal Crisis

Scleroderma renal crisis, the most dreaded complication of SSc, develops in 10 to 15% of patients, almost always within 4 years of disease onset.[11] Prior to the advent of angiotensin-converting enzyme (ACE)-inhibiting drugs in the 1980s, scleroderma renal crisis was invariably fatal, often within weeks. The pathogenesis involves obliterative vasculopathy and luminal narrowing of the renal arcuate arteries. Progressive reduction in renal blood flow, aggravated by vasospasm, leads to juxtaglomerular hyperplasia and increased renin secretion, with further renal vasoconstriction resulting in a vicious cycle that culminates in malignant hypertension (Chapters 67 and 125).

Scleroderma renal crisis is a medical emergency. Although most patients present with abrupt onset of hypertension and progressive renal insufficiency, in some cases the blood pressure remains normal or only modestly elevated. Normotensive renal crisis is associated with a poor outcome. Hypertensive encephalopathy and retinopathy, pericarditis, and arrhythmias may complicate scleroderma renal crisis. Urinalysis shows mild proteinuria, granular casts, and microscopic hematuria. When thrombocytopenia and microangiopathic hemolysis with fragmented red blood cells are detected, the diagnosis of thrombotic thrombocytopenic purpura (Chapter 172) is sometimes entertained. In many patients, oliguric renal failure develops over a period of weeks. Kidney biopsy can be useful for diagnosis and prognosis, but the characteristic lesions of intimal and medial proliferation and luminal narrowing are indistinguishable from the changes of accelerated hypertension.

Risk factors for scleroderma renal crisis include early-stage disease, rapidly progressive skin involvement and the presence of tendon friction rubs, African American race, male sex, and autoantibodies to RNA polymerases I and III. In contrast, the presence of anticentromere antibodies is associated with a low risk for scleroderma renal crisis. Pericardial effusion, new-onset anemia, and thrombocytopenia may be harbingers of impending scleroderma renal crisis, and a history of recent corticosteroid use is associated with a more than 10-fold increased risk. Accordingly, SSc patients with early and progressive cutaneous disease should be counseled to determine their blood pressure daily. In these patients, corticosteroids should be used only when absolutely required, and at low doses.

Once scleroderma renal crisis sets in, hospitalization and prompt initiation of short-acting ACE inhibitors is essential. The goal is adequate blood pressure control before the onset of renal failure. Despite appropriate timely intervention, more than half of patients with scleroderma renal crisis require hemodialysis, although some of these ultimately recover sufficient renal function to be able to discontinue hemodialysis. Oliguria or a serum creatinine level higher than 3 mg/dL at presentation predict poor outcome. The "prophylactic" use of ACE inhibitors to prevent scleroderma renal crisis is associated with a worse outcome and is not recommended.

Chronic Kidney Disease

Kidney biopsies in patients with SSc commonly show chronic changes including reduplication of elastic fibers, sclerosed glomeruli, tubular atrophy, and interstitial fibrosis. In one study, abnormal renal function or proteinuria was detected in more than one third of patients, none of whom progressed to end-stage renal disease. Rarely, glomerulonephritis associated with lupus serologies or antineutrophil cytoplasmic antibody–positive renal vasculitis occurs.

Cardiac Involvement

Cardiac involvement is frequently detected using sensitive diagnostic tools but is commonly clinically silent. Clinical cardiac involvement is more frequently seen in patients with dcSSc; it generally develops early in the course of the disease and is a poor prognostic factor. The endocardium, myocardium, and pericardium may be affected separately or together. Clinical manifestations include tachyarrhythmias, conduction abnormalities, valvular regurgitation, diastolic heart failure, and pericardial effusion. Systemic and pulmonary arterial hypertension, as well as lung and renal involvement, also affect the heart. Conventional echocardiography has a low sensitivity for detecting SSc heart involvement. Tissue Doppler echocardiography, single-photon emission computed tomography, and especially cardiac magnetic resonance imaging (cMRI) reveal a high prevalence of myocardial abnormalities such as abnormal ventricular relaxation and reversible perfusion defects. An elevated level of serum NT-pro-BNP is a sensitive marker for increased pulmonary artery pressure but may also indicate primary cardiac involvement. Myocarditis can develop in association with muscle inflammation. Pericardial effusion develops in more than 15% of SSc patients but is rarely significant.

Musculoskeletal Complications

Carpal tunnel syndrome (Chapter 420) occurs frequently and may be a presenting manifestation of SSc. Joint mobility is progressively impaired, especially in the hands. Large joint contractures can be accompanied by audible or palpable tendon friction rubs that are caused by extensive fibrosis and adhesion of the tendon sheaths and fascial planes at the affected joint. The presence of tendon friction rubs often signals aggressive disease. Frank joint inflammation is uncommon in SSc; however, erosive polyarthritis in the hands can occur. Muscle weakness may be a sign of deconditioning, disuse atrophy, and malnutrition. Less commonly, inflammatory myositis indistinguishable from idiopathic polymyositis (Chapter 269) occurs in early disease. A noninflammatory myopathy characterized by atrophy and fibrosis in the absence of elevated muscle enzyme levels may occur in late disease. Bone resorption affects the distal tufts of terminal phalanges (acro-osteolysis), mandibular condyles, ribs, and distal clavicles.

Other Clinical Manifestations

In addition to microangiopathy, involvement of larger blood vessels (>100 μm) is common in SSc. Manifestations of macrovascular disease include occlusion of the digital and ulnar arteries, leading to ischemic ulcerations and even loss of digits or limbs. Epidemiologic studies indicate increased risk of coronary artery disease in patients with SSc. Dry eyes and dry mouth are common in SSc, but in contrast to Sjögren syndrome (Chapter 268), salivary gland biopsy in such cases shows fibrosis rather than focal lymphocytic infiltration. Hypothyroidism due to thyroid fibrosis is common and may be associated with antithyroid autoantibodies. Although the brain and central nervous system are generally spared in SSc, autonomic neuropathy, as well as a primarily sensory neuropathy of the trigeminal nerve due to fibrosis or vasculopathy, can occur. Pregnancy in women with active SSc is associated with an increased rate of adverse fetal outcomes. Furthermore, cardiopulmonary involvement might worsen during pregnancy, and scleroderma renal crisis can occur. Inability to attain or maintain penile erection is due to vascular insufficiency and fibrosis; the problem is frequent and may be the presenting disease manifestation in males with SSc.

Systemic Sclerosis and Cancer

Patients with SSc have an increased risk of cancer. In these patients, lung cancer and esophageal adenocarcinoma typically occur in the setting of long-standing interstitial lung disease or GERD, and chronic inflammation and tissue repair may be contributing factors. In contrast, breast, lung, and ovarian carcinoma and lymphoma in SSc tend to occur in close temporal association with the clinical onset of SSc and are often associated with anti-RNA polymerase III antibodies. In these cases, SSc might be a paraneoplastic syndrome that is triggered by the antitumor immune response.

DIAGNOSIS

Skin induration in the fingers or proximally (associated with Raynaud phenomenon) and characteristic visceral organ manifestations are sufficient to establish the diagnosis of SSc. Occasionally, diagnostic full-thickness skin biopsy may be required for ruling out scleroderma mimics such as scleredema, scleromyxedema, or nephrogenic systemic fibrosis (see Table 267-1). Primary Raynaud phenomenon is differentiated from SSc by normal-appearing nailfold capillaries and absence of autoantibodies. Diagnosing SSc can be difficult in the early stages of the disease because initial symptoms and findings are often nonspecific and can be mistaken for rheumatoid arthritis, SLE, myositis, or undifferentiated connective tissue disease. Rarely, patients with SSc first present with accelerated hypertension or GI bleeding caused by watermelon stomach as the initial manifestation.

Laboratory Features

Anemia is common and may reflect chronic inflammation, GI bleeding from gastric vascular ectasia, erosive gastritis or chronic esophagitis, or folate and vitamin B_{12} deficiency due to small bowel bacterial overgrowth and malabsorption. Microangiopathic hemolytic anemia (Chapter 160) caused by mechanical trauma and red blood cell fragmentation is a hallmark of scleroderma renal crisis. In contrast to other connective tissue diseases, the erythrocyte sedimentation rate and C-reactive protein generally show only modest elevation. Monitoring serum levels of prealbumin and vitamin K is useful in patients with small bowel bacterial overgrowth and malabsorption.

Antinuclear autoantibodies (ANAs) are present in virtually all patients with SSc and can be detected at, or even prior to, disease onset. Autoantibodies specific for SSc are described in Table 267-3. Anticentromere antibodies are associated with PAH, but cardiac involvement, significant pulmonary fibrosis, or scleroderma renal crisis occurs only rarely in these patients. Topoisomerase-I antibody positivity is associated with reduced survival, whereas anticentromere antibody–positive patients have improved survival compared with those without this antibody. Antibodies to RNA polymerase III (recognized based on its speckled immunofluorescence pattern) are associated with increased risk for scleroderma renal crisis. Antibodies to β_2-glycoprotein I are not specific but in SSc identify increased risk for critical ischemia.

TREATMENT AND PREVENTION Rx

With the exception of ACE inhibitors for scleroderma renal crisis, no therapy to date has been shown to significantly alter the natural history of SSc. In contrast, organ-based treatments are effective in alleviating symptoms and slowing progression of the cumulative organ damage. A significant reduction in disease-related mortality has occurred during the past 25 years. Treatment must be tailored to each patient's unique needs. Because of the marked heterogeneity in clinical presentation, a thorough and individualized baseline evaluation is paramount. Optimal management incorporates the following principles: prompt diagnosis, accurate classification and risk stratification, early recognition and assessment of organ-based complications, and monitoring progression, disease activity, and response to therapy. Management of complications should be proactive, with regular screening and initiation of appropriate intervention at the earliest possible opportunity. Given the multisystemic nature of SSc, an integrated team-based management approach, typically at specialized medical centers, is desirable. The team should incorporate appropriate medical specialists. Patients are empowered by learning about potential complications, therapeutic options, and the natural history of their disease.

Disease-Modifying Therapy

Immunosuppressive Agents

Immunosuppressive agents that are highly effective in the treatment of other connective tissue diseases have generally shown modest or no benefit in SSc.[12] Corticosteroids may alleviate stiffness and aching in early-stage dcSSc but do not slow the progression of skin or internal organ involvement and are associated with an increased risk for scleroderma renal crisis. Therefore, corticosteroids should be avoided if possible; when absolutely necessary, they should be given at the lowest dose possible and for brief periods only.

Cyclophosphamide was shown to reduce the progression of symptomatic interstitial lung disease in early SSc.[■■] Compared with placebo, patients treated with oral cyclophosphamide showed stabilization and, rarely, modest improvement in respiratory symptoms, pulmonary function, and abnormalities on chest HRCT after 1 year of treatment, but these benefits were short-lived. The use of cyclophosphamide in SSc needs to be balanced against its potential for side effects, including bone marrow suppression, opportunistic infections, hemorrhagic cystitis, bladder cancer, and premature ovarian failure.

In small clinical trials, methotrexate was associated with a modest improvement in skin involvement. Mycophenolate mofetil treatment was shown to improve skin involvement and stabilize lung disease. There is some support in the literature for the use of immunomodulatory agents and interventions including rituximab, intravenous immunoglobulin, and extracorporeal photopheresis for the treatment of SSc. Recent reports suggest that rituximab might be effective in ameliorating skin and lung involvement. In patients with severe SSc who fail to respond to other treatments (Chapter 178), autologous hematopoietic stem cell transplantation (HSCT) improves long term, event-free survival despite an increased treatment-related mortality in the first year.[■] Because of this potential morbidity and mortality and its substantial cost, HSCT is presently considered an investigational therapy for SSc.

Antifibrotic Therapy

Because tissue fibrosis causes progressive and irreversible organ damage, drugs that block or slow the fibrotic process represent a rational approach to therapy. D-Penicillamine has been extensively used as an antifibrotic agent. In retrospective studies, D-penicillamine stabilized and improved skin induration, prevented new internal organ involvement, and improved survival. However, in a randomized controlled clinical trial, there was no difference in the extent of skin involvement between patients treated with standard-dose (750 mg/day) or very low-dose (125 mg every other day) D-penicillamine. Minocycline, bosentan, recombinant relaxin, interferon-γ, and inhibitors of tumor necrosis factor are putative antifibrotic agents that have failed to show meaningful benefit in SSc clinical trials. Small-molecule inhibitors of protein tyrosine kinases used in malignancies (e.g., imatinib, nilotinib, and dasatinib) block signaling by TGF-β and PDGF and thereby prevent fibrotic responses in vitro and in vivo. These agents are currently in clinical trials for SSc.

Treatment of Organ-Specific Complications

Gastrointestinal Complications

Because significant gastroesophageal reflux may occur in the absence of symptoms, all patients with SSc should be treated for this complication. Proton pump inhibitors may need to be given in relatively high doses and for prolonged periods, and patients should be instructed to elevate the head of the bed and eat frequent small meals. Recurrent GI bleeding due to GAVE can be treated with laser or argon plasma photocoagulation. Bacterial overgrowth due to small bowel hypomotility causes bloating and diarrhea and may lead to malabsorption, weight loss, and malnutrition. Treatment with short courses of rotating broad-spectrum antibiotics such as metronidazole, erythromycin, and tetracycline can eradicate bacterial overgrowth, but many patients relapse when antibiotics are stopped. In patients with malnutrition but intact small bowel function, enteral nutrition via a jejunostomy can be effective. In others, total parenteral nutrition may be indicated. Refractory hypomotility of the small bowel may respond to subcutaneous octreotide injections. Anorectal complications may respond to sacral neuromodulation.

Vascular Therapy and Raynaud Phenomenon

The goal of therapy is to reduce the frequency and duration of vasospastic episodes, prevent ischemic complications and enhance their healing, and slow the progression of obliterative vasculopathy. Patients should dress warmly, minimize cold exposure, and avoid drugs that could precipitate or exacerbate vasospastic episodes. Calcium-channel blockers such as nifedipine and diltiazem are used commonly for Raynaud's phenomenon but show only moderate benefit, and their use is often limited by side effects (palpitations, dependent edema, light-headedness). ACE inhibitors do not reduce the frequency or severity of episodes, but angiotensin II receptor blockers such as losartan are effective and generally well tolerated. Patients with severe Raynaud phenomenon require α_1-adrenergic receptor blockers (e.g., prazosin), 5-phosphodiesterase inhibitors (e.g., sildenafil), topical nitroglycerine, or intravenous prostaglandins. Low-dose aspirin and dipyridamole prevent platelet aggregation and may have a role as adjunctive agents but must be used with caution in light of the risk of bleeding from GAVE lesions. The endothelin-1 receptor antagonist bosentan reduces development of new ischemic ulcers. Intravenous prostacyclin infusion, local injections of botulinum toxin, and digital sympathectomy are options for some patients with critical digital ischemia. Patients with ischemic digital ulcerations may require

surgical débridement, especially if necrotic tissue is present. Empirical long-term therapy with statins and antioxidants may slow the progression of vascular damage.

Pulmonary Arterial Hypertension

All patients with SSc should be screened for PAH at initial evaluation, and those at high risk on a yearly basis. Treatment for symptomatic PAH should be started with an endothelin-1 receptor antagonist or a 5-phosphodiesterase inhibitor. Diuretics, oral anticoagulation, and digoxin may be used when appropriate. If hypoxemia is documented, supplemental oxygen should be given. If clinical response is inadequate, 5-phosphodiesterase inhibitors may be used in combination with endothelin-1 receptor antagonists. Prostacyclin analogues can be administered intravenously, by continuous subcutaneous infusion, or by frequent inhalations. Lung transplantation remains an option for selected patients with SSc-associated PAH who fail medical therapy.

Treatment and Prevention of Scleroderma Renal Crisis

Prompt recognition of impending or early scleroderma renal crisis is essential. Because patients with early-stage SSc and progressive skin involvement are at highest risk, they should monitor their blood pressure daily and report significant alterations immediately. Corticosteroids should be used only when absolutely necessary and at the lowest possible doses. When scleroderma renal crisis occurs, patients should be hospitalized and treatment with short-acting ACE inhibitors started immediately to achieve prompt blood pressure normalization. There is no evidence that "prophylactic" use of ACE inhibitors can prevent the development of scleroderma renal crisis or ameliorate its severity. Although up to two thirds of patients who develop renal crisis require dialysis, delayed recovery of renal function can occur. Kidney transplantation is appropriate for patients unable to discontinue dialysis after 2 years. Survival with renal transplantation in SSc is comparable to that in other connective tissue diseases, and recurrence of scleroderma renal crisis is rare.

Skin Care

Skin involvement in early SSc is inflammatory and can be controlled with systemic antihistamines or short-term low-dose corticosteroids. Because of the increased risk for scleroderma renal crisis, blood pressure should be carefully monitored. Cyclophosphamide, methotrexate, D-penicillamine, and mycophenolate have been associated with modest improvement in skin induration in early-stage SSc. Skin dryness can be managed with the use of hydrophilic ointments and emollient bath oils. Fingertip ulcerations should be protected by occlusive dressing to promote healing and prevent infection. Infected skin ulcers are treated with topical or oral antibiotics and may necessitate surgical débridement. No medical therapy has been shown to be effective in preventing soft tissue calcification or in promoting its dissolution, and surgical therapy is only occasionally effective.

PROGNOSIS AND NATURAL HISTORY

Patients with dcSSc have a more rapidly progressive course, greater internal organ involvement, and worse prognosis compared to those with lcSSc. However, the outcome of the disease is difficult to predict.

Early inflammatory symptoms of dcSSc such as fatigue, edema, arthralgia, and pruritus commonly subside after 2 to 4 years, and skin thickening reaches a plateau followed by slow regression, which characteristically occurs in an order that is the reverse of initial involvement, with softening on the trunk followed by proximal and finally the distal extremities. Sclerodactyly and finger contractures generally persist. Relapse or recurrence of skin thickening is rare. Visceral organ involvement develops and progresses most rapidly during the initial 2 to 4 years of the disease. New organ involvement rarely occurs once the skin involvement has plateaued. Similarly, scleroderma renal crisis almost invariably occurs within the first 4 years of disease. In patients with lcSSc, Raynaud phenomenon may precede other disease manifestations by years or even decades, and visceral organ complications such as PAH and primary biliary cirrhosis generally occur late in the course of the disease.

Age- and gender-adjusted mortality rates in patients with SSc are more than five-fold higher than in the general population. The 10-year survival rate is 55% for patients with dcSSc and 75% for patients with lcSSc. Survival correlates with the extent of skin involvement, which represents a surrogate for visceral organ involvement. The leading causes of death are pulmonary fibrosis, PAH, severe GI involvement, and cardiac disease. Markers of poor prognosis include male sex, African American race, older age of disease onset, low body mass index, extensive skin thickening with truncal involvement, and evidence of significant or progressive visceral organ involvement. Autoantibodies to topoisomerase-I or absence of anticentromere antibodies are markers of poor prognosis. In one study, SSc patients who had extensive skin involvement, vital capacity less than 55% of predicted, significant GI involvement, and clinically evident cardiac involvement or scleroderma renal crisis had a less than 40% 10-year survival. The severity of PAH is correlated with mortality, and SSc patients with a mean pulmonary arterial pressure of 45 mm Hg or higher had a 33% 3-year survival rate. In scleroderma renal crisis, therapy with ACE inhibitors has had a dramatic effect on survival, increasing from less than 10% at 1 year in the pre-ACE inhibitor era to better than 70% 3-year survival at the present time.

NEPHROGENIC SYSTEMIC FIBROSIS

Nephrogenic systemic fibrosis (NSF) is a novel complication of renal insufficiency with certain clinical features resembling SSc.[13] The condition was initially described in 2000 and is now recognized as an emerging problem in patients with chronic renal failure. It is estimated that 2% of patients on long-term hemodialysis might develop NSF. Originally considered a purely dermatologic scleromyxedema-like condition and termed *nephrogenic fibrosing dermatopathy*, NSF is now recognized to be associated with visceral organ involvement and is therefore more accurately termed *nephrogenic systemic fibrosis*. The cutaneous manifestations of NSF share histopathologic and clinical features with other scleroderma-spectrum disorders, notably fasciitis and scleromyxedema. In most patients with NSF, the condition develops while undergoing long-term dialysis. However, no association with a particular route or type of renal replacement therapy has been demonstrated. Furthermore, NSF has also been described in patients who have never received dialysis. Histologic hallmarks include cutaneous fibrosis with mucin deposition and accumulation of spindle-shaped cells, including numerous CD34-positive cells, in the lesional skin.

The clinical hallmark of NSF is thickening and "woody" tightness of skin over the lower and, less commonly, upper extremities and contractures at large joints. A link between NSF and exposure to gadolinium-containing MRI contrast agents was suggested in 2006, leading to a warning by the U.S. Food and Drug Administration regarding the use of these agents in patients with renal insufficiency. This was followed by a substantial decline in the incidence of NSF. The course of NSF is generally progressive, and the prognosis is poor. Some patients show improvement with adjustment to renal replacement therapy, and others respond to renal transplantation. Anecdotal reports describe treatment with phototherapy, imatinib mesylate, and immunosuppressive agents. However, in most patients with NSF, the induration is resistant to therapy and leads to progressive induration, joint contractures, and reduced mobility.

The topic of immunoglobulin (Ig)G4-related disease is discussed in Chapter 275.

REVIEW QUESTIONS

1. Which of the following does not contribute to the pathogenesis of systemic sclerosis (SSc)?

A. Vascular wall remodeling
B. Tissue fibrosis
C. Vasculitis
D. T cells
E. Hypoxia

Answer: C Vasculitis does not typically occur in SSc. Vascular remodeling leading to hypoxia, inflammation, and fibrosis are the hallmarks of the disease.

2. Which is a characteristic autoantibody seen in SSc patients?

A. Anticentromere
B. Anti-CCP
C. Antihistone
D. Antiphospholipid
E. Anti-Smith

Answer: A Anticentromere is a hallmark SSc-associated autoantibody, whereas the other autoantibodies are seen in rheumatoid arthritis (B), lupus (C, E), and the antiphospholipid syndrome (D).

3. Which is a major factor in SSc morbidity?

A. Glomerulonephritis
B. Episcleritis
C. Amyloidosis
D. Pulmonary hypertension
E. Bowel infarction

Answer: D Pulmonary hypertension develops in up to 15% of SSc patients and is a major cause of morbidity and mortality. The other clinical features are uncommon in SSc and indicate other autoimmune or rheumatic diseases.

4. In patients with SSc-associated lung disease, lung biopsy may show:

A. Honeycombing
B. Interstitial fibrosis
C. Plasma cell accumulation
D. Intimal proliferation in the small vessels
E. All of the above

Answer: E All of the listed pathologic features can be noted in lung biopsies from patients with SSc-associated interstitial lung disease.

5. Which of the following drugs may contribute to scleroderma renal crisis?

A. NSAIDs
B. Glucocorticoids
C. Mycophenolate
D. Rituximab
E. Penicillamine

Answer: B The use of glucocorticoids has been shown to increase the risk of new-onset scleroderma renal crisis in patients with SSc.

SJÖGREN SYNDROME

XAVIER MARIETTE

DEFINITION

Sjögren syndrome (SS) is a systemic autoimmune disease characterized by lymphocytic infiltrates of salivary and tear glands, leading to oral and ocular dryness, and by autoantibody secretion. It can be encountered either alone

(primary Sjögren syndrome [pSS]) or in the presence of other systemic autoimmune diseases (secondary Sjögren syndrome [sSS]) like rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), inflammatory myositis, and systemic sclerosis. SS in the setting of RA usually follows RA diagnosis by many years and is mainly manifested by keratoconjunctivitis sicca, with systemic features being rather uncommon. Associated with other systemic autoimmune disease, the presentation of sSS is very close to pSS. Of note, pSS may be also associated with organ-specific systemic autoimmune disease, such as autoimmune thyroiditis and primary biliary cirrhosis.

EPIDEMIOLOGY

Primary SS is a common disease that affects 0.1 to 0.6% of the general adult female population.[1] A higher prevalence of the disease has been reported (0.5 to 2%), but this must be considered with caution because the reported prevalence of SS depends on the classification criteria used in the various studies, and the prevalence of sicca symptoms in the general population is high. Conversely, in recent studies with strict criteria, a lower prevalence has been found: 1.02 per 10,000 adults.[2] Primary SS has a female preponderance (female-to-male ratio at least 9 : 1). The age peak of the disease occurs after menopause in the mid-50s.

PATHOPHYSIOLOGY

Recent years have witnessed major advances in the pathophysiologic mechanisms of the disease. Several studies have confirmed the role of innate immunity, genetics, and B-cell activation and the relation between abnormalities in them.

The presence of an interferon (IFN) signature has been shown both in salivary glands and blood.[3] Plasmacytoid dendritic cells, the professional cells secreting type 1 IFN, are present within the glands. Type 2 IFN-dependent genes can be overexpressed in salivary glands. Natural killer (NK) cells, another actor of innate immunity able to secrete type 2 IFN are present in salivary glands of patients and play a role in the disease.[4]

In line with this IFN signature, multiple viral agents have been incriminated as etiologic factors for either the development or the modulation of SS; these include Epstein-Barr virus, retroviruses, and coxsackieviruses, but in all cases the data remain controversial.[5]

The genetics of pSS is now better understood with the reports of two genome-wide association studies (GWAS).[6] Like in other systemic autoimmune diseases, HLA is the most important region associated with the disease, and especially HLA-DR3-DQ1 in patients with autoantibodies. Interestingly, other genes associated with the disease are involved in the IFN response. These include IFN regulatory factor 5 *(IRF-5)*, a pivotal transcription factor in the type 1 IFN pathway, and signal transducer and activator of transcription 4 *(STAT-4)*, and *IL-12A*, involved in the type 2 IFN pathway. Other genes found to be associated with the disease are *TNIP1*, playing a role in control of nuclear factor (NF)-κB activation, and *CXCR5*, involved in germinal center formation.

The presence of ectopic salivary gland germinal centers demonstrates the importance of B-cell activation in pSS. Different cytokines may explain this B-cell activation. Several studies have focused on the role of BAFF (B-cell activating factor of the tumor necrosis factor [TNF] family), a cytokine that promotes B-cell maturation, proliferation, and survival. It has been shown that BAFF is enhanced in sera and in salivary glands from pSS patients. Interestingly, BAFF can be secreted by salivary gland epithelial cells, the target of autoimmunity, after stimulation by the innate immune system (type 1 or type 2 IFN, or viral infections). Thus, this cytokine is likely to be a link between innate immunity and autoimmunity.

The current hypothetical scenario for the development of pSS is based on the successive activation of innate and adaptive immune systems (Fig. 268-1). Environmental factors such as viral infections or hormonal imbalance may act at the initial stage of the disease by activating epithelial cells. This epithelial cell activation is promoted in patients who carry susceptibility factors in the genes for IFN pathway proteins. These patients experience a greater degree of IFN pathway activation, which leads to BAFF overproduction,

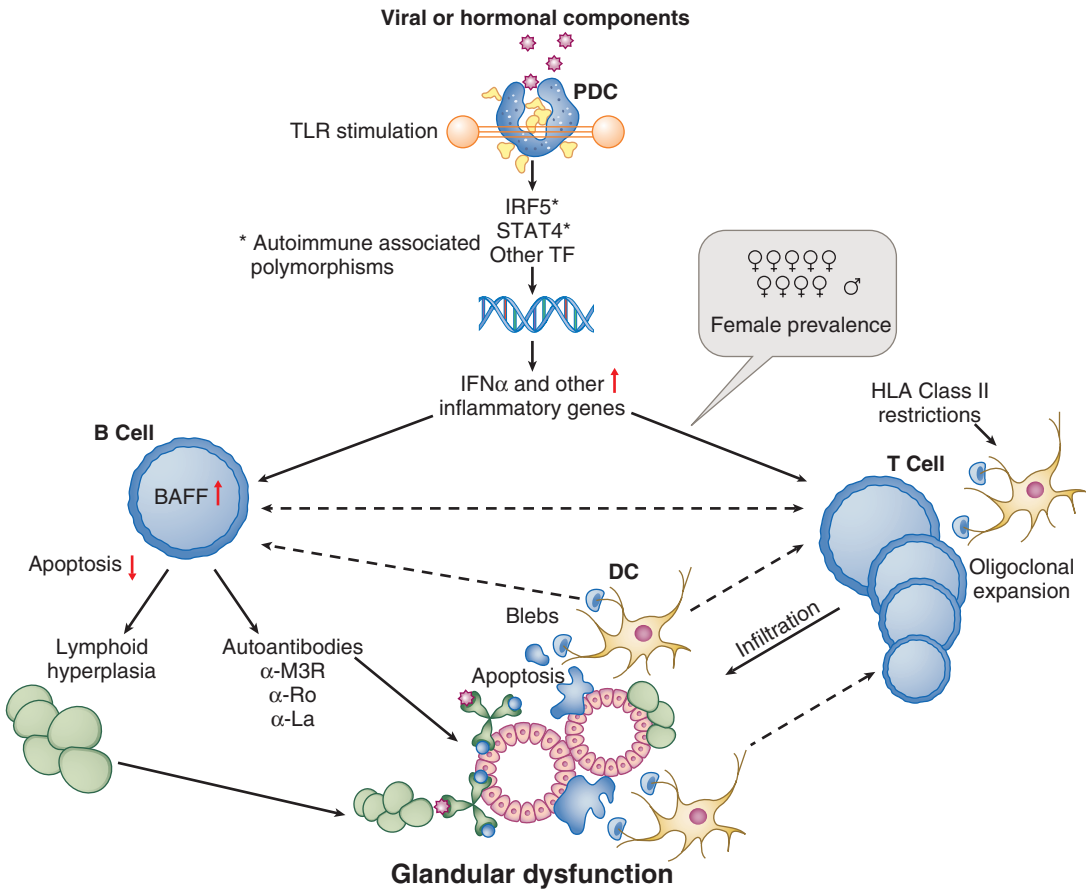

FIGURE 268-1. Hypothetical scenario for development of primary Sjögren syndrome. An environmental factor (e.g., virus) causes epithelial cell and dendritic cell (DC) activation. Plasmacytoid DCs are also activated by immune complexes, promoting interferon (IFN) pathway activation, which leads to BAFF overproduction and to B- and T-cell activation. B-cell activation leads to autoantibody production within germinal center–like structures. Interleukin-12 secreted by myeloid DCs leads to natural killer cell and T-helper 1 activation, which promotes tissue damage and IFN-γ production. IFN-α and IFN-γ enhance BAFF secretion. Epithelial cells release autoantigens that participate in immune complex formation and perpetuate the vicious cycle of immune system overactivation. BAFF = B-cell activating factor of the tumor necrosis factor family; IRF5 = interferon regulatory factor 5; PDC = plasmacytoid dendritic cell; STAT4 = signal transducer and activator of transcription 4; TF = transcription factors; TLR = toll-like receptors.

B- and T-cell activation, and secretion of autoantibodies, especially in predisposed patients. These autoantibodies constitute immune complexes that participate in the maintenance of IFN-α production. Altogether, these steps promote a vicious cycle of immune system activation leading to tissue damage.

CLINICAL MANIFESTATIONS

Glandular

Decreased salivary secretion results in mouth dryness and increased incidence of oral infections, mucosal friability, and dental caries due to loss of the lubricating, buffering, and antimicrobial capacities of saliva.[7] Fungal infections (primarily candidiasis) are also common. Parotid salivary gland or other major salivary gland enlargement can also occur. Persistent enlargement should be carefully followed, however, to exclude bacterial superinfection and, more importantly, the development of lymphoma.

Decreased lacrimal flow and impaired lacrimal composition lead to damage of the corneal and conjunctival epithelia, a condition known as keratoconjunctivitis sicca. As a result of keratoconjunctivitis sicca, SS patients might experience foreign-body sensation, grittiness, irritation, photosensitivity, and thick rope-like secretions at the inner canthus, all leading to increased discomfort and possibly visual impairment, with considerable functional disability. Furthermore, ocular complications include corneal ulceration and scarring, bacterial keratitis, and eyelid infections that require continuous ophthalmologic care and treatment.

Systemic

In addition to the sicca features, systemic manifestations occur in approximately 20 to 30% of pSS patients. Of note, it has been increasingly appreciated that the extraglandular manifestations in SS can be divided into two major types according to the underlying pathophysiologic mechanism. Thus, lymphocytic infiltration of the epithelia of organs beyond the exocrine glands (e.g., renal, liver, and bronchial epithelial cells) results in interstitial nephritis, autoimmune cholangitis, and obstructive bronchiolitis, respectively. These clinical features seem to appear early and usually have a benign course. On the other hand, immune complex deposition as a result of the ongoing B-cell hyperreactivity can give rise to the extraepithelial manifestations—palpable purpura, glomerulonephritis, interstitial pneumonitis, and peripheral neuropathy—that are linked to increased morbidity and risk for lymphoma development. The main systemic manifestations are listed in Table 268-1. Peripheral neuropathy may occur through various mechanisms. Vasculitis may be present with cryoglobulinemia, leading to both sensory and motor symptoms. More frequently, pure sensory neuropathy is present, sometimes purely ataxic and sometimes in the form of small-fiber neuropathy. This latter entity is difficult to diagnose because clinical and electromyographic examinations are normal. The diagnosis may be made by skin biopsy showing rarefaction of sensory small fibers.

Sjögren Syndrome and Non-Hodgkin Lymphomas

Chronic polyclonal B-cell activation is commonly present in pSS, which may explain why this autoimmune disease has the strongest association with the development of B-cell lymphoma (relative risk, 15 to 20). More recent studies have estimated this risk at a lower level: 6 in Denmark and Sweden, 7 in Taiwan, and 9 in Norway.

Lymphomas complicating pSS have specific features (Chapter 185). They are mostly B-cell non-Hodgkin lymphomas with a predominance of low-grade, marginal-zone histologic type. Mucosal localization is predominant, notably as mucosa-associated lymphoid tissue (MALT) lymphomas. Interestingly, lymphomas often develop in organs where pSS is active, such as salivary glands.

In the setting of SS, chronic autoimmune B-cell activation plays the major role in the lymphomagenesis process, and the identified predictors of lymphoma development in pSS are in line with this phenomenon. The main clinical predictors are permanent swelling of salivary glands, splenomegaly, lymphadenopathy, and palpable purpura. The main biological predictors are positivity of rheumatoid factor (RF), cryoglobulinemia, lymphopenia (especially CD4 lymphopenia), low complement levels, and a monoclonal component in serum or urine. Three novel predictive factors for lymphoma development have been recently described: (1) the presence of ectopic germinal centers associated with the occurrence of lymphoma in pSS patients[8]; (2) demonstration that BAFF levels are increased in pSS patients with current or previous lymphoma compared with patients without lymphoma[9]; (3) abnormalities of the gene *TNFAIP3* coding for the A20 protein that regulates NF-κB activation, found in up to 77% of MALT lymphomas complicating pSS.[10] In half of the cases, *TNFAIP3* mutations or deletions occur within lymphoma cells; in the other 50%, they involve germline *TNFAIP3* mutations with functional consequences.

TABLE 268-1 EXTRAGLANDULAR MANIFESTATIONS OF PRIMARY SJÖGREN SYNDROME

CONSTITUTIONAL SYMPTOMS
Fatigue
Low-grade fever
SKIN AND VASCULAR
Small vessel vasculitis
Raynaud phenomenon
Photosensitivity reactions similar to subacute cutaneous systemic lupus erythematosus
Xerosis
UPPER AND LOWER AIRWAYS
Pyogenic sialoadenitis or parotitis
Interstitial pneumonitis or fibrosis
Chronic bronchitis
Bronchiectasis
Bronchiolitis obliterans with organizing pneumonia
Chronic obstructive pulmonary disease
MUSCULOSKELETAL
Polyarthralgia, polyarthritis
Myopathy, polymyositis
RENAL
Type I renal tubular acidosis
Tubular interstitial nephritis
Glomerulonephritis
NEUROLOGIC
Peripheral motor sensory neuropathy
Pure sensory neuropathy (including pure ataxic neuropathy)
Small fiber sensitive neuropathy
Multiple sclerosis–like focal lesions
Spinal cord dysfunction, including transverse myelitis
NEOPLASIA
Lymphadenopathy, MALT (mucosa-associated lymphoid tissue) lymphoma

Laboratory Findings

The most common serologic finding in pSS is hypergammaglobulinemia. The elevated γ-globulins contain several autoantibodies directed against non–organ-specific antigens, such as RF and antinuclear antibody (ANA). Specific ANA, anti-SSA/Ro, and anti-SSB/La antibodies are present in 60 to 80% and 30 to 40% of patients, respectively, and anti-SSB/La is never present without anti-SSA/Ro. Of note, the presence of anti-SSA/Ro, possibly with anti-SSB/La, may mediate complete heart block of newborns owing to cross-mimicry between specific fetal myocardial antigens and epitopes of the SSA/Ro-SSB/La complex.

Anemia of chronic inflammation and high erythrocyte sedimentation rates (due to hypergammaglobulinemia) are frequently encountered, whereas C-reactive protein levels are usually within normal limits. Cytopenias (most frequently lymphopenia and neutropenia) can also occur. In the setting of interstitial nephritis, the presence of hypokalemic, hyperchloremic acidosis might reveal distal renal tubular acidosis.

A monoclonal immunoglobulin can be detected in 10 to 15% of patients with SS, depending on the technique used. Approximately 20% of patients with SS have cryoglobulins in their sera. Complement levels may be decreased, especially C4. This low C4 level may be either genetically determined or secondary to consumption (in immune complexes or cryoglobulinemia).

DIAGNOSIS

Differential Diagnosis

The definition of pSS had suffered for a long time from the absence of accurate and consensus-driven diagnostic criteria. This is important because the patients' main symptoms (dryness, fatigue, and pain) are frequent in the general population. They can be caused by numerous drugs (Table 268-2), anxiety and/or depression, other comorbidities, or aging (Table 268-3). Sarcoidosis can mimic the clinical picture of SS. However, in sarcoidosis minor salivary gland biopsy reveals noncaseating granulomas, and autoantibodies

TABLE 268-2 DRUGS AND TOXINS THAT MIGHT DECREASE LACRIMAL AND SALIVARY SECRETION

STRONG EFFECT	MODERATE EFFECT
Atropine, atropinic antiparkinsonian drugs, anticholinergic antihistaminic drugs	β-Adrenergic blockers
Antidepressants: imipraminic (amitriptyline) and inhibitors of monoamine oxidase	α-Adrenergic blockers
Neuroleptics	Calcium channel blockers
Morphine, codeine, tramadol	Benzodiazepines
A-type botulinum toxin	Inhibitors of serotonin reuptake (very slight effect)
Class IA antiarrhythmic (disopyramide)	H_1 antihistaminic drugs
Isotretinoin	Diuretics
Toxins and psychotropic drugs: tobacco, ecstasy, cannabis, cocaine	Some antiretroviral drugs

TABLE 268-3 THE DIFFERENT CAUSES OF SICCA SYMPTOMS

Drugs, particularly psychotropic drugs (see Table 268-2)
Aging, postmenopausal estrogen deficiency
Prolonged use of contact lenses
Fibromyalgia and chronic fatigue syndrome
Anxiodepressive syndromes
Head and neck radiotherapy
Diabetes (uncontrolled)
Severe hyperlipidemia
Amyloidosis
Sarcoidosis
Lymphoma
Graft-versus-host disease
Some viral infections (HIV, HCV, HTVL-1)
IgG4-related sialoadenitis
Sjögren syndrome

HCV = hepatitis C virus; HIV = human immunodeficiency virus; HTVL-1 = human T-lymphocytic virus-1.

are typically absent. Other SS mimickers include chronic graft-versus-host disease, amyloidosis, infection with viruses such as HIV, human T-lymphocytic virus-I (HTLV-I), and hepatitis C virus (HCV), and IgG4-related disease (Chapter 275). The latter disease is important in the differential diagnosis of SS. It more often involves men with salivary or lacrimal gland enlargement (previously called Mickuliz disease) with previous organ-specific autoimmune disease (like autoimmune pancreatitis) without anti-SSA/SSB antibodies. Sicca symptoms without salivary lymphoid infiltrate and without anti-SSA/SSB antibodies may be part of the fibromyalgia syndrome (Chapter 274), and several acronyms have been proposed for designating these patients: sicca asthenia polyalgia syndrome (SAPS) or dry eyes and mouth syndrome (DEMS).

Diagnostic Criteria

International agreement has established a definition of SS based on the American-European Consensus Group (AECG) criteria, which require the presence of either focal lymphocytic infiltrates in minor salivary glands with a focus score of 1 or more, or anti-SSA/SSB autoantibodies (Table 268-4). A new set of preliminary criteria for SS classification was proposed by an expert consensus panel (American College of Rheumatology [ACR]-Sjögren International Collaborative Clinical Alliance [SICCA]). According to these criteria, classification of an individual as a pSS patient requires the presence of two out of three of the following objective items: (1) a positive serum test for anti-Ro/SSA and/or anti-La/SSB antibodies, or positive rheumatoid factor (RF) and antinuclear antibody (ANA) (titer > 1: 320); (2) presence of keratoconjunctivitis sicca, defined by an ocular staining score over 3; and (3) presence of focal lymphocytic sialoadenitis, defined by a focus score of 1 focus/4 mm^2 or above in a labial salivary gland biopsy.[11]

Assessment of Activity of the Disease

An international expert group recently set up an SS activity score under the umbrella of the European League Against Rheumatism (EULAR). Two indices have been developed: (1) a patient-administered questionnaire to assess subjective features, the EULAR Sjögren Syndrome Patient Reported Index (ESSPRI), based on three different visual analogic scores: dryness, fatigue, and limb pain[12]; and (2) a systemic activity index to assess systemic complications, the EULAR Sjögren Syndrome Disease Activity Index (ESSDAI).[13] The latter index comprises 12 domains with 3 or 4 levels of activity for each domain. Determination of the threshold of moderate activity as well as the minimal clinically important improvement is in progress, with the objective to base inclusion criteria and primary end-points of future clinical studies on ESSDAI levels.

TABLE 268-4 CLASSIFICATION CRITERIA FOR SJÖGREN SYNDROME

I. OCULAR SYMPTOMS
Positive response to at least one of these three questions: 1. Have you had daily, persistent, troublesome dry eyes for more than 3 months? 2. Do you have a recurrent sensation of sand or gravel in the eyes? 3. Do you use tear substitutes more than three times a day?
II. ORAL SYMPTOMS
Positive response to at least one of these three questions: 1. Have you had a daily feeling of dry mouth for more than 3 months? 2. Have you had recurrent or persistently swollen salivary glands as an adult? 3. Do you frequently drink liquids to aid in swallowing dry food?
III. OCULAR SIGNS
Objective evidence of ocular involvement, defined as a positive result in at least one of the following two tests: 1. Schirmer test (≤5 mm in 5 min) 2. Rose bengal score (≥4 according to van Bijsterveld scoring system)
IV. HISTOPATHOLOGY
Focus score ≥1 in a minor salivary gland biopsy specimen (a focus is defined as an agglomerate of at least 50 mononuclear cells; the focus score is defined by the number of foci in 4 mm^2 of glandular tissue)
V. SALIVARY GLAND INVOLVEMENT
Objective evidence of salivary gland involvement, defined by a positive result in at least one of the following three diagnostic tests: 1. Salivary scintigraphy 2. Parotid sialography 3. Unstimulated salivary flow (≤1.5 mL in 15 min)
VI. AUTOANTIBODIES
Presence in the serum of the following autoantibodies: antibodies to Ro (SSA) or La (SSB) antigens, or both
RULES FOR CLASSIFICATION
In patients without any potentially associated disease, primary Sjögren syndrome is diagnosed if: Four of six criteria are met, including IV or VI; *or* Three of four criteria from III, IV, V, and VI are met For secondary Sjögren syndrome, criteria I or II plus any two from criteria III, IV, and V should be met
EXCLUSION CRITERIA
Preexisting lymphoma, AIDS, sarcoidosis, graft-versus-host disease, past head and neck radiation treatment, use of anticholinergic drugs, and hepatitis C

From Vitali C, Bombardieri S, Jonsson R, et al. Classification criteria for Sjögren syndrome: a revised version of the European criteria proposed by the American-European Consensus Group. *Ann Rheum Dis.* 2002;61:554-558.

TREATMENT

Symptomatic Treatment

A recent systematic review of the literature confirms benefits for muscarinic agonists (pilocarpine hydrochloride and more recently cevimeline hydrochloride) for sicca features (oral dryness and, to a lesser extent, ocular dryness). Topical cyclosporine collyrium (0.05%) also was effective for moderate or severe ocular dryness and inflammation in a randomized controlled trial versus placebo, as were 0.1% clobetasone butyrate eyedrops. Environmental measures (avoidance of hot air heating systems or excessive air conditioning, use of a humidifier, appropriate glasses to protect the eye from evaporating air flow) and "little means" (sugar-free chewing gums, regular water drinking, salivary substitutes) might be useful. Regular dental examinations and oral hygiene are crucial for reducing subsequent oral health issues (i.e., caries and periodontal disease associated with xerostomia). To treat pain, simple analgesics should be used first, particularly acetaminophen/paracetamol, which does not cause dryness.

Immunomodulatory Drugs

To date, no immunomodulatory drug has proved efficacious in pSS. Severe organ manifestations of pSS have to be treated in accordance with treatment modalities used in SLE or other connective tissue diseases. Randomized trials have assessed hydroxychloroquine in pSS and failed to demonstrate any clinical efficacy.[A3] In spite of these negative results on clinical outcomes, hydroxychloroquine is frequently used in pSS, especially to treat arthralgia with or without synovitis or purpura. Controlled studies are needed to assess the use of methotrexate, leflunomide, mycophenolate sodium, azathioprine, and cyclosporine. Intravenous gamma globulin (IVIG) has been used in the treatment of SS-associated sensorimotor neuropathies or non-ataxic sensory neuropathy without any necrotizing vasculitis.

Biologics

Two randomized controlled trials (RCT) of infliximab and etanercept did not show any efficacy of TNF-blocker agents in pSS on a composite primary outcome including limb pain, fatigue, and dryness visual analogue scales (VAS).[A4] B-cell targeting appears to be a promising strategy in pSS. Three randomized controlled trials assessed efficacy of the monoclonal anti-CD20 antibody (rituximab). In the first one, a significant improvement from baseline in a fatigue VAS was observed in the rituximab group but not in the placebo group.[A5] In the second one, rituximab demonstrated significant efficacy compared to placebo in improving stimulated salivary flow, the primary end-point, but also oral and ocular dryness, fatigue VAS, and systemic complications.[A6] In the third study, the composite primary end-point, using 4 VAS, was achieved at 6 weeks but not at 6 months.[A7] Lastly, recent data derived from the French Autoimmune and Rituximab (AIR) registry, including 78 pSS patients with mainly systemic manifestations, suggested the efficacy of rituximab on systemic manifestations in approximately two thirds of the patients.[14] Overall, rituximab seems to be useful in cases of persistent parotid swelling or systemic complications, especially in cryoglobulinemia-induced vasculitis. Inhibitors of BAFF, especially the anti-BAFF monoclonal antibody belimumab (which is approved in SLE), has been used in pSS in a first open phase 2 study, with promising results.[15]

FUTURE DIRECTIONS

SS is a model of autoimmune disease, because it can be primary or associated with other autoimmune diseases; it represents autoimmunity where the risk of lymphoma is most important. SS is the autoimmune disease for which the target tissue of autoimmunity is the most easily available, with the lip biopsy being necessary for diagnosis. Recent progress in pathophysiology has emphasized a number of similarities with SLE that support consideration of SS as a sort of lupus of the mucosa. Even if the pathogenetic mechanisms of the disease remain largely unknown, improved knowledge of the effector mechanisms will allow identification of new targets for future therapy. Moreover, with the recently validated composite activity scores of ESSPRI and ESSDAI, the tools are now available to begin new clinical trials with novel drugs for this disease that will improve the poor quality of life currently associated with it.

REVIEW QUESTIONS

1. A 59-year-old woman is referred to your office because of dry mouth, grittiness of eyes, and a rash on both legs. Physical exam discloses unilateral parotid enlargement and a purpuric rash of the lower extremities. Past medical history is unremarkable to date. Among the following diagnostic tests, which one is the most useful to establish the diagnosis of Sjögren syndrome?

A. Complement levels
B. Cryoglobulins
C. Serum protein electrophoresis
D. Salivary flow
E. Anti-Ro/SSA antibodies

Answer: E Anti-Ro/SSA positivity is one of the two required 2002 European/American classification criteria for Sjögren syndrome (SS) and one out of the three 2012 preliminary ACR/SICCA 2012 criteria. Low complement levels, especially C4, and cryoglobulinemia have been designated as adverse prognostic factors for lymphoma development and mortality among SS patients. However, they are not included in the classification criteria. Hypergammaglobulinemia or monoclonal gammopathy are likewise not included in the classification criteria of SS. Salivary flow rate of less than 1.5 mL/15 minutes is an objective criterion of oral dryness, included in the 2002 European/American classification SS criteria but not in the 2012 preliminary ACR/SICCA criteria. It is not as specific as anti-Ro/SSA antibodies.

2. A 55-year-old woman presents with mild pain affecting her hands, as well as ocular and mouth dryness for 10 years. Her examination reveals positive ocular staining for both eyes, revealing keratoconjunctivitis sicca, positive anti-Ro/SSA antibodies, and negative HCV and HIV serology. Additional testing included complete blood count, revealing lymphopenia with normal hemoglobin levels and platelet counts. Mixed monoclonal cryoglobulinemia and low C4 levels were also detected. Which of the following statements is true?

A. The patient fulfills both the the 2002 American/European Consensus Group (AECG) criteria and 2012 preliminary ACR/SICCA criteria for primary SS (pSS).
B. The patient fulfills only the 2002 AECG criteria for pSS.
C. A minor salivary gland biopsy is mandatory to classify the patient as having SS according to 2002 AECG group criteria for pSS.
D. A minor salivary gland biopsy is mandatory to classify the patient as having SS according to 2012 preliminary ACR/SICCA criteria for pSS.
E. The patient suffers from sicca asthenia polyalgia syndrome.

Answer: A Two out of three 2012 preliminary ACR/SICCA criteria are fulfilled, as well as four out of six 2002 AECG criteria. Since anti-Ro/SSA antibodies are present, no histopathologic confirmation is required for the classification of pSS according to 2002 AECG criteria in the presence of subjective and objective symptoms and signs of salivary and lacrimal gland involvement. Sicca asthenia polyalgia syndrome is a diagnosis of exclusion and refers to the presence of fibromyalgia-like features in association with sicca symptomatology.

3. Which of the following is the best option for improving the patient's ocular dryness?

A. Methotrexate
B. Pilocarpine
C. Hydroxychloroquine
D. Ocular cyclosporine drops
E. Infliximab

Answer: D Ocular cyclosporine drops have proved useful in the treatment of dry eye. The efficacy of methotrexate on ocular dryness has never been demonstrated. Ocular dryness is less frequently improved than salivary dryness with secretagogues (i.e., pilocarpine). The efficacy of hydroxychloroquine on dryness has not been demonstrated. No efficacy of infliximab has been demonstrated in pSS.

4. Which of the following features is ***not*** considered an adverse predictor for lymphoma development in Sjögren syndrome?

A. Presence of splenomegaly
B. Presence of purpura
C. Salivary flow rate less than 1 mL/15 minutes
D. Presence of persistent parotid gland enlargement
E. Presence of CD4 lymphopenia

Answer: C All the other items are predictive factors of lymphoma. An association has not been reported between salivary flow rate and risk of lymphoma development.

5. A 55-year-old woman is referred to your department for polysynovitis and palpable purpura. She fulfills the AECG 2002 criteria for Sjögren syndrome. Which of the following treatments would you recommend to treat these systemic manifestations?

A. Infliximab
B. Intravenous immunoglobulin
C. Pilocarpine
D. Rituximab
E. Cyclophosphamide

Answer: D Three randomized controlled trials (RCTs) and one registry study suggested possible efficacy of rituximab in pSS, at least in some systemic manifestations. Two RCTs did not demonstrate any efficacy of tumor necrosis factor blockers (i.e., infliximab) in pSS. IVIG has been proposed in open studies in the treatment of SS-associated neuropathies without vasculitis, but never has demonstrated any efficacy in other systemic manifestations. The secretagogue pilocarpine has no effect on systemic manifestations. The systemic manifestation presented by the patient is not severe enough to propose cyclophosphamide.

269

INFLAMMATORY MYOPATHIES

STEVEN A. GREENBERG

OVERVIEW

The inflammatory myopathies are a heterogeneous group of acquired disorders in which the immune system is thought to play a major pathogenic role. Though some genetic disorders affecting muscle also have significant involvement of the immune system and are treated with immunosuppressive therapy as standard of care (e.g., treatment of Duchenne's muscular dystrophy with corticosteroids), these genetic disorders are not classified as inflammatory myopathies. The four major subtypes of inflammatory myopathy are: dermatomyositis (DM), polymyositis (PM), immune-mediated necrotizing myopathy (IMNM), and inclusion body myositis (IBM; also called sporadic inclusion body myositis [sIBM]). These disorders have distinct clinical and pathologic features and pathophysiologies (Table 269-1). Whereas DM and PM have been described in the medical literature for over 100 years, IMNM and IBM have only become defined as syndromes distinct from PM within the last few decades.

EPIDEMIOLOGY

The prevalence of DM has been estimated at 100[1] to 210 per million. The estimated prevalence of PM is confounded by frequent misdiagnosis of IBM and muscular dystrophies as PM. Traditionally, PM has been considered more prevalent (70 per million[2]), but comparative studies with attention to IBM have found a prevalence of PM of 35 per million, approximately half the prevalence of IBM of 70 per million. The prevalence of IMNM is unknown.

DM peaks in prevalence in childhood (7 to 15 years) and in midlife (30 to 50 years), whereas PM peaks in prevalence in midlife. IBM is rarely diagnosed before the age of 40 and is most common after the age of 50. DM and PM have female predominance; IBM has male predominance. Ethnicity and worldwide distribution influence the development of various inflammatory myopathies.

PATHOBIOLOGY

The pathophysiologies of various forms of inflammatory myopathy are poorly understood. These disorders do share in common injury to muscle by the immune system. Much of the theory of pathophysiology of these disorders comes from microscopic examination of muscle biopsies and the distinct pathologies of these disorders (Fig. 269-1).

The muscle pathology of DM involves loss of muscle blood vessels and injury to myofibers at the edges of muscle fascicles (i.e., perifascicular atrophy; see Fig. 269-1). The relationship of these two features to each other is uncertain but has been postulated to be due to a primary injury to muscle capillaries, followed by ischemic injury to myofibers. An alternative view is that a common factor injures both myofibers and capillaries.[3] Skin pathology shows features analogous to that of muscle, with an interface dermatitis consisting of injury to the basal layer of keratinocytes.

Much evidence points toward DM as mediated by the type 1 interferon cytokine family, consisting mainly of interferon (IFN)-α and IFN-β.[4,5] Numerous studies of DM skin and muscle samples show marked upregulation of type 1 IFN-inducible transcripts and proteins uniquely in DM among muscle diseases, and similarly to systemic lupus erythematosus among skin diseases. The presence of autoantibodies in some patients with DM, such as antibodies to the type 1 IFN-inducible protein MDA5, is of uncertain significance but seems likely due to an immune reaction to proteins that are not normally expressed at high levels or exposed to the immune system. The paraneoplastic associations of DM suggest that in such patients, an immune reaction against an underlying malignancy results in bystander injury to muscle and skin.

Because PM is a diverse group of disorders, the mechanisms involved are likely to be varied. Pathologically, there is an appearance of invasion of muscle fibers by adaptive immune system cells (T cells) that appears to be antigen driven, so that cytotoxic T cell–mediated autoimmunity directed against an unknown target has been a favored hypothesis. The antigens targeted by this process and the fundamental cause are unknown.

TABLE 269-1 CLASSIFICATION OF INFLAMMATORY MYOPATHIES

DISORDER	AGE RANGE	CLINICAL FEATURES	MUSCLE PATHOLOGY
Dermatomyositis	Juvenile and adult forms	Proximal weakness plus skin	Perimysial and perivascular inflammation, perifascicular atrophy
Polymyositis	Adult (rare in childhood)	Proximal weakness	Endomysial inflammation with invasion of non-necrotic muscle fibers
Immune-mediated necrotizing myopathy	Adult	Proximal weakness	Multifocal necrotic muscle fibers
Inclusion body myositis	Adult > 40 years old	Prominent quadriceps and finger flexor weakness; treatment refractory	Endomysial inflammation with invasion of non-necrotic muscle fibers plus rimmed vacuoles
Overlap syndromes	Adult	Myositis plus defined connective tissue disease	Nonspecific inflammation
Other (granulomatous myositis, eosinophilic myositis)	All ages	Proximal or distal weakness	Specific to type (e.g., granulomas present with granulomatous myositis)

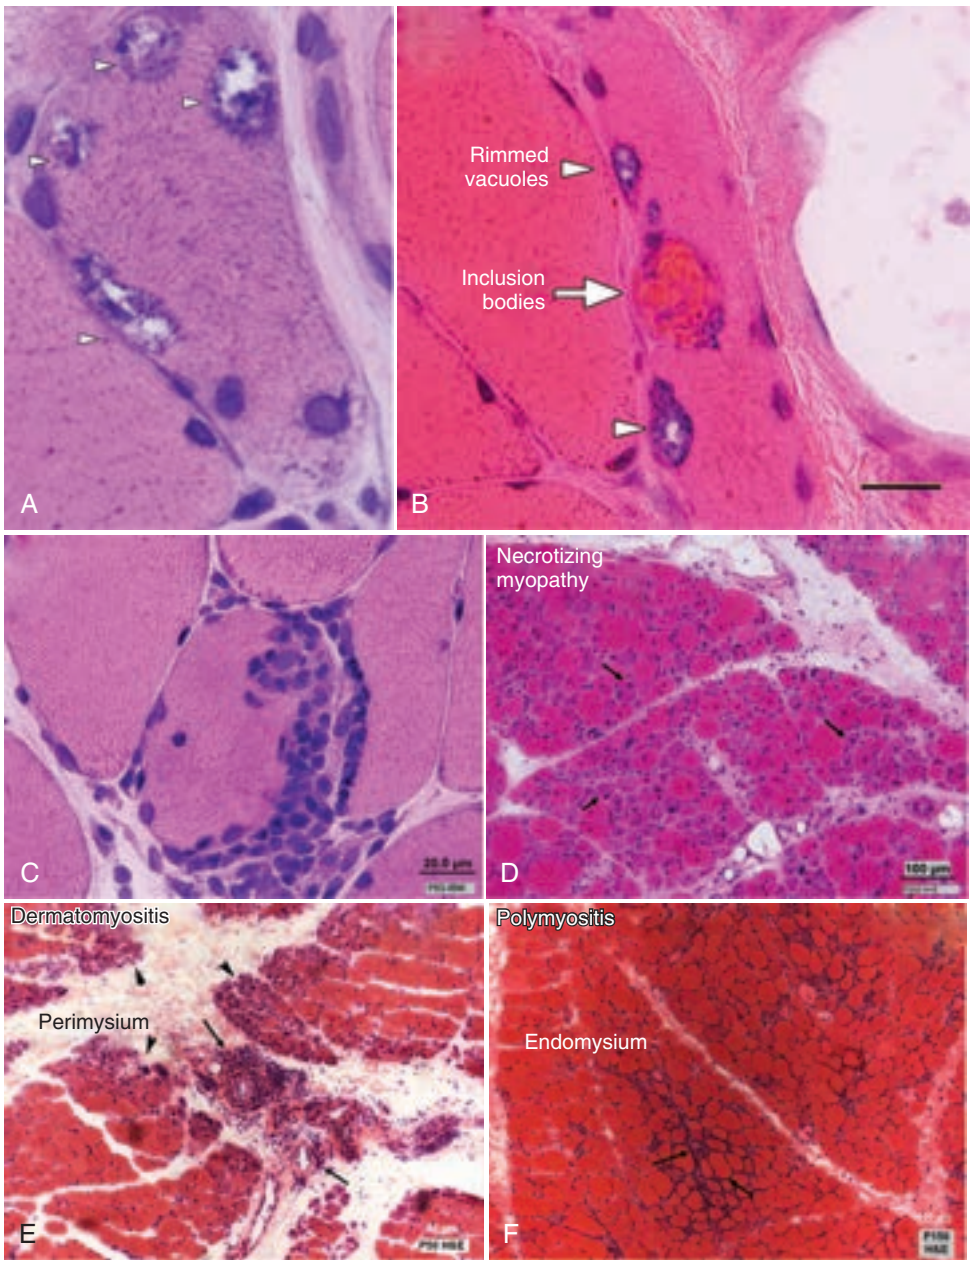

FIGURE 269-1. Pathologies of inflammatory myopathies. A and **B**, Rimmed vacuoles (*arrowheads*) of inclusion body myositis (IBM). **C**, Invasion of non-necrotic muscle fiber in IBM. **D**, Scattered necrotic and regenerating myofibers in immune-mediated necrotizing myopathy. **E**, Perivascular and perimysial inflammation (*arrows*), with perifascicular atrophy (*arrowheads*), in dermatomyositis. **F**, Endomysial inflammation in polymyositis. IMNM is also a poorly understood disorder.[6] It can also be paraneoplastic, suggesting cross-reactions by the immune system with the underlying malignancy and with muscle antigens. More commonly, IMNM occurs in association with treatment with statin drugs. The identification of autoantibodies against the target of statins, 3-hydroxy-3-methylglutaryl-coenzyme A reductase (HMGCR), in the majority of patients who develop IMNM in association with statin use suggests that the upregulation of HMGCR in muscle is directly toxic to muscle and triggers an immune reaction against it.

The pathogenesis of IBM is complex. Two dual pathologies have been noted: degeneration of myofibers and of myonuclei in particular, evident as formation of rimmed vacuoles (see Fig. 269-1A and B), and involvement of the immune system.[7] The accumulation of more than 75 different proteins into sarcoplasmic aggregates in a small percentage of IBM myofibers has been reported, and has given rise to a number of molecular toxicity hypotheses in which certain specific protein aggregates are theorized as injurious to myofibers.

The immune system involvement in IBM is notable in that whereas most other forms of inflammatory myopathy are generally responsive to immunomodulatory treatments, IBM is refractory to treatment. This is particularly remarkable in that IBM has the greatest evidence of all the inflammatory myopathies of a highly refined antigen-driven adaptive immune system involvement. Pathology shows very chronic and often marked but variable inflammatory infiltrates of T cells, myeloid dendritic cells, and plasma cells in muscle. Studies of the T-cell receptors have strongly suggested that T-cell autoimmunity is driven by one or more specific antigens, though the identity of any of these antigens is unknown.

Studies of a B-cell pathway in IBM have led to identification of an autoantibody that is highly specific to IBM among muscle diseases. Circulating autoantibodies against a 43-kD muscle protein were reported in 2011, and the identity of this 43-kD protein as cytoplasmic 5′ nucleotidase 1A (cN1A; NT5C1A) was reported in 2013.[8,9] cN1A is a nucleotidase that is most abundant in skeletal muscle and involved in the metabolism of nucleic acids. Serum anti-cN1A autoantibodies are present in 50 to 70% of patients with IBM, depending on which assays and what cutoffs are used, and highly specific to IBM (>90 to 95%) among muscle diseases. The role of blood testing for anti-cN1A autoantibodies in the diagnosis and management of patients with suspected IBM is currently being defined, potentially shortening the time to diagnosis, reducing the misdiagnosis rate, and avoiding more invasive muscle biopsy in some patients.

TABLE 269-2 CLINICAL DIAGNOSTIC CRITERIA FOR INFLAMMATORY MYOPATHIES

DISORDER	DIAGNOSIS
Dermatomyositis	1. Diagnostic skin involvement (heliotrope rash, Gottron's papules) *OR* diagnostic muscle biopsy finding of perifascicular atrophy *OR* 2. All of the following: • Suggestive skin involvement • Subacute or chronic proximal or distal weakness • Muscle biopsy showing perimysial or perivascular inflammation without features suggesting another disorder (e.g., endomysial inflammation, rimmed vacuoles) *OR* skin biopsy showing interface dermatitis along with clinical exclusion of lupus erythematosus
Polymyositis	All of the following: 1. Subacute or chronic proximal weakness 2. Elevated serum creatine kinase (CK) 3. Muscle biopsy showing invasion of endomysial inflammation 4. Response to immunotherapy *OR* appropriate consideration and exclusion of limb-girdle muscular dystrophies and inclusion body myositis
Immune-mediated necrotizing myopathy	Both of the following: 1. Subacute or chronic proximal weakness 2. Muscle biopsy showing necrotizing myopathy, with scattered necrotic or regenerating myofibers and a lack of inflammation other than macrophage invasion of necrotic muscle fiber
Inclusion body myositis	All of the following: 1. Adult > 40 years old 2. Finger flexion or quadriceps weakness 3. Muscle biopsy showing endomysial inflammation *OR* the presence of serum anti-cN1A autoantibodies 4. Muscle biopsy showing rimmed vacuoles *OR* invasion of non-necrotic muscle fibers *OR* the presence of serum anti-cN1A autoantibodies

cNIA = cytoplasmic 5′ nucleotidase 1A.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

A diagnosis of inflammatory myopathy is considered when a patient presents with proximal or distal weakness without sensory symptoms, or in patients with the characteristic skin lesions of DM. Less frequently, asymptomatic elevated creatine kinase (CK) levels lead to a diagnosis of inflammatory myopathy. Most patients with DM, PM, or IMNM present with subacute proximal weakness of the arms and legs progressing over months, though these diseases may present acutely. Patients with IBM present later in life, usually symptomatic from slowly progressive weakness of knee extensors and finger flexors. More specific diagnostic considerations for these disorders are considered individually (Table 269-2). Most patients undergo muscle biopsy, or skin biopsy in the case of suspected DM, as part of the diagnostic evaluation.

Dermatomyositis

Patients with DM typically present with characteristic skin lesions or muscle weakness. Virtually pathognomonic skin features are a heliotrope rash, a violaceous periorbital macular erythema, sometimes with edema, and Gottron's papules, violaceous papules over dorsal metacarpophalangeal and interphalangeal joints of the hands (Fig. 269-2).[10] Periungual telangiectasias and thrombosed capillaries, poikiloderma over photoexposed areas such as the upper back ("shawl sign"), non-scarring alopecia, and subcutaneous calcification are other suggestive signs. Prominent pruritus is also a common feature of DM. Muscle weakness in DM is less specific, occurring in a pattern indistinguishable from many other muscle diseases.

Useful laboratory studies for the evaluation of suspected DM include serum CK (though CK can be normal or even below typical laboratory lower limits of normal in patients with highly active disease) and DM-associated autoantibody studies (e.g., anti-Jo-1, anti-Mi2, and anti-MDA5). Occasional patients have abnormal serum aldolase but normal serum CK. Skin biopsy showing a cell-poor interface dermatitis supports the diagnosis of DM. Muscle biopsy showing perimysial and perivascular inflammation also supports a diagnosis of DM, whereas the presence of perifascicular atrophy in a muscle biopsy is pathognomonic for DM. Because DM is associated with malignancy, appropriate laboratory and radiologic studies should be performed to search for underlying malignancy in all newly diagnosed patients. The most common DM-associated malignancies tend to reflect the overall age and gender cancer rates within the individual patient's population (i.e., breast, lung, and colorectal cancer in Western countries; nasopharyngeal cancer in Asian populations). This observation supports the notion of DM as a paraneoplastic process that can develop in virtually any kind of cancer.

Research diagnostic criteria for DM have been defined.[11] Clinical diagnostic criteria are outlined in Table 269-2. The clinical features of muscle weakness in DM are entirely nonspecific, with no particular pattern indicative of DM rather than other muscle diseases. In practice, certain dermatologic clinical findings (heliotrope rash, Gottron's papules) or muscle biopsy findings (perifascicular atrophy) are considered nearly pathognomonic for DM.

Polymyositis

The diagnosis of PM is often problematic, with historically many patients with genetically defined limb-girdle muscular dystrophies and IBM being misdiagnosed as PM. The 1975 criteria for PM that are frequently cited allow for a diagnosis of "definite" PM without a muscle biopsy. Other research criteria require muscle biopsy. In clinical practice, the core criteria for the diagnosis of PM are subacute proximal weakness, elevated serum CK, and muscle biopsy showing endomysial inflammation without features suggestive of another diagnosis such as IBM (see Table 269-2). Patients with defined connective tissue disorders such as Sjögren's syndrome or mixed connective tissue disease have "overlap syndromes," often also classified as PM. Patients with IMNM have historically been classified as PM but are increasingly classified separately. Patients with IBM are frequently misdiagnosed as PM because of a lack of appreciation of characteristic IBM finger flexor weakness, and because muscle biopsies show endomysial inflammation. The presence of autoantibodies such as anti-Jo-1 argue more for PM than IBM, though these may be seen in DM as well.

FIGURE 269-2. Clinical findings in dermatomyositis. A, Erythematous to violaceous raised papules overlying the metacarpal and interphalangeal joints, known as Gottron's papules. These are considered the hallmark finding in dermatomyositis. **B,** Cuticular overgrowth and periungual capillary changes, which include dilated and tortuous blood vessels with areas of atrophy, telangiectasia, vessel dropout, and bushy loop formation along the fingernail bed. **C,** Erythema and minimal edema involving the upper eyelids, with occasional telangiectasia, known as the heliotrope rash. **D,** Subcutaneous calcification erupting through skin (*arrowhead*), seen clinically and by x-ray.

Immune-Mediated Necrotizing Myopathy

IMNM has increasingly been separated from the PM category. Acute or subacute proximal weakness indistinguishable from that of PM or DM and an elevated CK are nonspecific, but muscle biopsy showing scattered necrotic or regenerating myofibers without inflammation other than macrophages invading these necrotic myofibers is typical of IMNM. The presence of anti-HMGCR (3-hydroxy-3-methylglutaryl-coenzyme A reductase) or anti-SRP (signal recognition particle) antibodies both suggest IMNM. IMNM, particularly when associated with anti-SRP antibodies, may be paraneoplastic, and laboratory and radiologic evaluation for malignancy should be considered.

Inclusion Body Myositis

IBM has a clinical presentation distinct from other inflammatory myopathies.[12] IBM weakness is always slowly progressive rather than the acute or subacute weakness more typically seen in other forms of inflammatory myopathies. Clinical diagnostic criteria are shown in Table 269-2. IBM has a high misdiagnosis rate, estimated at approximately 50% of patients. Symptoms of IBM rarely are present before the age of 40 years and most commonly occur after the age of 50. The distribution of weakness is usually in finger flexors or quadriceps rather than proximal arms (shoulder abduction) or proximal legs (hip flexion), more typical of PM or DM. IBM is a highly atrophying muscle disease, and loss of bulk in medial and lateral anterior thighs and ventral forearms is characteristic. Patients present with difficulty walking, buckling of knees, or weakness of grip. The diagnosis of IBM can be highly suspected in such patients of appropriate age and findings on examination of quadriceps atrophy and weakness of finger flexors, especially flexor digitorum profundi, responsible for flexion of distal fingertips. Examination of the strength in these distal fingertips, which needs to be done one finger at a time, is often the single most helpful approach to the diagnosis of IBM.

Serum CK is either normal or modestly elevated (typically < 5 times the upper limit of normal). A serum autoantibody, anti-cN1A (also called anti-NT5C1A), appears highly specific to IBM among muscle diseases and may be of diagnostic value. Most patients undergo muscle biopsy, with characteristic features being the presence of rimmed vacuoles seen on hematoxylin and eosin (H&E) and Gomori trichrome staining, along with endomysial inflammation or invasion of non-necrotic muscle fibers. Immunohistochemical stains detecting p62 or TDP-43 are of additional highly specific diagnostic value.

TREATMENT

Rx

Generally, most patients with DM, PM, and IMNM respond to immunomodulatory therapies, whereas patients with IBM are almost universally refractory. A general approach to treatment is shown in Figure 269-3.

Treatment of Dermatomyositis and Polymyositis

Most patients with DM and PM are treated with and respond to corticosteroids.[13,14] Dosing is typically prednisone at 1 mg/kg/day orally until significant improvement occurs (typically 1 to 3 months), followed by gradual taper of 10 mg/day/month. Second-line agents include methotrexate, azathioprine, cyclosporine, and intravenous immunoglobulin. Second-line agents are used for two reasons: they may have a better side-effect profile than chronic higher doses of corticosteroids, and they may be necessary for patients whose responses are insufficient to corticosteroids alone. An important decision is whether to start second-line agents concurrently with initial corticosteroid treatment or wait and see how low a dose of corticosteroids offers satisfactory control, and then add agents only if the corticosteroid dose cannot be lowered sufficiently. Thus, in the former approach, prednisone 60 mg/day and methotrexate 7.5 mg PO weekly might be started concurrently, and the methotrexate dose increased weekly to 15 to 20 mg PO weekly. Once improvement is substantial, the dose of prednisone may be tapered over 3 to 6 months. Stability on methotrexate alone would then be followed by gradual reduction in its dose.

For patients with severe initial presentations, the combination of corticosteroids and periodic intravenous immunoglobulin (1 g/kg every 2 weeks) may offer a better chance for more rapid improvement.

Approximately seven randomized placebo controlled trials have been reported to date in DM or PM. These studies have almost always used the Bohan and Peter criteria for the diagnosis, which may result in inclusion of patients with limb-girdle muscular dystrophies and IBM misdiagnosed as having PM. The largest trial, rituximab in myositis (RIM), enrolling 200 subjects, used a trial design in which all subjects received active drug, but comparator groups were treated "early" or "late" (8 weeks later), and efficacy was based on time to improvement. This study found no significant differences between these early and late treatment groups' time to improvement, as defined by a specific definition of improvement (DOI) used in that study.

Treatment of Inclusion Body Myositis

A number of controlled and uncontrolled trials of IBM have been published. None of these demonstrated efficacies of the therapeutic

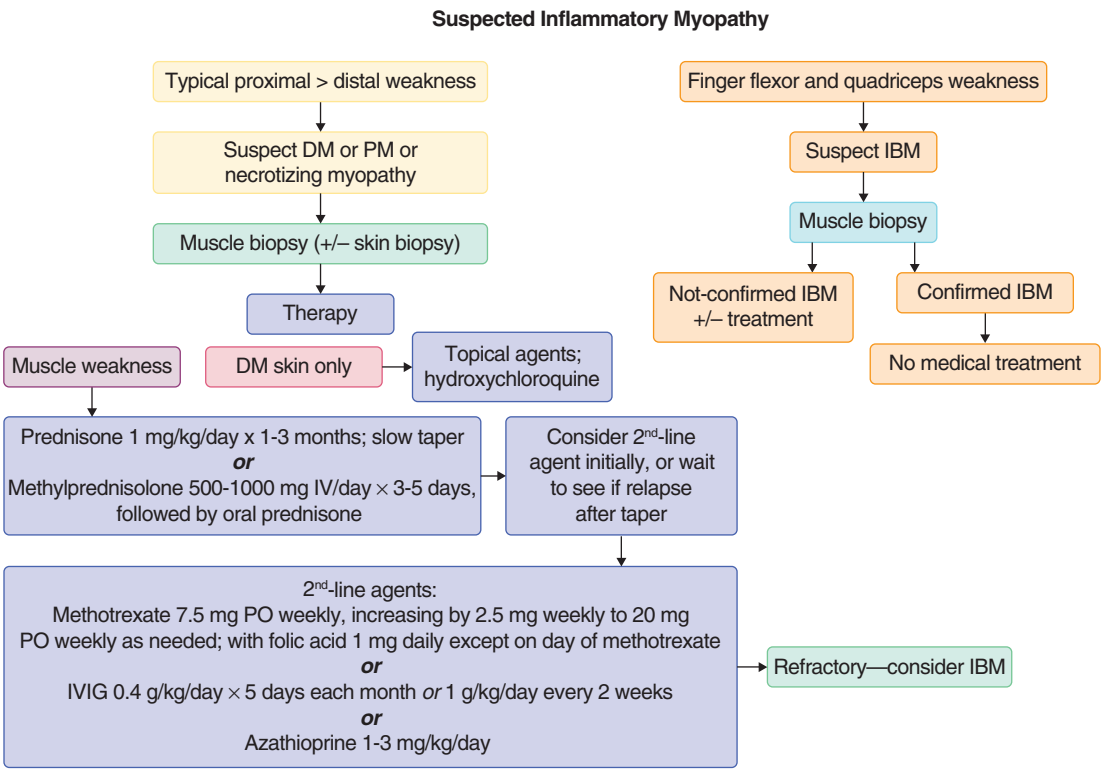

FIGURE 269-3. Approach to treatment of suspected inflammatory myopathy. DM = dermatomyositis; IBM = inclusion body myositis; IVIG = intravenous immunoglobulin; PM = polymyositis. With permission from the Inclusion Body Myositis Foundation, Inc.

interventions, which have included prednisone, intravenous immunoglobulin, methotrexate, antithymocyte globulin, oxandrolone, interferon-β, and alemtuzumab.[15] Current management of patients with IBM is supportive, involving avoidance of falls and the use of ankle supports and gait assistive devices. Tendon transfer to improve hand function has been used.

PROGNOSIS

Most patients with adult DM, PM, and statin-associated IMNM have a good prognosis but require long-standing immunomodulatory therapy. Many patients with juvenile DM may go into long-standing remission or cure with aggressive initial treatment. Patients with anti-SRP–associated IMNM may have severe and difficult-to-treat disease. Patients with IBM generally have a slowly progressive course, with one series showing a mean time to loss of ambulation of 12 years.

REVIEW QUESTIONS

1. A 65-year-old man developed slowly progressive difficulty arising from a chair and experienced buckling of the knees while walking, resulting in several falls. Muscle biopsy showed endomysial inflammation and rimmed vacuoles. The correct diagnosis is:

A. Polymyositis
B. Dermatomyositis
C. Inclusion body myositis
D. Immune-mediated necrotizing myopathy
E. Overlap syndrome

Answer: C Inclusion body myositis (IBM). IBM is a later-onset, slowly progressive disease presenting with prominent quadriceps or finger flexion weakness. In this case, the knee buckling indicates quadriceps weakness. Endomysial inflammation can be seen in either polymyositis or IBM, but rimmed vacuoles confirm IBM as the correct diagnosis.

2. A 35-year-old woman developed proximal weakness and a purplish papular rash over the dorsum of the hands. A skin biopsy might be expected to show what feature and lead to which diagnosis:

A. Lymphocytoclastic vasculitis AND polymyositis
B. Interface dermatitis AND dermatomyositis
C. Granulomas AND granulomatous myositis
D. Necrotic cells AND necrotizing myopathy
E. Necrotic cells AND dermatomyositis

Answer: B This patient has Gottron's papules (see Fig. 296-2A), virtually pathognomonic for dermatomyositis. Skin biopsy in dermatomyositis shows an interface dermatitis, with pathology of the basal layer of keratinocytes lying at the border (interface) between the epidermis and the dermis.

3. A 60-year-old man with proximal weakness and mildly elevated serum creatine kinase (CK) is diagnosed with polymyositis and treated with high-dose prednisone 80 mg/day for several months, before slow taper of prednisone to 30 mg/day by month 6. His serum CK improves, but no improvement in strength is present and he appears mildly weaker. Which statement is most likely true?

A. He has refractory polymyositis and needs more aggressive therapy.
B. He has developed steroid myopathy in addition to his polymyositis.
C. The diagnosis of polymyositis should be reconsidered, and he could undergo a second muscle biopsy or blood diagnostic testing for anti-cN1A autoantibodies as the next step.
D. The diagnosis of polymyositis should be reconsidered; he may have inclusion body myositis or a limb-girdle muscular dystrophy.
E. C and D

Answer: E Patients with IBM in particular, and sometimes limb-girdle muscular dystrophy, are often misdiagnosed as having polymyositis. Serum CK, modestly elevated in IBM, may lower with prednisone treatment, but patients rarely have improved strength.

4. Which syndrome can be paraneoplastic and should prompt thorough investigation for an underlying malignancy?

A. Dermatomyositis
B. Polymyositis
C. Inclusion body myositis
D. Granulomatous myositis
E. All of the above

Answer: A Dermatomyositis. A new diagnosis of dermatomyositis should prompt a thorough investigation for an underlying malignancy, with reported rates estimated at 15 to 23%.[12] The types of malignancy found in patients with dermatomyositis generally reflect those found in age-, sex-, and population-matched persons without dermatomyositis. Therefore, breast, lung, and colorectal cancer are the three most common cancers from Western country cohorts, while nasopharyngeal carcinoma is the most common dermatomyositis-associated cancer in Asian studies. This finding further supports the role of dermatomyositis as a paraneoplastic process that can occur with virtually any kind of cancer. (Ungprasert P, Bethina NK, Jones CH. Malignancy and idiopathic inflammatory myopathies. *N Am J Med Sci.* 2013;5:569-572.)

5. Normal serum CK in a patient with proximal muscle weakness excludes the diagnosis of:

A. Dermatomyositis
B. Inclusion body myositis
C. Muscular dystrophy
D. Granulomatous myositis
E. None of the above

Answer: E None of the above. Serum CK is a helpful indicator of muscle disease when elevated, but normal CK does not exclude muscle disease. In particular, patients with very active dermatomyositis frequently have normal serum CK.

270 THE SYSTEMIC VASCULITIDES

JOHN H. STONE

DEFINITION

The vasculitides are a heterogeneous group of disorders linked by the common finding of destructive inflammation within blood vessel walls. The most current nomenclature scheme[1] identifies at least 27 different forms of primary vasculitis (Table 270-1). The major forms of vasculitis are discussed in this chapter.

CLASSIFICATION

Classification by Vessel Size

The etiology of most forms of vasculitis remains unknown, and major gaps exist in our understanding of the pathophysiologic processes. The most valid basis for classification of the vasculitides is the size of the predominant blood vessels involved. The vasculitides are categorized initially by whether the vessels affected are primarily large, medium, or small (Table 270-2). Large vessels are considered the aorta, its primary branches, and any vessel that is not located within an organ such as a muscle, kidney, nerve, or the skin. Medium-sized vessels, in contrast, consist of the main visceral arteries and their branches. (Thus, the renal artery is considered a large vessel, but its intrarenal branches—the interlobar and arcuate arteries—are medium-sized vessels). Finally, small vessels include smaller intraparenchymal arteries as well as arterioles, capillaries, and veins.

Medium-vessel vasculitis and even large-vessel vasculitis can also affect small arteries. However, Large-vessel vasculitis affects large arteries more often than medium or small-vessel vasculitis, medium-vessel vasculitis affects predominantly medium arteries, and small-vessel vasculitis affects predominantly small arteries and other small vessels.

Additional Considerations in Classification

Several considerations other than blood vessel size are relevant to the classification of vasculitis (see Table 270-2). These are (1) age, sex, and ethnic

background of the patient; (2) tropism for particular organs; (3) presence or absence of granulomatous inflammation; (4) participation of immune complexes in the pathophysiologic process; and (5) detection of characteristic autoantibodies in the patients' serum, such as antineutrophil cytoplasmic antibodies (ANCAs).

Age, sex differences, and ethnic variation are discussed later in the section on Epidemiology. The organ tropisms of these disorders are illustrated by the following examples. Whereas immunoglobulin (Ig)A vasculitis (IgAV, also known as Henoch-Schönlein purpura) typically affects the skin, joints, kidneys, and gastrointestinal (GI) tract, granulomatosis with polyangiitis (GPA; formerly Wegener granulomatosis) classically involves the upper airways, lungs, and kidneys. In contrast to both IgAV and GPA, Cogan syndrome involves the eyes, the audiovestibular apparatus of the inner ear, and (in 10 to 15% of cases) the large arteries.

The presence or absence of granulomatous inflammation is a crucial element of vasculitis diagnosis and classification. Granulomatous inflammation implicates a small number of vasculitides that bear this hallmark, including GPA, giant cell arteritis, Takayasu arteritis, and eosinophilic granulomatosis with polyangiitis (EGPA; Churg-Strauss syndrome).

Immune complexes are essential to the pathophysiologic mechanism of some forms of small- and medium-vessel vasculitis. Complexes of IgA1, for example, are found in IgAV. Immune complexes consisting of IgG, IgM, complement components, and the hepatitis C virion characterize most cases of mixed cryoglobulinemia. In contrast, "pauci-immune" types of small- and medium-vessel vasculitis, such as GPA and microscopic polyangiitis, have little immunoglobulin or complement deposition within diseased tissues. Many but not all patients with pauci-immune forms of vasculitis are ANCA positive.

TABLE 270-1 NAMES FOR VASCULITIDES ADOPTED BY THE 2012 INTERNATIONAL CHAPEL HILL CONSENSUS CONFERENCE ON THE NOMENCLATURE OF VASCULITIDES.[1]

LARGE-VESSEL VASCULITIS
Takayasu arteritis
Giant cell arteritis
MEDIUM-VESSEL VASCULITIS
Polyarteritis nodosa
Kawasaki disease
Buerger disease*
SMALL-VESSEL VASCULITIS
Antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis
Microscopic polyangiitis
Granulomatosis with polyangiitis (formerly Wegener granulomatosis)
Eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome)
Immune complex small-vessel vasculitis
Antiglomerular basement membrane disease
Cryoglobulinemic vasculitis
Immunoglobulin (Ig)A vasculitis (Henoch-Schönlein purpura)
Hypocomplementemic urticarial vasculitis
VARIABLE-VESSEL VASCULITIS
Behçet syndrome
Cogan syndrome
SINGLE-ORGAN VASCULITIS
Cutaneous leukocytoclastic angiitis
Cutaneous arteritis
Primary central nervous system vasculitis
Isolated aortitis
VASCULITIS ASSOCIATED WITH SYSTEMIC DISEASE
Lupus vasculitis
Rheumatoid vasculitis
Sarcoid vasculitis
Others (e.g., IgG4-related aortitis)
VASCULITIS ASSOCIATED WITH PROBABLE ETIOLOGY
Hepatitis C virus–associated cryoglobulinemic vasculitis
Hepatitis B virus–associated vasculitis
Syphilis-associated aortitis
Drug-associated immune complex vasculitis
Drug-associated ANCA-associated vasculitis
Cancer-associated vasculitis
Others

*Buerger disease (thromboangiitis obliterans) is not always considered to be a primary form of vasculitis and was not included in this consensus statement on nomenclature.[1]

EPIDEMIOLOGY

The epidemiologic features of individual forms of systemic vasculitis vary tremendously by geography (Table 270-3). This may reflect genetic influences, variation in environmental exposures, and other unknown disease risk factors. For example, whereas Behçet syndrome is rare in North Americans, affecting only 1 person in approximately 300,000, this condition is several hundred times more common among inhabitants of countries bordering the ancient Silk Route. Similarly, although Takayasu arteritis is rare in the United States—on the order of 3 new cases per million people per year—this disease is reportedly the most common cause of renal artery stenosis in India, where the incidence may be as high as 200 to 300 per million per year.

Age is an important consideration in the epidemiology of vasculitis. Eighty percent of patients with Kawasaki disease are younger than 5 years. In contrast, giant cell arteritis virtually never occurs in patients younger than 50 years, and the mean age of patients with this disease is 72. Age may also have an impact on disease severity and outcome. In IgAV, the overwhelming majority of cases in children (who represent 90% of all cases) have self-limited courses, resolving within several weeks. In adults, however, IgAV has a higher likelihood of chronicity and a poor renal outcome.

The distribution of sex varies across many forms of vasculitis. Buerger disease is the only form of vasculitis with a striking male predominance. The greater prevalence of smoking among males in most societies probably explains this predilection. In contrast, Takayasu arteritis has an overwhelming

TABLE 270-3 EPIDEMIOLOGY OF SELECTED VASCULITIDES

DISEASE	UNITED STATES	ELSEWHERE	AGE, SEX, AND ETHNIC PREDISPOSITIONS
Giant cell arteritis	Incidence: 240/million (Olmsted County, MN)	220-270/million (Scandinavian countries)	Age > 50 yr, mean age 72 yr; females 3 : 1; northern European ancestry
Takayasu arteritis	Incidence: 3/million	200-300/million (India)	Age < 40 yr; females 9 : 1; Asian
Behçet syndrome	Prevalence: 3/million	3000/million (Turkey)	Silk Route countries
Polyarteritis nodosa	Incidence: 7/million	7/million (Spain)	Slight male predominance
Kawasaki disease	Incidence: 100/million*	900/million (Japan)	Children of Asian ancestry
Wegener granulomatosis	Incidence: 4/million	8.5/million (United Kingdom)	Whites ≫ blacks

*Among children younger than 5 years. From Gonzalez-Gay MA, Garica-Porrua C. Epidemiology of the vasculitides. *Rheum Clin North Am.* 2001;27:729-749.

tendency to occur in females (a 9 : 1 female-to-male ratio). The pauci-immune forms of vasculitis, such as GPA, EGPA, and microscopic polyangiitis, occur in males and females with approximately equal frequencies, but the phenotypic expression of these conditions may be affected by both age and sex.

The strongest link between any single gene and vasculitis is the association of HLA-B51 with Behçet syndrome. In Behçet syndrome, 80% of Asian patients have the HLA-B51 gene. The prevalence of HLA-B51 is significantly higher among patients with Behçet syndrome in Japan than among non-disease control subjects (55% versus < 15%). Among the sporadic cases of Behçet syndrome involving whites in the United States, however, HLA-B51 occurs in fewer than 15% of cases.

With the exception of Buerger disease and smoking, no definitive associations have been confirmed between disease and environmental or occupational exposures. Associations have been reported but not confirmed between exposures to silica and some types of pauci-immune vasculitis. Studies of potential associations between exposures of any type and vasculitis, however, are complicated frequently by difficulties in obtaining reliable measurements of the levels of the relevant exposure, the likelihood of recall bias among patients who are diagnosed with vasculitis, and the choice of appropriate control groups.

PATHOBIOLOGY

Table 270-4 illustrates the pathologic characteristics of selected forms of vasculitis. Specific pathologic features are discussed in the subsections on each disease. The type of inflammatory cell infiltrate in vasculitis is independent of the size of blood vessels involved. Mixed cell infiltrates in vasculitis are the rule rather than the exception, and histopathologic patterns of vasculitis may include leukocytoclasis (degranulation and destruction of neutrophils within blood vessel walls), granulomatous findings (with or without giant cells), lymphoplasmacytic infiltrates, varying degrees of eosinophilic infiltration, necrosis, and combinations of all these findings.

PATHOPHYSIOLOGY

Some pathophysiologic mechanisms are common to many different forms of vasculitis, regardless of the size of the predominant blood vessels involved. Immune complex deposition, for example, is present in several types of vasculitis that involve both medium-sized and small blood vessels. In this section, the general concepts related to the pathogenesis of large-vessel vasculitides are discussed separately from those of medium- and small-vessel vasculitides.

Large-Vessel Vasculitides

The pathologic process in large-vessel vasculitis appears to begin in the adventitia. In both Takayasu arteritis and giant cell arteritis, abundant numbers of activated T lymphocytes are found within inflamed arterial walls, centering on the adventitia. In Takayasu arteritis, most of these T cells appear to be of the $CD8^+$ subtype. Current evidence suggests that the cytotoxic functions of these cells, mediated by perforin and granzyme B, contribute to smooth muscle cell damage in this disease. $CD4^+$ T-cell responses in Takayasu arteritis have not been well defined.

In giant cell arteritis (Chapter 271), much evidence now suggests an antigen-driven disease, with the site of immunologic recognition events being the adventitia. $CD4^+$ T cells that secrete interferon (IFN)-γ appear to be recruited to the adventitia by a specific antigen(s), the identity of which remains unknown. Both the T cells that orchestrate the transmural inflammation and the inciting antigens are theorized to reach the adventitia through the vasa vasorum. Subsequently, T-cell signals from the adventitia stimulate macrophages and multinucleated giant cells to elaborate an array of downstream mediators, including metalloproteinases and platelet-derived growth factor. Interleukin (IL)-6, known to be a crucial cytokine in giant cell arteritis and probably Takayasu arteritis as well, is produced by macrophages residing in the blood vessel wall. The results of this inflammatory cascade are granulomatous inflammation, destruction of the internal elastic lamina, arterial wall hyperplasia, smooth muscle cell proliferation, intimal thickening, vascular occlusion, and in some cases, weakening of the vessel wall, leading to dilation and aneurysm formation.

Medium- and Small-Vessel Vasculitides

Several different pathophysiologic mechanisms are operative among the medium- and small-vessel vasculitides. In many cases, the mechanisms outlined in the following sections overlap.

Immune Complex–Mediated Vascular Injury

Immune complex–mediated tissue injury does not produce a single clinical syndrome but rather applies to many forms of vasculitis and overlaps with injuries caused by other immune mechanisms. Numerous variables influence immune complex–mediated injury, including the physical properties of the immune complexes (e.g., their size), the ability of the immune complexes to activate complement, the antigen-to-antibody ratio, and the hemodynamic features of specific vascular beds. Immune complexes participate in the pathophysiologic process of some forms of both medium- and small-vessel vasculitis, including polyarteritis nodosa, cryoglobulinemia, IgAV, cutaneous leukocytoclastic angiitis, and rheumatoid vasculitis.

Role of Antineutrophil Cytoplasmic Antibodies

ANCAs are directed against antigens that reside within the primary granules of neutrophils and monocytes. Two types of ANCA are relevant to vasculitis: (1) those directed against proteinase 3 (PR3), known as PR3-ANCA; and (2) those directed against myeloperoxidase (MPO), termed MPO-ANCA. ANCA interact with cytokines, neutrophils, monocytes, and other elements of the immune system to amplify ongoing inflammation in certain forms of vasculitis. A striking and still unexplained feature of ANCA-associated vasculitis (AAV) is that patients with primary forms of these conditions virtually never have antibodies to both PR3 and MPO. Despite the specificity of these antibodies, however, evidence for a primary role of ANCA in the etiology of human disease is still absent.

In GPA, abnormal cytokine regulation interacts with the production of ANCA to fuel the inflammatory response. T_H1 cytokines such as IFN-γ, IL-12, and tumor necrosis factor (TNF) appear to play important roles. Under the direction of IL-12, $CD4^+$ T cells from patients with GPA produce elevated levels of TNF, and peripheral blood mononuclear cells secrete increased amounts of IFN-γ. Serum levels of soluble receptors for TNF are elevated in patients with active GPA and normalize with the induction of remission. In vitro priming of activated neutrophils with TNF markedly

TABLE 270-4 PATHOLOGIC CHARACTERISTICS OF SELECTED FORMS OF VASCULITIS

	TAKAYASU ARTERITIS	POLYARTERITIS NODOSA	GRANULOMATOSIS WITH POLYANGIITIS (WEGENER GRANULOMATOSIS)	CHURG-STRAUSS SYNDROME	HENOCH-SCHÖNLEIN PURPURA	CUTANEOUS LEUKOCYTOCLASTIC ANGIITIS
Vessels involved	Elastic (large) or muscle (medium-sized) arteries	Medium-sized and small muscle arteries	Small arteries and veins; sometimes medium-sized vessels	Small arteries and veins; sometimes medium-sized vessels	Capillaries, venules, and arterioles	Capillaries, venules, and arterioles
Organ involvement	Aorta, aortic arch and major branches, and pulmonary arteries	Skin, peripheral nerves, gastrointestinal tract, and other viscera	Upper respiratory tract, lungs, kidneys, skin, eyes	Upper respiratory tract, lungs, heart, peripheral nerves	Skin, joints, gastrointestinal tract, kidneys	Skin, joints
Type of vasculitis and inflammatory cells	Granulomatous with some giant cells; fibrosis in chronic stages	Necrotizing, with mixed cellular infiltrate	Necrotizing or granulomatous (or both); mixed cellular infiltrate plus occasional eosinophils	Necrotizing or granulomatous (or both); prominent eosinophils and other mixed infiltrate	Leukocytoclastic, with some lymphocytes and variable eosinophils; IgA deposits in affected tissues	Leukocytoclastic, with occasional eosinophils

enhances the ability of ANCA to stimulate neutrophil degranulation. Despite the strong rationale for anti-TNF strategies in GPA, however, a randomized trial of etanercept showed no efficacy in the maintenance of disease remissions.

B-cell depletion is a more effective approach to the treatment of AAV. The efficacy of this treatment strategy probably relates to the removal of several B-cell functions beyond their evolution into plasma cells and the production of ANCA. These other B-cell functions include cytokine production, antigen presentation, and B cell–T cell crosstalk.

Superantigen Model

The degree of immune activation in Kawasaki disease and the acute but generally self-limited nature of this illness imply a potential role for superantigens. Superantigens are proteins produced by microbial pathogens (e.g., *Staphylococcus aureus* or *Streptococcus* species) that are capable of stimulating large populations of T cells in a manner unrestricted by the class II major histocompatibility complex (MHC). Superantigens bind directly to conserved amino acid residues outside the antigen-binding groove on class II MHC molecules, thereby selectively stimulating T cells that express particular β-chain variable gene segments. Through the binding of this MHC-superantigen complex to its cognate T-cell receptors, as many as 20% of circulating lymphocytes may become activated, leading to a potentially enormous outpouring of cytokines. With regard to the etiology of Kawasaki disease, substantial attention has focused on toxic shock syndrome toxin 1, an exotoxin produced by *S. aureus*.[2] Superantigens have also been postulated to play roles in the susceptibility to disease flares in GPA. Nasal carriage of *S. aureus* and superantigens associated with these organisms has been linked to a greater likelihood of disease flares in some studies.

Anti–Endothelial Cell Antibodies

Anti–endothelial cell antibodies can induce endothelial cell injury and lysis through either complement-mediated cytotoxicity or antibody-dependent cellular cytotoxicity. Both of these mechanisms have been demonstrated to cause endothelial injury in in vitro assays employing sera from patients with systemic vasculitis. The ability of these antibodies to damage endothelial cells is an appealing argument for their potential role in forms of vasculitis in which the endothelium is the focus of the inflammation (as opposed to the more external vessel wall layers). However, the true relevance of anti–endothelial cell antibodies to human disease and their importance within the larger context of other disease mechanisms remain unclear.

CLINICAL MANIFESTATIONS

Large-Vessel Vasculitides

Takayasu Arteritis

Takayasu arteritis (Chapter 78) affects the aorta and its major branches. In contrast to atherosclerosis, which is characterized by focal irregular lesions, the lesions of Takayasu arteritis are long, smooth, tapered stenoses (E-Fig. 270-1). The most commonly involved arteries are the subclavian and innominate arteries. Takayasu arteritis has been termed "pulseless disease" because of its ability to obliterate peripheral pulses (particularly in the upper extremities). Exuberant collateral circulation develops over time in response to the gradual narrowing of major arteries, making the loss of digits or limbs from ischemia extremely rare. The pulmonary circulation is involved in approximately 50% of cases of Takayasu arteritis.

Patients with severe narrowing of the aortic arch vessels supplying the head may develop Takayasu retinopathy, a hypotensive retinopathy leading to neovascularization. In contrast, patients with prolonged hypertension associated with renal artery stenosis demonstrate the classic ocular features of hypertension: "copper wiring" and multiple retinal infarctions. This complication is particularly difficult to diagnose and dangerous because vascular narrowings of large arteries to the arms and legs can cause underestimations of the true central aortic pressure. Takayasu arteritis involvement of the ascending aorta may lead to aortic dilation, aortic regurgitation, aneurysm formation, and aortic rupture.

TREATMENT Rx

The cornerstone of treatment of Takayasu arteritis is glucocorticoids. For patients with marked symptoms and signs of an inflammatory phase, prednisone (1 mg/kg/day) is usually effective in controlling the disease. This dose should be tapered within 8 to 12 weeks to less than 20 mg/day and ultimately to less than 10 mg/day as a maintenance dose. Emerging data support a role for IL-6 inhibition in patients with Takayasu arteritis whose prednisone doses cannot be tapered to reasonable levels. Patients have been treated with tocilizumab 8 mg/kg administered intravenously each month or with a corresponding subcutaneous preparation.

Giant Cell Arteritis

Giant cell arteritis is the other primary form of vasculitis that involves arteries far larger than vasculitides of any other category. This disease is discussed in detail elsewhere (Chapter 271).

Medium-Vessel Vasculitides

Polyarteritis Nodosa

Polyarteritis nodosa has a striking predilection for certain organs, particularly the skin, peripheral nerves, GI tract, and kidneys.[3] This disease usually begins with nonspecific symptoms such as malaise, fatigue, fever, myalgias, and arthralgias. Overt signs of vasculitis may not occur until weeks or months after onset of the first symptoms. Skin lesions of polyarteritis nodosa include livedo reticularis, subcutaneous nodules, ulcers, and digital gangrene. A majority of patients with polyarteritis nodosa (>80% in some series) have vasculitic neuropathy, typically in the pattern of a mononeuritis multiplex.

The classic GI manifestation of polyarteritis nodosa is "intestinal angina," the occurrence of postprandial abdominal pain. Polyarteritis nodosa can also affect individual GI tract organs such as the gallbladder or appendix, presenting as cholecystitis or appendicitis. The typical renal manifestation of polyarteritis nodosa is vasculitic involvement of the medium-sized intrarenal arteries, leading to renin-mediated hypertension and renal infarctions. Cardiac lesions, which usually remain subclinical, may lead to myocardial infarction or congestive heart failure. Polyarteritis nodosa usually spares the lungs.

The diagnosis of polyarteritis nodosa requires either a tissue biopsy or an angiogram that demonstrates microaneurysms (Fig. 270-1). Simultaneous nerve and muscle biopsies (e.g., sural nerve and gastrocnemius muscle) are of high yield if there is a clinical suspicion of vasculitic neuropathy. Symptoms suggestive of a neuropathy can be confirmed by electrodiagnostic studies that demonstrate a sensorimotor axonal neuropathy, often in a mononeuritis multiplex pattern. The pathologic changes in polyarteritis nodosa are limited to the arterial circulation, and the lesions are segmental, favoring the branch points of arteries. In gross pathologic specimens, aneurysmal bulges of the arterial wall may be visible. Histologic sections reveal infiltration and destruction of the blood vessel wall by inflammatory cells, accompanied by fibrinoid necrosis. Granulomatous inflammation is absent.

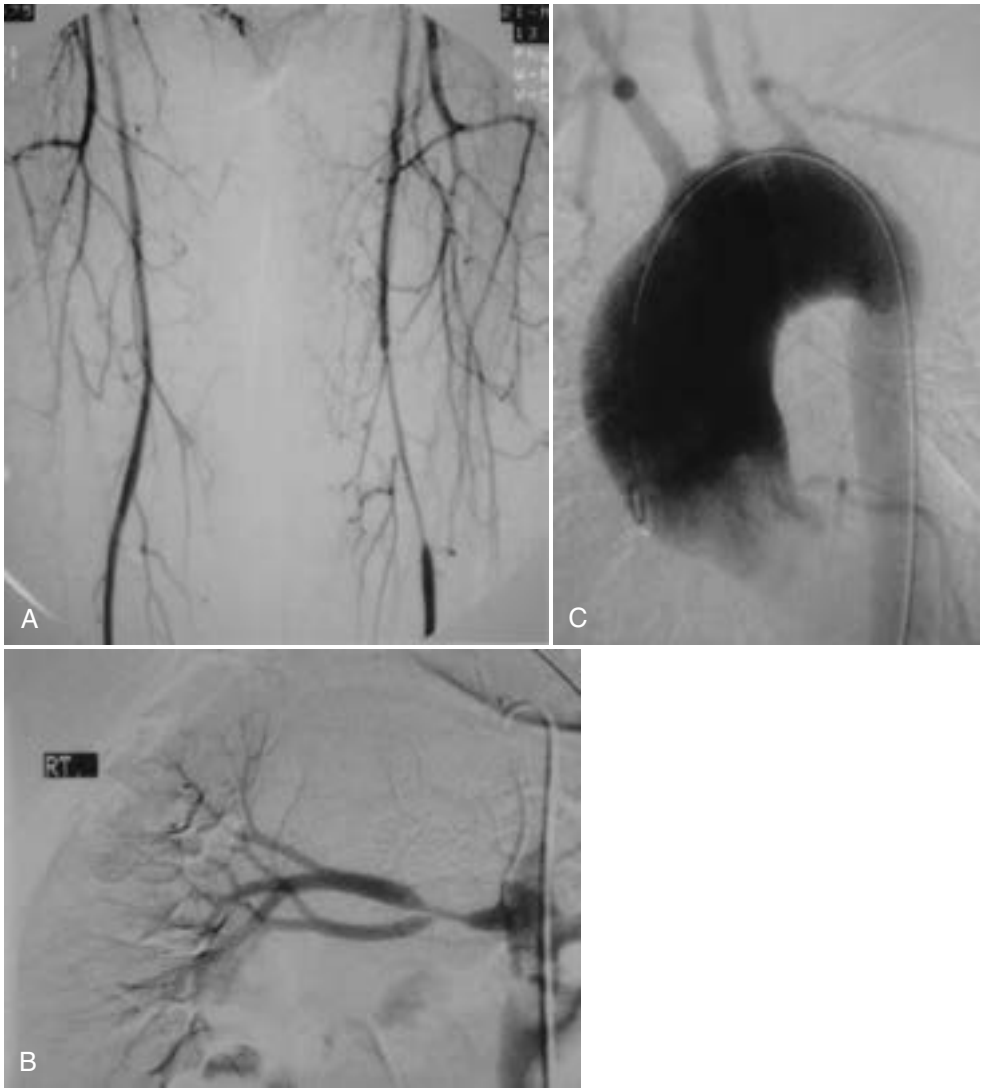
TREATMENT Rx

Approximately half of patients with polyarteritis nodosa achieve remissions or cures with high doses of glucocorticoids alone. Cyclophosphamide (2 mg/kg/day, adjusted for renal dysfunction) is indicated for patients whose disease is refractory to glucocorticoids or who have serious involvement of major organs. In recent years, therapeutic regimens involving lamivudine or entecavir and plasma exchange have substantially improved the treatment of hepatitis B virus (HBV)-associated polyarteritis nodosa. Because of increasing use of the HBV vaccine, fewer than 10% of polyarteritis nodosa cases now are associated with HBV infections.

Kawasaki Disease

Kawasaki disease occurs exclusively in young children. Because of its striking mucocutaneous findings and lymphadenopathy, Kawasaki disease is also known as mucocutaneous lymph node syndrome. Features of Kawasaki disease include high fevers, cervical adenopathy, conjunctival congestion, buccal erythema, prominence of the tongue papillae ("strawberry tongue"), a polymorphous truncal rash, erythema of the palms and soles, and desquamation of skin from the fingertips occurring days to weeks into the illness.[4] In its acuity and severity, Kawasaki disease resembles toxic shock syndrome and scarlet fever, both of which are mediated by superantigens (see Pathophysiology).

In a small number of patients with Kawasaki disease, panvasculitis in the coronary vessels leads to acute cardiac complications. Coronary arteritis leads to narrowing of the vessel lumen by the migration of myointimal cells



E-FIGURE 270-1. Large-vessel disease in Takayasu arteritis. Long, smooth tapering in the left common femoral artery (A) and the right renal artery (B). Dilation of the ascending aorta (C). Aortic regurgitation necessitated an aortic valve replacement and replacement of the ascending aorta with a Gore-Tex graft.

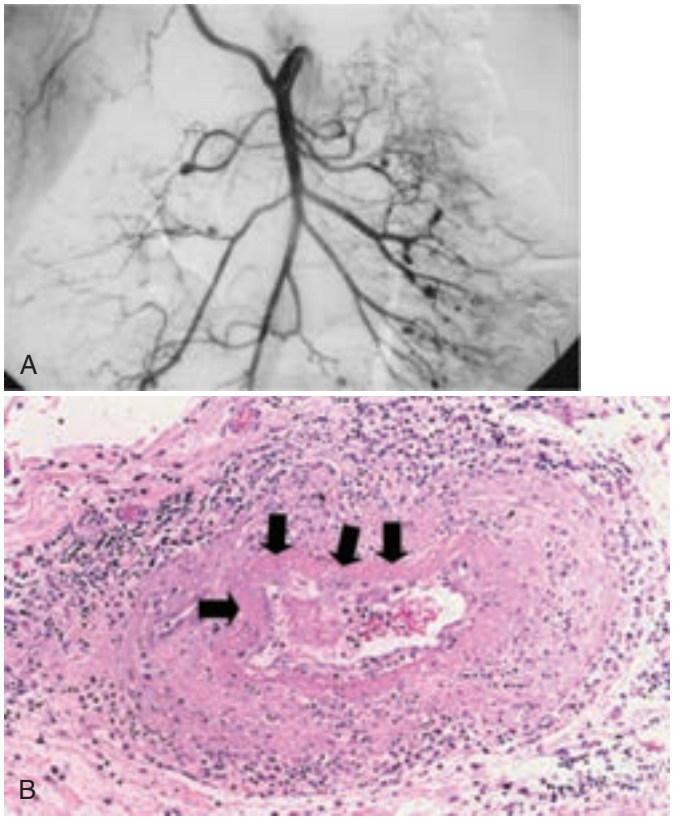


FIGURE 270-1. Vasculitis of medium-sized arteries in polyarteritis nodosa. A, Mesenteric angiogram showing numerous aneurysms in medium-sized arteries. B, Fibrinoid necrosis (*arrows*) in a jejunal artery from a patient who required surgical resection of necrotic bowel.

from the media through the fragmented internal elastic lamina. Direct complications include aneurysmal dilation and thrombosis of the coronary arteries, leading to myocardial infarction and possibly to death (in 1 to 2% of patients with Kawasaki disease during the acute illness). Late mortality from myocardial infarction may occur from the thrombosis of coronary artery aneurysms formed during the initial inflammatory stage. Such myocardial infarctions have been reported in middle-aged individuals who had febrile illnesses consistent with Kawasaki disease in childhood.

TREATMENT Rx

The recommended therapeutic regimen in Kawasaki disease is the combination of intravenous immune globulin (IVIG; 400 mg/kg/day on 4 consecutive days) and acetylsalicylic acid (100 mg/kg/day, lowered to 3 to 5 mg/kg/day after resolution of the fever). IVIG prevents the formation of coronary aneurysms in most cases. Glucocorticoids are reserved for salvage therapy in patients whose treatment with IVIG and acetylsalicylic acid has failed.

Buerger Disease

Buerger disease, also known as thromboangiitis obliterans (Chapter 80), is not always considered to be a primary form of vasculitis and was not included in the most recent consensus statement on nomenclature. Buerger disease has a remarkably strong yet poorly understood association with cigarette smoking and simply does not occur in the absence of exposure to tobacco. The vessels affected by Buerger disease are the distal medium-sized arteries and veins, particularly vessels at the levels of the ankles and wrists. The disease is characterized by thrombotic obliterations that begin distally and proceed proximally. Buerger disease tends to be segmental in nature, involving 5- to 10-cm lengths of blood vessels. Arterial obliteration leads to the development of collateral vessels with a "corkscrew" appearance on angiography. Vascular occlusion in Buerger disease often leads to the loss of digits and, if smoking persists, to loss of larger amounts of tissue (e.g., hands or feet). Despite the intense involvement of the extremities in Buerger disease, internal organ disease almost never occurs.

FIGURE 270-2. Cutaneous small-vessel vasculitis showing palpable purpuric lesions with necrosis and crusting.

TREATMENT Rx

Complete abstinence from tobacco is essential to the treatment of Buerger disease. Failure to stop smoking is associated with a dramatic increase in the risk of limb loss by amputation. No other therapeutic interventions, including glucocorticoids and anticoagulation, have dramatic effects on Buerger disease.

Small-Vessel Vasculitides

Antineutrophil Cytoplasmic Antibody–Associated Vasculitides

Granulomatosis with Polyangiitis

Classic GPA (formerly Wegener granulomatosis) involves the upper respiratory tract, lungs, and kidneys.[5] Distinctive features may also occur in the eyes, ears, and other organs. The three pathology hallmarks of GPA are (1) granulomatous inflammation in the upper or lower respiratory tract, (2) necrotizing vasculitis affecting arteries or veins, and (3) segmental glomerulonephritis associated with necrosis and thrombosis of capillary loops, with or without granulomatous lesions.

Approximately 90% of patients with GPA have nasal involvement, including crusting, bleeding, and obstruction. Cartilaginous inflammation may lead to nasal septal perforation and collapse of the nasal bridge ("saddle nose" deformity). Erosive sinus disease and subglottic stenosis (narrowing of the trachea just below the vocal cords) are highly characteristic of GPA.

Both conductive and sensorineural hearing loss can occur in GPA, though conductive lesions caused by middle ear disease are more common. Orbital masses ("pseudotumors" that develop behind the eye), scleritis, and peripheral ulcerative keratitis are the most dangerous ocular lesions. Episcleritis and conjunctivitis also occur. Anterior uveitis is rare. The clinical manifestations of GPA in the lung range from asymptomatic nodules to fulminant alveolar hemorrhage. The most common radiographic findings are pulmonary infiltrates, nodules, and cavitary lesions. Large-airway disease leading to bronchial narrowing is a challenging diagnosis to make because patients present with few symptoms until advanced disease is present.

The clinical presentation of renal disease in GPA is usually rapidly progressive glomerulonephritis: hematuria, red blood cell casts, and proteinuria (usually non-nephrotic). Without appropriate therapy, end-stage renal disease may ensue within weeks.

Sixty percent of patients with GPA have musculoskeletal symptoms during their disease course. The presenting complaint is frequently arthralgias or an oligoarthritis that is migratory in nature. Skin lesions in GPA include the full panoply of lesions associated with cutaneous vasculitis, including purpura (Fig. 270-2). Cutaneous nodules over the extensor surfaces of joints, particularly the elbow, may mimic rheumatoid nodules. These lesions are known as cutaneous extravascular necrotizing granulomata or Churg-Strauss lesions. Meningeal inflammation, presenting with headaches, cranial neuropathies, and a clinical picture compatible with chronic meningitis, is perhaps the most

common central nervous system (CNS) manifestation of GPA. Mononeuritis multiplex may affect the peripheral nervous system.

GPA is the prototype of conditions associated with ANCA. Positive results of immunofluorescence tests for ANCA in either the cytoplasmic (C-ANCA) or perinuclear (P-ANCA) pattern should be confirmed by enzyme immunoassays for antibodies to either proteinase 3 (PR3) or myeloperoxidase (MPO). An ANCA-negative assay sample does not exclude GPA, because a substantial minority of patients (between 15 and 40% overall) lack these antibodies. Furthermore, ANCA titers do not correlate reliably with disease activity.

TREATMENT Rx

Manifestations of GPA that constitute immediate threats either to the function of a vital organ or to the patient's life require treatment urgently. From the late 1960s until 2010, the combination of cyclophosphamide (2 mg/kg orally daily) and high doses of glucocorticoids (prednisone 1 mg/kg orally daily, tapered during 6 to 12 months) was the standard of care for GPA. Intermittent administration of cyclophosphamide by IV infusion is also effective in remission induction. However, a multicenter clinical trial that compared rituximab to cyclophosphamide in patients with either GPA or microscopic polyangiitis demonstrated that rituximab (375 mg/m^2 weekly times four) is at least as effective as the conventional regimen. Rituximab appears to be more effective for AAV patients who present with disease flares. An alternative dosing regimen of rituximab, 1 g times two separated by 2 weeks, may also be effective. Limited forms of GPA may respond to the combination of methotrexate (up to 25 mg/week) and glucocorticoids, but rituximab is now often employed in this setting as well. Rituximab (e.g., 500 mg every 6 months) is more effective than azathioprine for maintaining remission in patients who demonstrate a tendency to flare.

Microscopic Polyangiitis

Microscopic polyangiitis is characterized by (1) nongranulomatous necrotizing vasculitis with few or no immune deposits, (2) involvement of small (and possibly medium-sized) blood vessels in the arterial or venous circulation, and (3) tropism for the kidneys and lungs. Many cases of small-vessel vasculitis once regarded as polyarteritis nodosa are now classified more properly as microscopic polyangiitis. In contrast to polyarteritis nodosa, an ANCA-negative disorder, 70% of microscopic polyangiitis patients are ANCA positive.[6] Thus, microscopic polyangiitis is considered to be a form of AAV. The ANCAs in microscopic polyangiitis are usually directed against myeloperoxidase, leading to a perinuclear pattern of staining on immunofluorescence testing (P-ANCA). Microscopic polyangiitis is not characterized by granulomatous inflammation, and upper respiratory tract symptoms, if present at all, are much milder than those associated with GPA.

TREATMENT Rx

The approach to the treatment of microscopic polyangiitis is similar to the treatment of GPA. The combination of rituximab and glucocorticoids is the treatment regimen of choice for most patients with microscopic polyangiitis.

Eosinophilic Granulomatosis with Polyangiitis

EGPA is an eosinophil-rich form of granulomatous inflammation that involves the respiratory tract and other organs. The disease is associated with necrotizing vasculitis of small to medium-sized vessels. Two hallmarks of EGPA are asthma and eosinophilia. Several phases of EGPA are described:

- A prodromal phase characterized by the presence of allergic disease (typically asthma or allergic rhinitis), which may last months to many years
- An eosinophilia–tissue infiltration phase in which remarkably high peripheral eosinophilia may occur and tissue infiltration by eosinophils is observed in the lung, GI tract, and other tissues
- A vasculitic phase in which systemic necrotizing vasculitis afflicts a wide range of organs, ranging from the heart and lungs to peripheral nerves and skin

TREATMENT Rx

Patients with mild disease may be treated with prednisone. Those with evidence of neurologic, cardiac, renal, or GI involvement should be treated with cyclophosphamide in addition to glucocorticoids. Although clinical remissions are obtained in more than 90% of patients with EGPA, disease recurrences are seen in 25%. In most cases, relapses are heralded by the return of eosinophilia. Approximately 50% of cases of EGPA are associated with ANCA, usually directed against myeloperoxidase, but the percentage may be higher among untreated patients.

Immune Complex–Mediated Vasculitides

Anti–Glomerular Basement Membrane Disease

Anti–glomerular basement membrane (anti-GBM) disease is vasculitis affecting glomerular capillaries, pulmonary capillaries, or both, accompanied by the deposition of anti–basement membrane autoantibodies within basement membranes. Anti-GBM disease is discussed in detail elsewhere (Chapter 121).

Immunoglobulin A Vasculitis/Henoch-Schönlein Purpura

IgA vasculitis (IgAV) is characterized by non-thrombocytopenic purpura, arthritis, abdominal pain, and glomerulonephritis. The histopathologic findings are those of a leukocytoclastic vasculitis with IgA deposition. IgAV can develop at any age, but 80 to 90% of the cases occur in children. Although the cause is unknown, the disease's seasonal variation and the fact that two thirds of patients with IgAV experience antecedent acute upper respiratory illnesses suggest an infectious trigger. Medications such as antibiotics can also trigger IgAV, and environmental triggers are also likely. The diagnosis of IgAV can be confirmed only by demonstration of IgA deposition within and around blood vessel walls.

The classic IgAV patient presents with the acute onset of fever, palpable purpura on the lower extremities and buttocks, abdominal pain, arthritis, and hematuria. The clinician must be alert to the possibility of IgAV even when only parts of the syndrome are present. Most patients with IgAV, especially children, have a self-limited disease that lasts an average of 4 weeks.

TREATMENT Rx

Glucocorticoids ameliorate the GI, joint, and skin symptoms in many cases, but some patients respond surprisingly poorly to conventional doses of glucocorticoids, even in doses on the order of 40 to 60 mg/day. Anecdotal evidence suggests that pulse glucocorticoids (e.g., methylprednisolone 500 to 1000 mg/day times three doses) may abort persistent bouts of IgAV. The efficacy of glucocorticoids in the glomerulonephritis associated with this condition is controversial. Uncontrolled studies suggest that methylprednisolone pulses (1 g/day for three doses), followed by oral prednisone combined with azathioprine or mycophenolate mofetil may be useful in severe glomerulonephritis associated with IgAV.

Hypocomplementemic Urticarial Vasculitis

At least three subtypes of urticarial vasculitis are known: (1) normocomplementemic, a form that is generally idiopathic and benign (which may be viewed as a manifestation of cutaneous leukocytoclastic angiitis); (2) hypocomplementemic, a form that is often associated with a systemic inflammatory disease; and (3) hypocomplementemic urticarial vasculitis syndrome (HUVS), a potentially severe condition usually associated with autoantibodies to the collagen-like region of C1q. Most patients with the hypocomplementemic subtype have an underlying systemic disorder, such as systemic lupus erythematosus (Chapter 266) or Sjögren syndrome (Chapter 268). Many HUVS patients have C1q "precipitins," IgG autoantibodies to the collagen-like region of C1q that trigger the classical pathway of complement activation. The role of anti-C1q antibodies in disease pathogenesis remains unclear.

The lesions of urticarial vasculitis must be distinguished from the far more common chronic idiopathic urticaria (Chapters 252 and 440). Unlike idiopathic urticaria, the lesions of urticarial vasculitis last more than 48 hours, often have a purpuric component (i.e., they do not blanch), and resolve with postinflammatory hyperpigmentation. In urticarial vasculitis, lesions associated with vasculitis are often accompanied by stinging or burning. Urticarial vasculitis affects the capillaries and postcapillary venules, showing leukocytoclastic vasculitis on light microscopy. Direct immunofluorescence studies reveal both immunoglobulin and complement deposition in or around blood vessels of the upper dermis or the dermoepidermal junction.

TREATMENT Rx

Patients with urticarial vasculitis whose serum complement levels remain normal during attacks often have self-limited disease and require little therapy.

Other cases, especially HUVS, may cause life-threatening involvement of the lungs or other organs and require periods of intensive immunosuppression. Treatment decisions in HUVS must be individualized according to the patient's clinical status.

Cryoglobulinemia

Cryoglobulins are antibodies that precipitate from serum under conditions of cold and resolubilize on rewarming. Cryoglobulins are classified into types I, II, and III on the basis of whether monoclonality and rheumatoid factor activity (the ability to bind to the Fc portion of IgG) are present.[7] Type I cryoglobulins, which are monoclonal but lack rheumatoid factor activity, are associated with certain hematopoietic malignant neoplasms (e.g., multiple myeloma) and often lead to hyperviscosity rather than to vasculitis (Chapter 187). In contrast, type II and type III cryoglobulins may be associated with systemic vasculitis involving small (and often medium-sized) blood vessels. Vasculitis results from the deposition of cryoglobulin-containing immune complexes within blood vessel walls and the activation of complement.

Cryoglobulin types II and III are termed *mixed cryoglobulins* because they consist of complexes of both IgG and IgM antibodies. The IgM components in both type II and type III cryoglobulinemia possess rheumatoid factor activity (i.e., assays for rheumatoid factor are positive, indicating binding of the IgM antibody to the Fc portion of IgG). Whereas the IgM component in type II cryoglobulin is monoclonal, the IgM in type III cryoglobulin is polyclonal. Ninety percent of patients with vasculitis secondary to mixed cryoglobulins are hypocomplementemic, with C4 levels characteristically more depressed than C3. Infection with hepatitis C virus (HCV) accounts for at least 80% of the vasculitis cases associated with mixed cryoglobulins.[8]

TREATMENT Rx

Rapidly progressive sensorineural hearing loss requires early and requires aggressive therapy with high doses of systemic glucocorticoids. Some otolaryngologists also perform intratympanic injections of glucocorticoids. Cytotoxic agents can be considered for patients with suboptimal responses to glucocorticoids who still have salvageable hearing. Many Cogan syndrome patients become candidates for cochlear implants.

Variable-Vessel Vasculitides

The variable-vessel vasculitides have no predominant type of vessel involved but rather can affect vessels of any size (small, medium, and large) and any type (arteries, veins, and capillaries).

Cogan Syndrome

The combination of inflammatory eye disease and vestibuloauditory dysfunction is the sine qua non of Cogan syndrome.[9] In addition to inflammatory disease of the eyes and ears, up to 15% of patients with Cogan syndrome have vasculitis involving medium-sized to large blood vessels. Although the ocular manifestations vary, the classic presentation is the combination of interstitial keratitis and sensorineural hearing loss. Cogan syndrome may appear first in either the eyes or the ears. Although intervals as long as 1 to 2 years have been described between the start of disease in one organ and the appearance of disease in the other, the time between disease manifestations in these organs is usually only a matter of months. Patients usually present with photophobia and blurry vision, sometimes accompanied simultaneously by auditory or vestibular dysfunction. The vascular disease in Cogan syndrome resembles that of Takayasu arteritis.

TREATMENT Rx

The optimal therapy for most cases of cryoglobulinemic vasculitis is successful treatment of the underlying HCV infection. For cryoglobulinemic patients with relatively mild disease (e.g., frequent purpuric lesions, shallow cutaneous ulcers), short courses of prednisone followed by the institution of effective therapy for HCV may be sufficient. For patients with severe cutaneous ulcers, mononeuritis multiplex, glomerulonephritis, or other manifestations of severe disease, glucocorticoids, rituximab, and possibly a short course of plasma exchange may be indicated.

Behçet Syndrome

Behçet syndrome may affect small, medium, and large vessels in either the venous or the arterial circulation.[10] The most typical lesions in Behçet syndrome are mucocutaneous, reflecting the involvement of small blood vessels. The triad of recurrent mouth ulcers, genital ulcers, and eye inflammation is the classic presentation. The criteria for diagnosis of the International Study Group for Behçet Syndrome consist of one required manifestation—recurrent oral ulceration—plus at least two of the following: recurrent genital ulceration, characteristic eye or skin lesions, or a pathergy reaction (see later). However, the spectrum of Behçet syndrome encompasses many manifestations not included in these criteria.

Large-vessel complications of Behçet syndrome may include aneurysms in the pulmonary and systemic arterial systems. Venous complications include thromboses of the deep venous system, vena cava, portohepatic vein, and cerebral sinus. Pathergy—the development of pustules at the sites of sterile needle pricks—is a distinctive feature in many patients with Behçet syndrome, particularly those of Turkish origin. The arthritis of Behçet syndrome is a nondeforming, oligoarticular, asymmetrical arthritis of large joints. GI lesions in Behçet syndrome typically consist of ulcerations of the distal ileum or cecum. Crohn disease, which can cause genital ulcers as well as GI tract disease, may be particularly difficult to distinguish from Behçet syndrome.

TREATMENT Rx

Low-dose glucocorticoids are effective for intransigent mucocutaneous disease and may have a better side-effect profile than other medications used for this purpose (e.g., thalidomide). Intermittent courses of glucocorticoids during periods of particular mucocutaneous disease activity may be sufficient for patients with mild disease.

Severe disease in any organ system almost always requires high doses of prednisone (e.g., 1 mg/kg/day). Azathioprine (2 mg/kg/day), cyclosporine (3 to 5 mg/kg/day in two divided doses), methotrexate (up to 25 mg/week), and interferon alpha (3 million to 5 million units three times a week) are appropriate therapies for many complications of Behçet's syndrome. TNF inhibition with infliximab (5 mg/kg IV every 4 to 6 weeks) or adalimumab (40 mg every other week) is the treatment of choice for patients with the most severe forms of uveitis or meningoencephalitis.

Selected Single-Organ Vasculitides

Single-organ vasculitis is defined as vasculitis within the vessels of any type or size of a single organ, in the absence of any features (e.g., ANCA) suggesting one of the systemic forms of vasculitis.

Cutaneous Leukocytoclastic Angiitis

Cutaneous leukocytoclastic angiitis has also been termed *hypersensitivity vasculitis*. Cutaneous leukocytoclastic angiitis is the preferred name because no hypersensitivity or allergy is evident in many cases. Histories of exposure to new medications or to infections may be elicited. An immune complex deposition is central to the pathophysiologic process. Although it is occasionally associated with synovitis, other signs of systemic involvement are absent.

The skin lesions in cutaneous leukocytoclastic angiitis occur in "crops," coinciding with some period of elapsed time following exposure to the inciting antigen. The usual time between the exposure and the onset of clinically evident vasculitis is 10 to 14 days. The lesions typically occur first in dependent regions, such as on the lower extremities or buttocks. The rash may be asymptomatic but is usually accompanied by burning or tingling sensations.

TREATMENT Rx

Keys to the management of cutaneous leukocytoclastic angiitis include (1) exclusion of any underlying form of vasculitis that may cause subclinical involvement of other organs and (2) removal of any agent (e.g., a medication) that may have triggered the vasculitis. For patients in whom a precipitant can be identified, removal of the offending agent usually leads to resolution of the vasculitis within days to weeks. The type, intensity, and duration of therapy for cutaneous leukocytoclastic angiitis are based on the degree of disease severity. Mild cases may be treated simply with leg elevation, H_1 antihistamines, or low-dose prednisone. For persistent disease not associated with cutaneous gangrene, colchicine, hydroxychloroquine, or dapsone may be tried. For severe cases, high doses of glucocorticoids are indicated to suppress inflammation quickly and prevent skin ulceration.

Vasculitis of the Central Nervous System

CNS vasculitis includes two major categories of disease, one of which is not a true vasculitis. These conditions are primary angiitis of the CNS (PACNS)

TABLE 270-5 PRIMARY ANGIITIS OF THE CENTRAL NERVOUS SYSTEM (PACNS) VERSUS REVERSIBLE CEREBRAL VASOCONSTRICTION SYNDROME (RCVS)

	PACNS	RCVS
Female-to-male ratio	1 : 1	2-3 : 1
Onset	Subacute (weeks to months)	Sudden (seconds to minutes)
Headache	Insidious, dull	Thunderclap
Typical lumbar puncture findings	Abnormal in 50-80%: lymphocytic pleocytosis; elevated protein	Normal
Typical MRI findings	Multifocal subacute infarctions	Normal Watershed infarcts in minority
Typical angiogram findings	Normal in up to 40% of cases. Abnormal angiographic features when present cannot be distinguished from RCVS	Multifocal stenoses/dilatations
Utility of brain biopsy	Reasonable sensitivity in appropriately selected patients Important for excluding disease mimickers	Little to no role Helpful if confusing clinical situation confounds differentiation from PACNS or PACNS mimickers

MRI = magnetic resonance imaging.

and reversible cerebral vasoconstriction syndrome (RCVS). The diagnosis and management of these two conditions differ dramatically. The clinical, radiologic, and pathologic characteristics of PACNS and RCVS are shown in Table 270-5.

Primary Angiitis of the Central Nervous System

PACNS[11] typically develops in a subacute fashion, with the evolution of multifocal strokes, encephalopathy, headache, and other clinical features over months. Headache is often the first symptom. As the condition progresses, most patients develop lethargy, confusion, and memory loss. Some patients develop multifocal strokes, seizures, evidence of increased intracranial pressure, or myelopathy. The results of routine laboratory tests (e.g., erythrocyte sedimentation rate) are often normal in PACNS. Lumbar puncture demonstrates abnormalities of the cerebrospinal fluid in approximately 80% of cases, usually a modest monocytosis and elevated protein. Lumbar punctures should be performed in all patients in whom the diagnosis of PACNS is considered seriously. Although the findings on lumbar puncture in PACNS patients are nonspecific, a normal lumbar puncture argues against PACNS, and the procedure frequently identifies important PACNS mimickers such as infection or malignancy.

Magnetic resonance imaging (MRI) is the critical imaging modality in PACNS. Because of the subacute nature of the disorder, MRI studies reveal multifocal CNS infarctions in most cases. Strokes, hemorrhagic lesions, and mass lesions typically occur in more than one vascular territory. A normal brain MRI argues strongly against the diagnosis of PACNS. Angiography is less helpful in the evaluation of patients with PACNS for two main reasons. First, the sizes of blood vessels involved in PACNS are often too small to be resolved adequately, even by conventional angiography. The false-negative rate of angiography in PACNS is on the order of 35%. Second, the "classic" string-of-beads abnormality on angiography, produced by segmental arterial narrowing alternating with dilations, is nonspecific and can be mimicked perfectly by a host of nonvasculitic conditions (the most common of which is RCVS). No angiographic pattern is pathognomonic for PACNS, and there is a significant tendency to overdiagnose "vasculitis" on angiographic grounds alone. A normal brain MRI in the setting of an abnormal angiogram suggests RCVS, not PACNS.

TREATMENT Rx

When employed in appropriately selected patients whose history and radiologic studies suggest PACNS, brain biopsy is associated with reasonable positive and negative predictive values and frequently identifies important PACNS mimickers. Prednisone and cyclophosphamide are appropriate for treatment of patients who have abnormal findings on brain biopsy. Treatment courses of 6 to 12 months are recommended.

Reversible Cerebral Vasoconstriction Syndrome

Eighty percent of patients with RCVS[12] are women. RCVS is probably far more common than PACNS. Overtreatment of patients with RCVS who are misdiagnosed as having PACNS leads to substantial morbidity.

A careful history is the most important part of the evaluation. In contrast to the subacute course that typifies PACNS, RCVS usually begins in a more dramatic fashion with a "thunderclap" headache. Compared with PACNS, the neurologic signs are less severe in RCVS (e.g., encephalopathy is less common). RCVS frequently occurs in the setting of precipitants associated with vasospasm, such as in the postpartum setting or following the use of vasoactive agents such as nasal decongestants and recreational drugs.

The lumbar puncture is usually normal in RCVS, and brain MRI usually does not show multifocal CNS infarctions, with the exception of watershed infarctions mentioned earlier. The typical angiographic findings in RCVS—vascular narrowing and beading—are generally indistinguishable from those of PACNS and conditions that mimic PACNS. Multifocal vascular narrowing is particularly characteristic of RCVS. The most distinctive angiographic feature of RCVS is that the abnormalities are completely reversible, usually within 4 to 8 weeks. These abnormalities in RCVS are caused by vasospasm rather than true vasculitis. In the evaluation of patients with potential RCVS, a diagnostic strategy that can clinch the diagnosis is a follow-up angiogram 4 to 8 weeks after the first. Angiographic abnormalities due to RCVS will resolve in this interval.

TREATMENT Rx

Several approaches to the treatment of RCVS are reasonable. First, one may opt for watchful waiting. It is not clear that immunosuppression is either necessary or helpful. Moreover, attempts to treat vasospasm with calcium-channel blockers may lead to a vascular steal phenomenon, potentially causing harm. Second, because it is frequently difficult to do nothing for a patient with possibly serious CNS disease, calcium-channel blockers (e.g., nifedipine 30 mg three times daily) may be tried. Third, because of the frequent diagnostic uncertainty at the time of presentation, some clinicians opt to treat empirically with glucocorticoids (prednisone 1 mg/kg/day) for 1 month, followed by a taper over several weeks. Fourth, combinations of calcium-channel blockers and glucocorticoids are also reasonable, but cytotoxic therapy is not indicated in RCVS.

DIAGNOSIS

Differential Diagnosis

The major categories of diseases that can mimic vasculitis are displayed in Table 270-6. Certain features of a patient's case should raise the diagnostic suspicion for vasculitis. First, most cases of vasculitis do not begin suddenly but rather unfold subacutely during weeks or months. Second, pain is usually a prominent feature of vasculitis, resulting from arthritis or arthralgias, myalgias, headaches, neuropathy, testicular infarction, digital ischemia, sinusitis, otalgia, back pain (caused by aortic inflammation), postprandial abdominal pain (caused by mesenteric vasculitis), or other disease manifestations. Third, signs of inflammation such as fever, rash, weight loss, and elevated acute phase reactants are highly characteristic. Finally, multiorgan system involvement is the rule in vasculitis.

Ideally, the diagnosis of vasculitis is established through biopsy of an involved organ. Diagnoses based on angiography alone have many potential pitfalls, as discussed in the sections on PACNS and RCVS. Angiographic findings that are "consistent with vasculitis" must be interpreted in the proper context. A diverse array of other diseases, ranging from atherosclerosis to vasospasm to pheochromocytoma, may mimic the angiographic appearance of vasculitis. Systemic vasculitis can also be mimicked by two or more common medical problems or treatment complications occurring simultaneously in the same patient. Finally, high on the differential diagnosis of any individual form of vasculitis are other forms of vasculitis. For example, digital ischemia and splinter hemorrhages may be secondary to idiopathic polyarteritis nodosa. They may also be caused by polyarteritis nodosa associated with HBV infection, GPA, EGPA, microscopic polyangiitis, cryoglobulinemia, Buerger disease, or some other form of vasculitis. Because the

TABLE 270-6 MAJOR DISEASE CATEGORIES IN THE DIFFERENTIAL DIAGNOSIS OF VASCULITIDES

Other forms of vasculitis
Simultaneous occurrence of common medical problems in the same patient
Infections
Bacterial, viral, mycobacterial, fungal
Occlusive processes
Hypercoagulable states
Livedoid vasculopathy (atrophie blanche)

Fibromuscular dysplasia
Neutrophilic dermatoses
Pyoderma gangrenosum
Sarcoidosis
Reversible cerebral vasoconstriction syndrome

appropriate interventions for these conditions vary widely, careful distinction among these potential etiologies is essential.

TREATMENT

Rx

The intensity of treatment in patients with vasculitis must be guided by the degree of disease activity. Specifically, the treatment of vasculitis should be predicated not only on abnormal laboratory test results but also on clear evidence of active disease. In addition, the intensity of treatment must be adapted to the type of vasculitis. Whereas giant cell arteritis responds to high doses of glucocorticoids in essentially all cases, for example, GPA nearly always requires an additional agent (rituximab, cyclophosphamide, or methotrexate) for disease control. In contrast, despite the dramatic fashion in which they sometimes present, most cases of IgA vasculitis and cutaneous leukocytoclastic angiitis require no immunosuppressive treatment at all.

Conventional therapies such as glucocorticoids, immunomodulating agents, and cytotoxic drugs induce remissions and control vasculitis in most cases. Moreover, in some cases—a variable percentage, depending on the type of vasculitis—the disease is curable. Unfortunately, the treatments of vasculitis have enormous potential for toxicity. Regular monitoring of patients' bone marrow, renal, and hepatic function is essential to avoid treatment-induced toxicity. Prophylaxis against opportunistic infections, particularly *Pneumocystis* pneumonia (Chapter 341), is an important part of many vasculitis treatment regimens. During the tapering of immunosuppressive medications, disease flares are common in many forms of vasculitis.

A common error is treating patients with high doses of immunosuppressive agents for too long. The most appropriate use of medications such as cyclophosphamide and glucocorticoids is to induce remission as quickly as possible with early, aggressive treatment regimens, and then to convert patients to safer treatments for the maintenance of remission. Rituximab is replacing cyclophosphamide as the drug of choice for some forms of vasculitis, particularly AAV. Patients with AAV who demonstrate a tendency to flare are often retreated with rituximab (500 mg or 1 g) every 4 to 6 months, at least until lengthy periods of disease control are established. Current treatment approaches to specific vasculitides are described under their "Clinical Manifestations."

PROGNOSIS

Assuming that the diagnosis is made before the patient has become catastrophically ill, the prognosis in systemic vasculitis is determined largely by the answers to four questions:

1. Was the diagnosis established before the occurrence of major irreversible organ damage?
2. Was aggressive (but appropriately dosed) treatment begun in a timely fashion?
3. Was there careful monitoring during treatment, and were specific steps taken to avoid drug-induced toxicity (e.g., opportunistic infection)?
4. Were the potentially toxic medications that induced remission stopped at an appropriate juncture and replaced with less dangerous medications (or was treatment stopped altogether)?

For most forms of vasculitis, the factors that determine long-term drug-free remissions remain poorly understood. The likelihood of achieving sustained remissions after discontinuation of all medications (or cures) varies according to the specific type of vasculitis.

FUTURE DIRECTIONS

Compelling laboratory and naturally occurring animal models of disease, combined with the known associations among HBV, HCV, and vasculitis in humans, suggest that additional links between infection and systemic vasculitis may be established in the future. Important strides have been made in the description of cytokine and chemokine pathways that are operative in vascular inflammation, but relevant anticytokine interventions remain to be defined for clinical therapies. B-cell depletion is emerging rapidly as the treatment of choice for some forms of severe vasculitis. IL-6 inhibition strategies are also likely to play important roles soon in the large-vessel vasculitides. Additional studies are required to define the full spectrum of clinical utility of these and other biologic agents.

REVIEW QUESTIONS

1. Immunosuppressive therapy is known to be futile for which disease associated with vascular inflammation?

A. Buerger disease (thromboangiitis obliterans)
B. Granulomatosis with polyangiitis (formerly Wegener granulomatosis)
C. IgA vasculitis (Henoch-Schönlein purpura)
D. Giant cell arteritis
E. Mixed cryoglobulinemia

Answer: A The only effective intervention known for Buerger disease is smoking cessation. Neither immunosuppression nor anticoagulation is of any demonstrable benefit in relieving the severe digital ischemia associated with this disease.

2. Which form of systemic vasculitis is most likely to present with an orbital pseudotumor?

A. Takayasu arteritis
B. Granulomatosis with polyangiitis (formerly Wegener granulomatosis)
C. Microscopic polyangiitis
D. Polyarteritis nodosa
E. Behçet syndrome

Answer: B Two common ocular manifestations of granulomatosis with polyangiitis are scleritis and orbital pseudotumor. The latter can lead to proptosis and vision loss if blood circulation to the eye is compromised by the retrobulbar mass.

3. A 24-year-old man from Lebanon presents with multiple aphthous ulcers, bilateral ocular erythema, tender erythematous nodules over his anterior legs, and a deep venous thrombosis. An ophthalmologic examination reveals severe bilateral uveitis affecting both the anterior and posterior compartments of the eye. In addition to anticoagulation and the institution of glucocorticoid therapy, what is the most appropriate approach to treating his disease at this time?

A. Intravenous cyclophosphamide
B. Azathioprine
C. Intravenous immunoglobulin
D. Tumor necrosis factor inhibition
E. B-cell depletion

Answer: D Tumor necrosis factor inhibition is highly effective in Behçet disease and is employed in the presence of severe disease manifestations such as posterior uveitis or central nervous system (CNS) disease.

4. A 32-year-old woman presents with the rapid onset of the worst headache of her life 1 day after giving birth to a healthy baby boy. The delivery followed an uneventful pregnancy. The patient has no history of migraine headaches, and her past medical history is unremarkable. The patient's blood pressure is 140/90 mm Hg, and although her neurologic examination is nonfocal, the severity of the headache prompts a computed tomographic (CT) scan of the brain. This is negative for an intracranial bleed, and the headache resolves after approximately 24 hours, during which time it was profoundly disabling.

Approximately 18 hours later, the headache returns, again rising to a crescendo within several minutes of onset. A repeat head CT is negative and a lumbar puncture is also performed, revealing a normal opening pressure, 1 white blood cell/mL (100% lymphocytes), and a cerebrospinal fluid protein of 40 mg/dL (normal 30 to 50 mg/dL). The headache improves following round-the-clock narcotic treatment but then worsens again on the third postpartum day. A magnetic resonance imaging study is negative for hemorrhage, cerebral infarctions, and masses, but a four-vessel cerebral angiogram shows alternating areas of vascular narrowing and dilatation (beading) in multiple vascular distributions.

What is the most appropriate intervention for this patient now?

A. Tighter blood pressure control, with transfer to the intensive care unit for sodium nitroprusside therapy
B. Addition of a baby aspirin to her anticoagulation with low-molecular-weight heparin
C. Pulse methylprednisolone (1000 mg/day for 3 days) followed by prednisone 60 mg/day and cyclophosphamide 100 mg/day
D. Nifedipine 30 mg three times daily
E. Proceed to brain biopsy

Answer: D Nifedipine. This patient has a history that is classic for reversible cerebral vasoconstriction syndrome (RCVS), an entity that mimics CNS vasculitis but is not an inflammatory condition. The features suggesting RCVS in this patient are the presence of a "thunderclap" headache, the nonfocal neurological examination, the normal cross-sectional imaging and lumbar puncture, and the diffuse beading on angiography. This beading represents vasospasm, which is the essential pathophysiology of RCVS. Calcium-channel blockers are often used in therapy, but prolonged courses of immunosuppression are not indicated. Brain biopsy can be diagnostic in primary angiitis of the CNS, but would not be indicated in a patient like this who has typical clinical and radiographic features of RCVS.

5. A 4-year-old boy presents with 3 days of a febrile illness with temperatures to nearly 105° Fahrenheit. Physical examination reveal an erythematous "strawberry" tongue, swollen lips, and a pink macular rash on the trunk. There is also tender cervical and axillary lymphadenopathy and diffuse swelling of the distal upper and lower extremities. Which treatment is indicated immediately now to prevent the occurrence of coronary aneurysms?

A. Intravenous immunoglobulin
B. High-dose aspirin therapy
C. Pulse methylprednisolone
D. Plasma exchange
E. Anticoagulation with heparin

Answer: A This child has Kawasaki disease, and the most feared complication of this disorder is formation of coronary aneurysms, which can lead to myocardial infarction. If administered in a timely manner, intravenous immunoglobulin prevents the occurrence of such aneurysms.

271

POLYMYALGIA RHEUMATICA AND TEMPORAL ARTERITIS

ROBERT F. SPIERA

DEFINITION

Polymyalgia rheumatica (PMR) and temporal arteritis, also called giant cell arteritis (GCA), are companion systemic inflammatory disorders of unknown etiology that represent a spectrum from severe proximal aches and pains and constitutional symptoms to an occlusive granulomatous vasculitis of medium and large vessels that can lead to permanent blindness or other organ and tissue damage. These disorders occur primarily in patients older than 50 years, in women more than in men; they are propagated by antigen-driven, cell-mediated (T_H1) immune mechanisms that may be associated with specific genetic markers and are highly responsive to corticosteroids.

EPIDEMIOLOGY

In the United States, the average annual incidence of PMR is 52.5 per 100,000 patients aged 50 years and older and increases with age. The prevalence is about 0.5 to 0.7%. Internationally, the frequency varies according to country, with the highest rates occurring in the Scandinavian countries.[1] The incidence and prevalence of GCA are approximately one third those of PMR.

PATHOBIOLOGY

The etiology of PMR and GCA is unknown, but both demonstrate familial aggregation and have a genetic association with human leukocyte antigen (HLA)-DR4 and a demonstrated sequence polymorphism encoded within the hypervariable region of the *HLA-DRβ1*04* gene.[2] Other genetic

associations have been suggested, including polymorphisms that may be seen in increased frequency in patients with the disease. Disease in genetically predisposed patients may be triggered by environmental factors such as viruses or endogenous antigens such as elastin, and their inflammatory manifestations are directed by specific patterns of cell-mediated, T_H1-associated cytokines. The cytokine production by the mononuclear cells in the involved tissues appears to influence the clinical phenotype. Cytokine profiles characterized in temporal artery biopsy specimens obtained from patients with PMR and GCA differ. GCA tissue contains the T-lymphocyte products interferon-γ and interleukin (IL)-2 and the macrophage products IL-1β, IL-6, and transforming growth factor-β. In PMR vascular tissue, transcripts are found for transforming growth factor-β, IL-1, and IL-2 but not for interferon-γ.[3] Patients with GCA who present with fever of unknown origin and who do not have ischemic symptoms, such as visual loss, have low interferon-γ levels. Arteries that express high interferon-γ levels typically have multinucleated giant cells present; these cells remove debris and secrete cytokines that stimulate intimal hyperplasia and lead to angiogenesis. IL-17-producing T_H17 cells have also been found in involved vascular tissue and peripheral blood of patients with untreated GCA but disappear rapidly with institution of corticosteroid therapy, whereas T_H1 cells are more persistent, speaking to the possibility that more than one antigenic trigger may be involved.[4]

The adventitia is considered the immunologic center in the pathogenesis of GCA. Macrophages and T lymphocytes enter the vessel wall through the vasa vasorum with the aid of adhesion molecules and come into contact with an inciting antigen. Here, it is likely that clonal proliferation of $CD4^+$ T cells is triggered by the presentation of unknown antigens by antigen-presenting cells. The activated CD4 cells produce interferon-γ that attracts macrophages to the arterial wall. Some of these macrophages fuse at the intima-media to form multinucleated giant cells. These cells produce vascular endothelial growth factor, which triggers neovascularization, both at the intima-media junction and at the level of the vasa vasorum, sprouting from the adventitia to the media. The subsequent immunologic events lead to a characteristic topography of mononuclear cells throughout the vessel wall. Products of the giant cells and macrophages at the intima-media junction include collagenase and nitric oxide, both of which probably contribute to tissue damage. The pathologic impact of cytokines leads not only to the characteristic medial damage but also to significant intimal hyperplasia that eventually, if it is not treated, may cause luminal narrowing and tissue ischemia.

In GCA, a transmural (involving all layers of the vessel) inflammatory infiltrate, comprising predominantly mononuclear cells and commonly with giant cells, is found in the superficial temporal arteries as well as in other large and medium-sized arteries. In elderly patients, fragmentation of the internal elastica is characteristic and helps differentiate this vascular lesion from that of atherosclerosis. Often, macrophages containing fragments of elastic tissue are found at the intima-media junction, the histologic center of the inflammatory process. As mentioned earlier, immunochemical techniques demonstrate differing patterns of cells and their proinflammatory and profibrotic products in the adventitia, media, and intima. Intimal proliferation may be prominent and lead to luminal narrowing. Fibrinoid necrosis, a common histologic feature in polyarteritis nodosa, is not seen in GCA.

In PMR, mononuclear cell inflammation can be found not only in the proximal joints, such as the shoulders, but also in the surrounding tendons, bursae, and soft tissues consistent with enthesitis. Although muscle pains may be present, no muscle inflammation is found.

CLINICAL MANIFESTATIONS

PMR and GCA are systemic inflammatory disorders that occur primarily in patients older than 50 years, in women more than in men (2:1), and in whites. PMR and GCA are particularly uncommon in African Americans. Shared characteristics of the two disorders include significant cytokine-driven constitutional symptoms, such as fever, fatigue, and weight loss, as well as a markedly elevated erythrocyte sedimentation rate (ESR), anemia, and thrombocytosis. The musculoskeletal hallmark of PMR is proximal, severe, and symmetrical morning and even day-long stiffness, soreness, and pain in the shoulder, neck, and pelvic girdles.[5] Fifty percent of patients with GCA share this characteristic proximal pain syndrome. Carpal tunnel syndrome and hand and knee synovitis may be seen in patients with PMR, but the overall presentation remains predominantly proximal, as opposed to rheumatoid arthritis, in which distal synovitis dominates. Whereas patients with PMR may appear to have proximal muscle weakness, this is invariably due to pain and not muscle inflammation (Table 271-1). Magnetic resonance imaging (MRI)[6] and ultrasound studies[7] in patients with PMR have confirmed the presence of inflammation of extra-articular synovial structures, in particular subacromial and subdeltoid bursae in the shoulders.

TABLE 271-1 GIANT CELL ARTERITIS: CLINICAL FEATURES

INFLAMMATORY

Leg or arm claudication
Diminished pulses, blood pressure asymmetry
Aortic aneurysms
LATE COMPLICATIONS
Aortic aneurysms
Thoracic aorta
Abdominal aorta
Corticosteroid complications
Osteoporosis
Fractures
Cataracts

Specific signs and symptoms of GCA are best appreciated in their anatomic and physiologic contexts. GCA preferentially affects certain blood vessels, including the branches of the external carotid artery, the ophthalmic artery and particularly its posterior ciliary branches, and the large arteries that arise from the aortic arch and abdominal aorta. Headache and scalp pain are probably the most frequent symptoms, occurring in 50 to 75% of patients. Headache is often the first manifestation of GCA and is described as boring, severe, and constant, unresponsive to simple pain medications and persisting through the night. Classically, patients complain of persistent and prominent temporal headaches, but occipital pains can also occur. Ear, pinna, or parotid gland pain may occur secondary to involvement of the posterior auricular artery. Jaw claudication and pain due to masseter muscle ischemia on chewing occur in 50% of patients. Lingual and maxillary artery involvement can lead to jaw or tongue pain on chewing or talking. The superficial temporal artery may become tortuous, prominent, nodular, or tender, but these findings are not invariable, and an abnormal temporal artery may be found on biopsy in vessels that appear normal. It is important to note that a dry, nonproductive cough can be a feature of the disease because this often may direct the clinician away from considering GCA and more toward consideration of an infectious or neoplastic respiratory cause of the symptoms. Rarely, mononeuritis multiplex and/or sensorineural hearing loss can occur but should lead the clinician to consider other possible vasculitides such as antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis or polyarteritis nodosa.

Fixed or intermittent symptoms related to vasculitic involvement of the ophthalmic arteries and its branches are the most dreaded in this illness and demand immediate therapeutic intervention. These symptoms are related to vascular narrowing due to both active inflammation and endothelial injury–mediated vasospasm. Decreased vision secondary to arteritis is the most common serious consequence of GCA, occurring in 20 to 50% of patients who present to ophthalmologists. It is the presenting symptom in 60% of patients with GCA who develop visual loss. A careful history of most patients who present with "sudden" visual loss reveals that preceding headache, constitutional symptoms, and PMR occurred in approximately 40% of patients. Even the evolution of the visual loss was often staggered, with amaurosis fugax in 10% and a partial field defect progressing to complete blindness over days. If GCA remains untreated, the second eye may become involved within

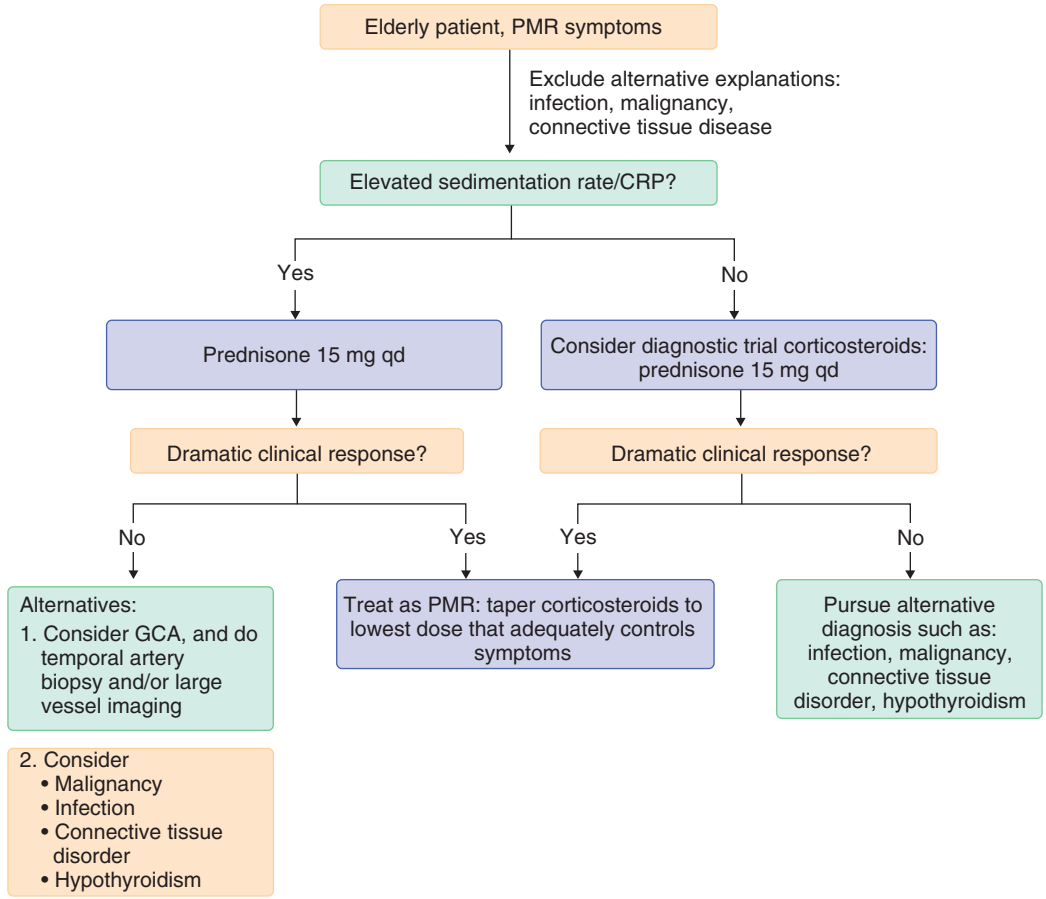

FIGURE 271-1. Diagnostic algorithm for polymyalgia rheumatica (PMR). CRP = C-reactive protein; GCA = giant cell arteritis.

1 to 2 weeks. The posterior ciliary arteries are the most frequently involved; thus, anterior ischemic optic neuropathy is the most common lesion, which can be easily defined by an ophthalmologist. Occlusion of the central retinal artery and its branches is uncommon; thus, exudates, hemorrhages, and frank vasculitis are infrequent. Five percent of patients with GCA may present with diplopia or ptosis, which may precede visual loss. The final visual abnormality can be a composite of many ischemic events occurring together in the optic nerve, the extraocular muscles, the chiasm, and the brain itself. Because GCA primarily involves arteries that contain elastica and the elastic lamina is lost as vessels pierce the dura, intracerebral lesions such as strokes are uncommon but not unheard of.

Large artery involvement most commonly presents as arm or leg claudication; rarer manifestations are stroke, subclavian steal syndrome, intestinal infarction, and symptomatic aortic aneurysm. Thus, a subclinical arteritis can exist and demands long-term monitoring. There is an emerging appreciation that some older patients classified as having GCA can present with large vessel disease resembling Takayasu's arteritis clinically, with a paucity of cranial ischemic symptoms but often the presence of PMR-like symptoms. Conversely, in patients presenting with typical GCA with cranial symptoms and a positive temporal artery biopsy, large vessel disease with aortic wall thickening is markedly more frequent than in matched controls without GCA, even early in the disease course. Steroid-treated PMR and GCA are self-limited illnesses lasting 1 to 2 years in most patients. However, a subgroup of patients with both disorders can have active inflammatory disease as manifested by persistent symptoms and blood test signs of active inflammation for 7 to 10 years. Of note is the fact that thoracic aneurysms with giant cells in the tissue can develop as long as 15 years after the diagnosis, successful treatment, and discontinuation of steroids. Indeed, the incidence of thoracic and aortic aneurysms is markedly higher in patients with prior history of presumably successfully treated GCA than in age-matched control subjects. Conversely, in studies of repaired aortic aneurysms, pathologic findings consistent with GCA have been found in approximately 2 to 4% of specimens from individuals without previously recognized or suspected arteritis. In most studies, survival rates for patients with PMR and GCA are similar to those of unaffected persons of the same age. However, one study did show that survival was decreased in a group of patients with GCA who had permanent visual loss and required more than 10 mg of prednisone per day at 6 months. This probably supports the experience that the morbidity and mortality are caused by steroid-related treatment complications in this high-risk, elderly group of patients possessing many comorbid conditions.

DIAGNOSIS

The diagnoses of PMR and GCA are based on clinical facts, with supporting but not diagnostic aid obtained from laboratory tests and temporal artery biopsy (Fig. 271-1).[8] No physician should await an abnormal finding on temporal artery biopsy or demand the presence of an elevated ESR before making the definitive diagnosis of GCA in the setting of a characteristic clinical picture. That said, the laboratory hallmark of PMR and GCA is an elevation in IL-6-stimulated acute phase reactants such as the ESR and C-reactive protein. The ESR is usually in excess of 50 mm/hour and may exceed 100 mm/hour. An ESR in the low 20s or 30s, however, does not exclude a diagnosis of PMR or GCA if other characteristic clinical features are present and especially if the patient is already taking steroids.

Normocytic, normochromic anemia and thrombocytosis occur in approximately 50% of patients with both disorders and are excellent guides to the state of inflammation. In both PMR and GCA, the frequency of rheumatoid factor, antinuclear antibody, ANCA, monoclonal proteins, and cryoglobulins is not higher than in age-matched control subjects, and complement is not reduced. Alkaline phosphatase activity may be elevated in one third of patients, primarily those with GCA. Although these tests are not indicated in PMR and GCA, muscle enzymes and electromyography are normal, and muscle biopsy shows type II fiber atrophy but no inflammation.

Superficial Temporal Artery Assessment

Temporal artery tenderness, nodularity, and diminished pulsation are typical findings on physical examination in a patient with GCA. Color duplex ultrasonography has been used as an adjunctive noninvasive diagnostic tool in GCA. A hypoechoic halo around the superficial temporal artery has been reported in 73% of patients with biopsy-proven GCA. The halo, representing edema in the arterial wall, was observed bilaterally in a significant subset of patients and disappeared in a mean of 16 days after the initiation of steroids in one study. The presence of the halo in this study had a sensitivity of 73% and was 100% specific for GCA. Other groups have been unable to replicate this experience, however, finding Doppler ultrasonography to be no more

sensitive or specific than physical examination in patients thought to have the disease. Findings of stenosis or occlusion of temporal arteries by Doppler ultrasound have also been recognized as being modestly sensitive and specific for the diagnosis of GCA in some studies. Operator dependency remains a challenge to the more widespread use of this modality diagnostically. [^{18}F] Fluorodeoxyglucose–positron emission tomography may be helpful in identifying large vessel inflammation suggestive of GCA, but it is not helpful in assessing the temporal arteries themselves, given their relatively small size and high background uptake in that area. Conventional angiography is rarely used in the diagnosis of GCA. Some studies have suggested that MRI/magnetic resonance angiography (MRA) may be a helpful noninvasive diagnostic modality. Superficial cranial arteries can be visualized, and mural inflammatory changes and luminal narrowing can be identified. Large vessel involvement can also be assessed. Studies have suggested sensitivities and specificities of MRI/MRA similar to those of biopsy in the diagnosis of GCA. Nevertheless, temporal artery biopsy remains the diagnostic "gold standard" in GCA, and given the relatively easy accessibility of the artery and potentially significant morbidity of therapy in GCA, histologic confirmation is favored in most cases.

Although temporal artery biopsy continues to be an important diagnostic test for the presence of GCA, a few caveats must be stated. First, in a patient in whom the clinical diagnosis is likely, treatment with steroids should be instituted immediately without waiting for the biopsy results. Second, because of the skipped nature of the pathologic inflammatory lesions in the vessel wall, as many as 20 to 30% of biopsy specimens may be normal despite an overwhelming diagnostic likelihood of GCA. However, because the biopsy is helpful in confirming the diagnosis of GCA, in which high doses of steroids are used, the following guidelines are given. Patients with pure PMR and no GCA signs or symptoms do not need a biopsy. However, because 10% of these patients may develop such clinical manifestations of GCA within the next year, they should be told to report such symptoms immediately. When GCA is likely, an outpatient biopsy should be performed on the symptomatic side of the head, preferably including inflamed areas with tenderness or nodularity and incorporating 2 to 3 cm of vessel. Multiple sections should be requested because of the segmental nature of the disease process. Some rheumatologists routinely request bilateral biopsies, which may increase the likelihood of obtaining an abnormal finding by up to 5%, whereas others perform a contralateral biopsy if the first specimen is normal. Diagnostic biopsy findings continue to be present for as long as 2 to 4 weeks after the clinical diagnosis is made and steroid treatment instituted.[9]

Differential Diagnosis

The systemic nature of these disorders and the fact that they occur in elderly people demand careful diagnostic scrutiny to avoid missing a malignant neoplasm or major infection and possibly treating patients inappropriately with high-dose steroids. This is true in PMR because there is no diagnostic test and in GCA because the GCA biopsy finding may be normal in the face of active, vision-threatening vasculitis. Infections that must be considered and ruled out if clinically appropriate include tuberculosis, endocarditis, and hepatitis B and C. Malignant neoplasms such as lymphoma and multiple myeloma may mimic PMR, and an age-appropriate cancer evaluation is always indicated in this age group. Autoimmune disorders such as elderly-onset rheumatoid arthritis and systemic lupus erythematosus, as well as dermatomyositis and other types of vasculitis, must be considered in the differential diagnosis and sorted out by employing clinical information and serologic testing. There is support for the concept that elderly-onset rheumatoid arthritis is the same disorder as PMR with negative rheumatoid factor, a more proximal focus of joint inflammation, and a good response to low-dose prednisone. The distinction may be semantic because neither disorder tends to evolve into an erosive arthritis. A more protracted clinical course, however, is often seen in patients in whom distal synovitis is a prominent feature, and those patients are classified as having elderly-onset rheumatoid arthritis. PMR and GCA should always be thought of in the setting of a fever of unknown origin because symptoms and signs can be occult or the history incomplete.

TREATMENT

Rx

Both PMR and GCA are highly responsive to corticosteroids, which are the preferred treatment choice.[10] This response is so characteristic that an immediate and dramatic improvement in PMR and GCA symptoms within 1 to 3 days after steroid institution supports the diagnosis. Conversely, a lack of rapid and significant improvement in signs, symptoms, and function within 5 to 7 days should lead the clinician to suspect the initial impression and consider an alternative diagnosis (e.g., tumor or infection) or the presence of GCA in PMR patients that might require a higher steroid dose. Because the inflammatory burden of the two disorders is different, different doses of steroids are employed at the onset of treatment. Whereas PMR usually responds to 15 mg of prednisone daily, GCA usually requires 40 to 60 mg of prednisone per day in divided doses or higher doses if organ or tissue damage is present or threatened.[11] In GCA, if visual symptoms are present as a fixed loss or amaurosis fugax, the patient often should be treated with high-dose intravenous methylprednisolone with doses ranging from 40 mg every 8 hours to 1 g/day for 3 days, followed by high-dose oral steroids in divided doses.

Within 2 to 3 days after the institution of steroids, most symptoms of PMR or GCA clear rapidly, and patients describe a miraculous improvement. The steroid dose is then maintained for 2 to 3 weeks, during which the ESR, C-reactive protein, hemoglobin, and platelet counts normalize. Steroid taper is then instituted and guided by the clinical response. In PMR, taper is commonly by 1 mg every 7 to 10 days; in GCA, taper is by 5 to 10 mg every 7 to 10 days. In GCA, the use of alternate-day corticosteroid regimens to minimize steroid side effects is generally not recommended because randomized controlled trials have demonstrated higher rates of treatment failure with alternate-day dosing schedules. It is important that the taper be guided primarily by clinical findings (e.g., PMR stiffness, headache, fatigue) and that the level of ESR elevation be considered within that clinical context. One should never "chase the ESR" because the elderly patient would be subjected inappropriately to a dangerously high cumulative dose of steroids with their attendant side effects. An increased dose of prednisone should be based on a change in symptoms, not solely on an increase in the ESR. One possible exception is in a patient with a history of GCA and prior abrupt vision loss in one eye, in whom any further compromise of vision would be catastrophic. The effective dose demanded for a flare often can be as low as 5 to 10 mg of prednisone, and uncommonly up to 60 mg/day to control symptoms (e.g., visual abnormalities). A persistently elevated ESR (>50 mm/hour) without PMR or GCA symptoms should alert the physician to look for alternative causes, such as infection. Treatment is a careful balancing act between disease control and avoidance of steroid-related toxicity. The overall goal of the patient and the physician is to attain the best disease control with the lowest dose of steroids. In most patients, prednisone can be tapered safely in 1 to 2 years. However, other patients may need to take low doses of steroids for 2 years or more. The higher the initial dose and cumulative dose, the greater the likelihood that the patient will develop a major steroid side effect such as sepsis, osteoporosis, osteonecrosis, diabetes, emotional lability, or myopathy. Appropriate immunizations, osteoporosis regimens (calcium, vitamin D, and bisphosphonates), and metabolic monitoring are mandatory in all patients prescribed chronic steroid therapy.

The major feared outcome in GCA is ischemic complications of the disease, most often vision loss or, less frequently, cerebrovascular accident. Vision loss is usually irreversible, and although it is uncommon after the diagnosis is suspected and glucocorticoid therapy is instituted, it can occur early in the course of treatment. Aspirin is known to be protective against ischemic events in patients with atherosclerosis and has anti-inflammatory effects in inflamed blood vessels, including inhibition of interferon-γ. A recently reported cumulative meta-analysis of retrospective studies showed that antiplatelet or anticoagulant therapy has a marginal benefit when used together with corticosteroids in patients with established GCA.[12] Although this has not been demonstrated in prospective randomized controlled trials, in most patients, adjunctive therapy with low-dose aspirin should be considered unless there is a strong contraindication to its use.

Alternative immunosuppressive agents have been tested in both PMR and GCA patients in an attempt to "spare steroids" and to control the inflammatory state. Studies examining the efficacy of methotrexate in GCA have yielded mixed results, with the largest, most recent study showing no incremental benefit from combined therapy. One individual patient meta-analysis of three randomized placebo controlled trials suggested a modest benefit to methotrexate in GCA in terms of affording a steroid-sparing benefit and reducing likelihood of flares. Given the modest nature of the benefit demonstrated and the potential toxicities of methotrexate in this elderly population, methotrexate is not routinely incorporated as first-line therapy in GCA. In PMR, methotrexate has been shown in one study to afford a benefit in terms of steroid sparing and possibly reducing numbers of flares. The magnitude of the benefit appears modest, and no reduction in corticosteroid-related side effects was demonstrated. At present, methotrexate is not routinely used in the management of either disease, but in individual patients with refractory disease or excessive corticosteroid morbidities, addition of weekly rheumatoid arthritis–level doses of methotrexate (7.5 to 20 mg/week) or azathioprine (2 mg/kg/day) is employed in selected instances. There have been case series suggesting cyclophosphamide may be of value in patients with refractory disease and/or unacceptable corticosteroid toxicity, but adverse events were common, and it is rare to use this agent in GCA.

Randomized controlled trials of TNF inhibitors including infliximab and adalimumab in GCA have failed to demonstrate benefit in terms of preventing

relapses or affording a steroid-sparing benefit.[13] Abatacept, a costimulatory molecule blocker, is presently being evaluated in large vessel vasculitis including GCA, in a large randomized trial, but those results are not yet available. Tocilizumab, an IL-6 inhibitor, has been of major interest in GCA and PMR because this cytokine seems pivotal in these disorders. Tocilizumab reliably reduces C-reactive protein and ESR, which in theory could be independent of a true beneficial effect on the underlying arteritis, but early controlled observations are encouraging.[14] This will be a challenge in assessing the true efficacy of Tocilizumab in GCA in the larger controlled clinical trials that are in progress.

FUTURE DIRECTIONS

Better understanding of the disease-causing roles of immunologically active cells and their cytokine products, along with genetics and correlations with clinical subsets, will lead to more focused treatment modalities and the avoidance of the need for long-term treatment with steroids. A recently published cohort study revealed that GCA is associated with increased risks for myocardial infarction, stroke, and peripheral vascular disease,[15] suggesting that greater attention should be paid to cardiovascular risk reduction in patients with this disease.

REVIEW QUESTIONS

1. A 74-year-old gentleman presents with a 7-week history of increasing generalized shoulder and hip pain, morning stiffness, low-grade fevers, and a dry cough. He was found to be anemic with a hemoglobin of 9.7 and had a thrombocytosis with a platelet count of 642 and an elevated sedimentation rate of 114. A search for infection and neoplasia has been unrevealing, including a bone marrow biopsy, which did not suggest a myeloproliferative neoplasm. He denies headaches, visual symptoms, or jaw claudication. The patient has reluctance regarding any further interventional procedures. Which of the following would be the best option to establish his diagnosis?

A. A computed tomographic (CT) angiogram with imaging of the aortic arch and its major branches
B. A conventional angiogram
C. Duplex ultrasound of his temporal arteries and axillae.
D. A positron emission tomography (PET) scan
E. Bilateral temporal artery biopsies

Answer: E The patient likely has giant cell arteritis. Although PET scanning, duplex ultrasound of temporal arteries, and CT angiography may be helpful in some patients, a temporal artery biopsy remains the gold standard and is the most specific if the biopsy can be established. Duplex sonography has yet to be proved reliably accurate. PET scanning and angiography, although potentially helpful, can provide in false-positive results in patients with severe atherosclerosis and false-negative results in patient without clear evidence of large vessel disease. Polymyalgia rheumatica (PMR) may be a possibility here (and this patient indeed has PMR), but the presence of dry cough and degree of inflammatory response makes concurrent giant cell arteritis (GCA) a pressing concern

2. A 77-year-old woman with a history of diabetes, osteoporosis, and modest alcohol use presents with 3 weeks of headaches and feeling systemically unwell and then loss of vision in her left eye 2 days ago. She is found to be anemic with a markedly elevated sedimentation rate, and a temporal artery biopsy confirms the diagnosis of GCA. She is started on 60 mg of daily prednisone. Which of the following would be an appropriate additional intervention at this point?

A. Add Infliximab 5 mg/kg monthly as a steroid-sparing intervention.
B. Add methotrexate 10 mg weekly with the hope of titrating that to 15 mg weekly to afford a steroid-sparing benefit.
C. Change her corticosteroid regimen to 120 mg on alternate days and plan an alternate day taper from there.
D. Add low-dose aspirin daily to her regimen.
E. Add tocilizumab 8 mg/kg monthly as a steroid-sparing intervention.

Answer: D Patients with GCA often struggle with comorbidities that raise concerns regarding prolonged exposure to corticosteroids. There is at this time, however, no proven steroid-sparing intervention that can decrease the risk for cranial ischemic complications or even that has been demonstrated to reduce corticosteroid-related adverse events. Low-dose aspirin has been shown in two retrospective studies to be likely protective against cranial ischemic complications, so if there is no contraindication, that would be an appropriate intervention. Methotrexate has been shown in one trial in one individual meta-analysis to have a corticosteroid benefit in terms of cumulative steroid dose and also reduced risk for flares, but in the largest multicenter study addressing its efficacy, it was not shown to be superior to placebo. Moreover, in this patient with comorbidities including diabetes and alcohol use, methotrexate could be morbid, so this would not seem an appropriate intervention at this point. Infliximab has been shown in a randomized, double-blinded, placebo-controlled trial not to be helpful in the treatment of GCA and can increase risk for infection in this patient already on high doses of corticosteroids with underlying diabetes. Alternate-day corticosteroid therapy has been shown to increase the risk for later flare and is not generally employed in GCA, particularly earlier in the course of treatment. Tocilizumab, an interleukin-6 inhibitor, is an agent of great interest in temporal arteritis, but it has not yet been shown to have a corticosteroid-sparing or disease-modifying benefit in this disorder; however, trials are presently in progress addressing this issue.

3. A 72-year-old man presents with a 2-month history of morning stiffness, mild synovitis in his knees, puffiness in his hands in the early morning hours, and severe shoulder and thigh girdle myalgias. He is mildly anemic with hemoglobin of 11.6 and has a markedly elevated sedimentation rate at 82. He is seronegative for rheumatoid factor, citric citrullinated peptide (CCP), and antineutrophil cytoplasmic antibodies. He has no evidence of peripheral joint erosions on plain radiographs. Which of the following would be the most appropriate therapeutic intervention at this point?

A. Begin naproxen 500 mg twice daily.
B. Begin methotrexate 10 mg weekly with the hope of bringing that dose up to 15 mg weekly in the next few weeks.
C. Begin methylprednisolone 12 mg daily.
D. Begin hydroxychloroquine 200 mg twice daily.
E. Begin methylprednisolone 12 mg daily along with methotrexate 10 mg weekly with a plan to taper the corticosteroids to off over the next 4 weeks.

Answer: C The patient described has PMR but presents with some peripheral synovitis, which can be seen in up to 10 to 15% of patients with PMR. The patient clinically is unlikely to have rheumatoid arthritis in the absence of seropositivity for rheumatoid factor and CCP, has typical shoulder and thigh girdle myalgias and morning stiffness, and does not have evidence of erosive disease radiographically. An initial trial of methylprednisolone 12 mg daily would have both therapeutic and likely diagnostic value because if his response is spectacular, that would strongly argue for PMR and continuing that approach to therapy. Although methotrexate and hydroxychloroquine have been agents of interest in polymyalgia rheumatica, their use has not been well established in double-blinded, placebo-controlled trials. One study suggesting a benefit to methotrexate in PMR did not demonstrate a benefit in terms of reducing numbers of corticosteroid-related adverse events, and at longer term follow-up, the initial benefits seen by the addition of methotrexate did not seem to persist. Naproxen would be unlikely to afford adequate relief to this patient and, given his comorbidities, would likely be as problematic if not more problematic than a trial of corticosteroids.

4. An 80-year-old gentleman with a prior history of giant cell arteritis successfully treated 7 years earlier presents with searing chest pain. His past medical history is otherwise only notable for borderline hypertension. He was successfully treated with a 1-year course of steroids but has been free of corticosteroids for 3 years. He has been feeling systemically well until recently. He had not seen a physician in 2 years. Which of the following explanations for his chest pain is of primary concern?

A. Dissecting thoracic aneurysm
B. Acute pericarditis
C. A myocardial infarction related to his increased risk for atherosclerosis given his prior history of GCA
D. Costochondritis related to a flare of PMR
E. Rib fracture

Answer: A Patients with a prior history of GCA are at increased risk for thoracic aortic aneurysms, even several years after completing therapy without evidence of residual active disease. The searing quality of his pain and his prior history of treated GCA make this a concern that should not be missed. The quality of his pain did not sound suggestive of a myocardial infarction, and patients with GCA have not been demonstrated to be at increased risk for atherosclerotic heart disease, although the possibility of that association has been of interest. Patients with GCA are not particularly at a higher risk for pericarditis. Although PMR can arise even years after successfully treated GCA (or even years after successfully treated PMR), the quality of his pain does not sound suggestive thereof, and costochondritis would not typically be a feature of PMR. The quality of the pain described did not sound suggestive of a rib fracture, but moreover that would be a diagnosis that could be overlooked at least initially without putting the patient at increased risk for a serious cardiovascular compromise.

5. A 72-year-old woman had presented with an 8-week history of progressively increasing morning stiffness, shoulder and thigh girdle myalgias and arthralgias, and fatigue. An extensive search for underlying infection and age-appropriate screening for underlying neoplasm were unrevealing. A serum immunofixation did not reveal a monoclonal gammopathy. She was found to be anemic with a hemoglobin of 10.7 and had a sedimentation rate of 108. She denied any headaches, scalp sensitivity, jaw claudication, or visual symptoms. She admitted to low-grade fevers but not greater than 100° F. PMR was suspected, and she was treated with methylprednisolone 12 mg daily in divided doses. Three days later, she called to report no significant improvement in her symptoms. It was suggested that her dose be raised to 16 mg daily in divided doses. She comes in for evaluation still complaining of similar myalgias and arthralgias, and her sedimentation rate remains elevated at 62, although her hemoglobin improved slightly to 10.9. Which of the following would be an appropriate next intervention?

A. Add methotrexate as a disease-controlling/steroid-sparing intervention.
B. Add infliximab to help achieve disease control.
C. Refer her for a bone marrow biopsy to exclude underlying myeloproliferative or lymphoproliferative disease.
D. Add hydroxychloroquine 400 mg daily.
E. Refer her for a temporal artery biopsy and raise the methylprednisolone to 32 mg daily.

Answer: E This patient presented with fairly typical PMR symptoms but in addition had low-grade fevers, which can be seen but are not as common as they are in GCA. Moreover, she was somewhat anemic. Her lack of response to 12 mg and then even 16 mg of daily methylprednisolone makes PMR unlikely unless in the context of a more substantial inflammatory disease such as GCA. GCA is found in approximately 10% of patients with "pure" PMR, and conversely, up to 50% of patients with GCA can present with PMR-like symptoms.

INFECTIONS OF BURSAE, JOINTS, AND BONES

ERIC L. MATTESON AND DOUGLAS R. OSMON

INFECTION OF BURSAE

Septic Bursitis

DEFINITION

Bursae are the satellite structures that form to protect tissues from bony prominences. The superficial bursae, including the olecranon, prepatella, infrapatella, and bursae over the first metatarsophalangeal bunions, are more likely to become infected than are the deep bursae, such as the subacromial, trochanteric, and iliopsoas bursae.[1]

EPIDEMIOLOGY

Olecranon bursitis may occur in as many as 10 in 100,000 persons. The majority of cases occur in men, and antecedent trauma to the skin is frequent.

PATHOBIOLOGY

Septic bursitis of superficial bursae is most commonly due to direct inoculation through the overlying skin; less commonly, it is secondary to overlying cellulitis. Most cases of deep septic bursitis are due to contiguous spread from adjacent infected joints or hematogenous seeding.

Predisposing risk factors for septic bursitis include trauma to the skin, as may occur in plumbers, athletes, and patients with chronic obstructive pulmonary disease (COPD) who frequently lean on the elbows; prepatellar or infrapatellar septic bursitis occurs in housecleaners, gardeners, and carpet layers. At least one third of patients with septic bursitis have an underlying comorbid illness such as diabetes mellitus, rheumatoid arthritis, gout, COPD, or alcoholism.

CLINICAL MANIFESTATIONS

In immune-competent patients, septic bursitis often but not always presents with fever and erythema and warmth of the overlying skin; there may be swelling of the bursae. In contrast to those with septic arthritis, patients with septic bursitis of superficial bursae have intact range of motion of the joints, which may be limited only at the extremes of flexion. Pain on motion of the joint and restriction of joint range of motion are highly suggestive of septic arthritis. Acute phase reactants such as C-reactive protein, the sedimentation rate, and the white blood cell count (WBC) may be elevated

DIAGNOSIS

Radiography should be performed to look for a foreign body and to evaluate the surrounding bones. Aspiration of bursal fluid is helpful in the diagnosis of patients who have pain, erythema, and/or swelling of an affected area. However, given the risk for contaminating the bursa if the aspiration occurs through skin involved with cellulitis, many clinicians choose to aspirate a bursa only if empirical antimicrobial therapy has failed. Ultrasound or computed tomography (CT) guidance greatly enhances the successful aspiration of superficial bursae. Care must be taken not to violate the joint space when aspirating a bursa to avoid inoculating the joint space.

The leukocyte count of the bursal fluid is generally lower than that seen in septic arthritis, with a mean of 13,500 cells/mm^3. Even in immune-competent hosts, cell counts can range from less than 1500 to greater than 100,000/mm^3. A leukocyte count greater than 2000/mm^3 has a sensitivity of 94% and a specificity of 79% for superficial (olecranon or prepatellar) bursitis. Bacterial culture and in vitro susceptibilities must be obtained; if additional fluid is available, a Gram stain may be obtained, although its sensitivity may be as low as 15%. The presence of crystals does not exclude the possibility of septic bursitis.

Staphylococcus aureus (Chapter 288) is the most common cause of septic bursitis, present in more than 80% of culture-proven cases, followed by β-hemolytic streptococci. Aerobic gram-negative bacilli, including *Escherichia coli*, *Campylobacter jejuni*, and *Pseudomonas* species, are rare causes of septic bursitis. Chronic bursitis may be associated with systemic infections due to *Brucella abortus*, atypical mycobacteria, or *Mycobacterium tuberculosis*, as well as fungi; the presence of these infections should raise the possibility of systemic infection.

Differential Diagnosis

In the immune-competent host, nonseptic bursitis (Chapter 263) may have a somewhat more indolent presentation than septic bursitis. The differential diagnosis includes gout, pseudogout, arthritis, and trauma with hemobursa. An overlying cellulitis may be confused with bursitis. Fever is usually not present in nonseptic bursitis due to mechanical or friction trauma.

TREATMENT

Rx

Treatment of septic bursitis is guided by knowledge of the putative underlying organisms, in most cases, *S. aureus*. Because the Gram stain is positive in less than two thirds of patients and cultures may be delayed, empirical therapy is guided by the clinical presentation. Most patients can be treated as outpatients, but those who are immunocompromised may require hospitalization for intravenous antibiotic therapy. Initial ambulatory treatment in patients without comorbidities may consist of an oral antistaphylococcal penicillin or first-generation cephalosporin. If community-acquired methicillin-resistant *S. aureus* (MRSA) is suspected, co-trimoxazole or minocycline may be added to one of these agents. In patients who are allergic to penicillin, oral clindamycin or linezolid may be used. Patients who have severe inflammation, are septic, or are immunocompromised may require hospitalization for initiation of treatment with intravenous nafcillin, oxacillin, or cefazolin; if MRSA is suspected, intravenous vancomycin, daptomycin, or linezolid should be used. Guidelines on the treatment of MRSA have been published.[2] Vancomycin can also be used in patients who are allergic to penicillin.

The duration of antimicrobial therapy is guided by the clinical response and comorbid states. It should be continued until there is no longer bursal inflammation. This may require several weeks of intravenous or oral therapy and multiple aspirations. Failure of the septic bursitis to respond to initial antibiotic therapy mandates a second course of therapy; recurrence thereafter or inability to adequately drain the bursa with needle aspiration is an indication for surgical intervention.

PREVENTION

Because superficial septic bursitis is often associated with occasional or avocational activities involving kneeling or resting on the elbows, using protective padding may be helpful.

PROGNOSIS

The optimal duration of therapy is unknown, but prognosis of superficial bursitis is generally excellent. The presence of comorbid conditions,

especially those associated with deep bursal infections, including septic arthritis, bacteremia, and osteomyelitis, is associated with more intractable and difficult disease.

INFECTION OF JOINTS

Septic Arthritis

DEFINITION

Septic arthritis refers to infection of a joint by a microorganism. It is associated with increased morbidity and mortality, as well as loss of articular integrity and function. Septic arthritis is usually caused by a bacterial infection.[3] Other microorganisms can cause infections with clinical characteristics that differ from those of bacterial infections; these are reviewed separately.

NONGONOCOCCAL SEPTIC ARTHRITIS

EPIDEMIOLOGY

The incidence of septic arthritis affecting native joints is about 5 to 8 in 100,000 patient years. Among patients presenting with an acutely swollen and painful joint, the prevalence of bacterial arthritis ranges widely, from less than 10% to as high as 27%, depending on the source population. Nongonococcal septic arthritis is the most common form of septic arthritis and is somewhat more common in men than in women.

PATHOBIOLOGY

More than 90% of cases of septic arthritis are due to staphylococci or streptococci (Table 272-1). Septic arthritis can result from direct inoculation (e.g., accidents, bites, surgery) or by extension from infected bone into an adjacent joint space. Approximately 75% of cases are due to hematogenous spread, particularly in patients with indwelling catheters and immunocompromised patients. Septic arthritis due to needle arthrocentesis (<1 in 10,000 procedures) or arthroscopy (4 cases per 1000 to 10,000 procedures) is very rare.

Bacteria causing septic arthritis produce an acute inflammatory reaction in the synovial membrane. Synovial hyperplasia and inflammatory cell immigration with the release of pro-inflammatory and cartilage-destroying cytokines and proteases result in damage to cartilage and bone. Bacterial toxins and DNA and superantigens, such as those seen in staphylococcal toxic shock syndrome, also contribute to cartilage and bone damage.

Risk factors for the development of septic arthritis include diabetes, alcoholism, cutaneous ulcers, intravenous drug use, prosthetic joints, rheumatoid arthritis, osteoarthritis, and low socioeconomic status, as well as advanced age, skin infection, indwelling intravenous catheters, cancer, and immunosuppressive therapies, including biologic response modifiers used in the management of autoimmune diseases such as rheumatoid arthritis and inflammatory bowel disease.

CLINICAL MANIFESTATIONS

Most patients with bacterial arthritis feel ill and have fever. Immunocompromised and elderly patients may not have a marked febrile response. Most cases (>80%) of septic arthritis are monoarticular; the knee is involved in more than 50% of cases. Polyarticular joint sepsis may be seen in immunocompromised patients and those with rheumatoid arthritis or systemic lupus erythematosus. Such patients frequently lack typical signs and symptoms of infection and may not appear to be particularly ill at presentation, but they may develop rapid cardiovascular decompensation. This is particularly true for patients who are taking glucocorticosteroids, other immunosuppressive agents, and biologic response modifiers, including tumor necrosis factor-α (TNF-α) inhibitors.

Patients with septic arthritis affecting nondiarthrodial joints, such as the acromioclavicular or sacroiliac joints, may have a history of intravenous drug use or may have intravenous catheters in place to treat other medical conditions. Infection of the symphysis pubis is associated with previous urinary tract surgery, pelvic malignancy, intravenous drug use, or vigorous weight-bearing physical activity, such as long-distance running, in female athletes.

A finding of microorganisms in the joint should lead to an appropriate history and physical examination to identify a source of hematogenous infection, such as cellulitis, pneumonia, or urinary tract infection. Staphylococci and β-hemolytic streptococci may enter directly through open wounds, whereas gram-negative infection may be associated with bowel or bladder disease.

DIAGNOSIS

Plain radiography should be performed to evaluate the surrounding bones and joint space and to provide a baseline for comparison after therapy is completed. Imaging modalities such as magnetic resonance imaging (MRI), CT, and plain radiography are useful to determine whether there is associated osteomyelitis and in cases of diagnostic uncertainty. Blood cultures are positive in up to 50% of patients with bacterial septic arthritis and should be obtained in all patients in whom this diagnosis is suspected.

TABLE 272-1 MICROORGANISMS RESPONSIBLE FOR ACUTE SEPTIC ARTHRITIS AND ACUTE AND CHRONIC OSTEOMYELITIS

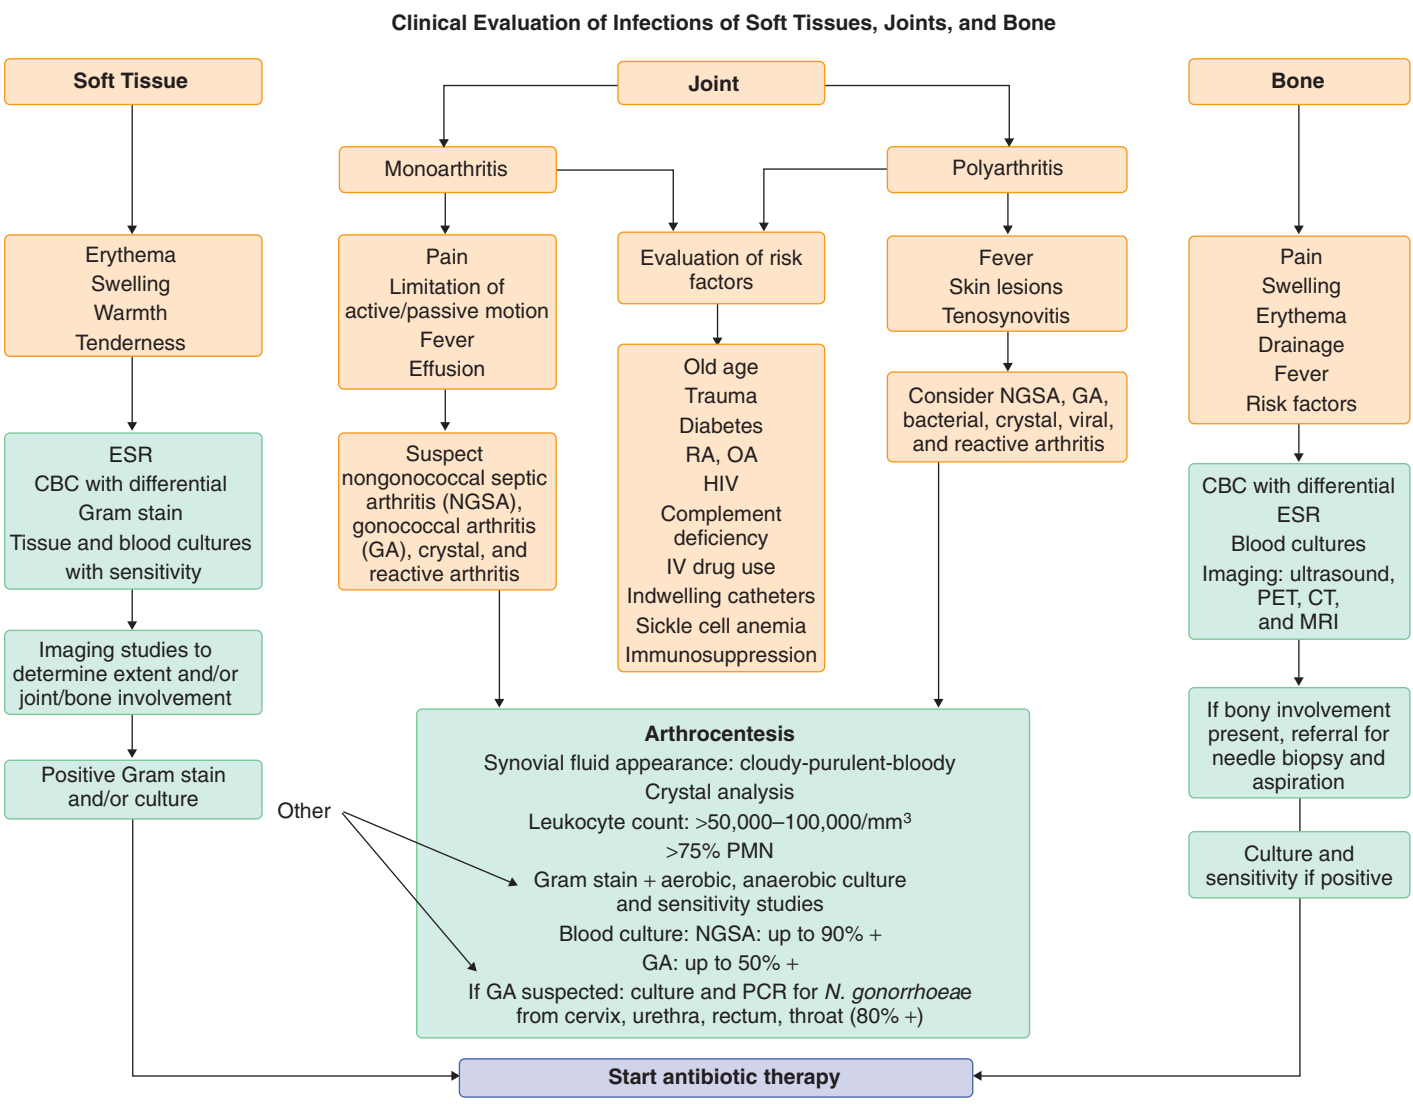

FIGURE 272-1. Clinical evaluation of infections of soft tissues, joints, and bone. CBC = complete blood count; CT = computed tomography; ESR = erythrocyte sedimentation rate; HIV = human immunodeficiency virus; IV = intravenous; MRI = magnetic resonance imaging; OA = osteoarthritis; PCR = polymerase chain reaction; PET = positron emission tomography; PMN = polymorphonuclear leukocyte; RA = rheumatoid arthritis.

If septic arthritis is suspected, synovial fluid arthrocentesis is indicated, and the fluid should be examined for bacterial culture and Gram stain; the latter is positive in only about 50% of patients. Specific cultures and stains for fungal and mycobacterial organisms should be done if there is a history of exposure or if antibacterial therapy has failed. Polymerase chain reaction (PCR) assays may be helpful for diagnosing less common joint infections such as *Borrelia,* but the value of PCR over standard culture for the diagnosis of staphylococcal or streptococcal joint infection has not yet been demonstrated. Other helpful examinations include leukocyte count and differential, as well as evaluation of the synovial fluid for the presence of crystals. The presence of gout or pseudogout crystals does not exclude the possibility of septic arthritis, particularly in patients whose WBC is above 50,000/mm^3.

A frequent clinical scenario is the patient who is anticoagulated. Because of the rapidly destructive nature of septic arthritis and the often profound systemic consequences, anticoagulation is not a contraindication to arthrocentesis. The procedure may be assisted by ultrasound guidance, especially when only small amounts of joint fluid are present or when the joint is difficult to aspirate. CT-guided arthrocentesis is particularly useful for aspiration of deep joints such as the hips and nondiarthrodial joints.

The total WBC and differential in synovial fluid are helpful in distinguishing infected from noninfected joints in immunocompetent patients. A diagnosis of septic arthritis is present in 47% of patients with a synovial WBC greater than 50,000/mm^3 and in 77% of patients with a WBC greater than 100,000/mm^3. It is important to realize that a WBC less than 50,000/mm^3, especially in immunocompromised patients, can be associated with septic arthritis, so the absolute WBC in synovial fluid is not, by itself, a reliable way to confirm or exclude a diagnosis of septic arthritis.

Differential Diagnosis

Symptoms of septic arthritis, such as acute joint pain, swelling, and even fever, with an increase in acute phase reactants, can be caused by crystalline arthritis (Chapter 273), especially pseudogout and gout, as well as psoriatic arthritis and reactive arthritis (Chapter 265). In patients who have preexisting inflammatory joint disease, such as rheumatoid arthritis, septic arthritis may be suspected if there is a sudden onset of acute or subacute monoarticular or pauciarticular joint swelling when the disease is otherwise well controlled. The presence or absence of fever is not a reliable indicator of an infected joint (Fig. 272-1).

TREATMENT

Rx

As soon as the joint has been aspirated and, ideally, after blood cultures have been obtained, prompt treatment with antibiotics must be instituted. Removal of purulent material and, where appropriate, débridement are essential. The choice of empirical antimicrobial therapy is based on which organisms are thought to be the likely cause of the septic arthritis and on the results of Gram stain and culture. No advantage of one antibiotic regimen over another has been demonstrated. If the initial Gram stain of the synovial fluid reveals gram-positive cocci, vancomycin is recommended, given the increasing frequency of infection due to MRSA and the need to initiate effective

antimicrobial therapy as soon as possible. Daptomycin and linezolid are alternative agents. If the initial Gram stain reveals gram-negative bacilli, an agent with broad coverage, including activity against *Pseudomonas aeruginosa,* is recommended. Such agents include ceftazidime, cefepime, imipenem, meropenem, piperacillin-tazobactam, and intravenous ciprofloxacin. If the Gram stain is negative, vancomycin alone in immunocompetent patients or in those unlikely to have gram-negative infection based on history and examination, or vancomycin plus one of the gram-negative antibacterials listed, is reasonable. Once culture and in vitro susceptibility results are available, therapy can be modified. The duration of antibacterial therapy usually ranges from 2 to 6 weeks.

The role of arthroscopic versus needle versus open drainage of the joint remains unsettled. Surgical management is appropriate for septic arthritis of the hip, for patients who fail to respond to serial needle aspiration and antibiotic therapy, and for patients who appear to be developing life-threatening complications such as necrotizing fasciitis. No studies have demonstrated the utility of lavage with or without synovectomy by arthroscopy versus arthrotomy or débridement. Patients should be mobilized as rapidly as possible to prevent joint contractures. In children, concomitant oral dexamethasone for 4 days can lead to more rapid symptomatic improvements.

PREVENTION

In patients requiring immunosuppression or glucocorticosteroid therapy to manage their underlying diseases, every effort should be made to use the lowest possible dose of these medications.

PROGNOSIS

Up to one third of patients with septic arthritis have a poor functional outcome, particularly older patients, patients with preexisting diseases of the joints such as osteoarthritis or rheumatoid arthritis, and patients with prosthetic joints. Poor joint outcome is associated with *S. aureus* infection in more than 50% of patients; mortality may be as high as 10 to 15%, particularly in patients who are immunocompromised or have polyarticular sepsis.

GONOCOCCAL SEPTIC ARTHRITIS

EPIDEMIOLOGY

Neisseria gonorrhoeae (Chapter 299) is a common cause of polyarthralgias and arthritis as well as oligoarticular arthritis and tenosynovitis in young, healthy patients. Disseminated gonococcal infection occurs in 0.5 to 3% of patients with gonorrhea (Chapter 299). Many of these patients have arthritis. Disseminated gonococcal infection and septic arthritis due to *N. gonorrhoeae* occur two to three times more often in women than in men. Most patients do not have a recent history of a symptomatic genital infection. The incidence of gonococcal arthritis is 133 cases per 100,000 population per year. Predisposing factors for disseminated gonococcal infection with arthritis include pregnancy, recent menstruation, complement deficiencies (C5, C6, C7, or C8), and systemic lupus erythematosus.

CLINICAL MANIFESTATIONS

Patients with gonococcal arthritis usually present with one of two clinical syndromes. The first is a purulent arthritis without skin lesions; the second is the triad of tenosynovitis, dermatitis, and polyarthralgias without purulent arthritis. The latter patients may have bacteremia and fever as well as maculopapular, vesicular, necrotic, pustular skin lesions anywhere on the integument. The arthritis is usually asymmetrical and may involve large or small joints, typically the elbows and knees or joints distal to these.

DIAGNOSIS

A high degree of clinical suspicion is required for diagnosis because many patients are asymptomatic for the primary infection. A thorough joint evaluation is important, as is an evaluation of soft tissues, particularly for tenosynovitis affecting the hands and feet. Cultures of blood, endocervix, and urethra are essential; cultures of the pharynx and rectum may be very helpful. *N. gonorrhoeae* is isolated in less than 30% of patients with the tenosynovitis-dermatitis syndrome and in about 50% of those with monoarthritis. PCR may be used to detect the gonococcal DNA in synovial fluid, skin lesions, urine, and throat samples, which are culture negative. Cultures should be submitted on Thayer-Martin media. Patients with suspected gonococcal arthritis should be screened for other coexisting sexually transmitted diseases (Chapter 285) such as syphilis, HIV, and chlamydia, as well as hepatitis B and C.

TREATMENT

Rx

Ceftriaxone is given for 2 to 4 days, followed by oral therapy to complete a minimum of 7 days of therapy, although up to 14 days of therapy is recommended. There is emerging resistance to fluoroquinolones, and unless specific in vitro susceptibility testing is available, their use is not recommended. Patients should also be treated for concomitant chlamydia with the regimens recommended by the Centers for Disease Control and Prevention (CDC). Most patients respond well to outpatient therapy, with complete resolution of the infection. Given emerging antimicrobial resistance, the most recent CDC guidelines for treating *N. gonorrhoeae* should be reviewed.

Viral Arthritis

Patients with viral syndromes may have polyarthralgias or inflammatory polyarthritis, which can mimic rheumatoid arthritis (Chapter 264). The most common viral infections associated with arthritis include hepatitis A, B, and C; cytomegalovirus; parvovirus B19; rubella; measles; and HIV. Other forms of viral arthritis are caused by adenovirus, echovirus, Epstein-Barr virus, and herpes zoster in North America and Europe; chikungunya and o'nyong-nyong viruses, especially in Africa; and Ross River virus in Australia. Chikungunya virus, which can cause severe bone and joint pain, has spread to the Caribbean basin and mainland United States.[4] Arthritis related to viral infections is likely principally reactive in nature, rather than being caused by direct synovial infection.

Other Forms of Infectious Arthritis

FUNGAL ARTHRITIS

Fungal arthritis is unusual and most commonly occurs in immunocompromised patients. Treatment with high doses of immunosuppressants, anti-TNF agents, and possibly other biologic response modifiers used in the treatment of rheumatoid arthritis and other autoimmune diseases may increase the risk for fungal infections. The infections are often systemic and may be indolent. An understanding of the epidemiology of the organisms as well as the patient's risk factors, including occupational and avocational risk factors, is essential to the diagnosis. The most common fungi in the United States include *Blastomyces dermatitidis*, *Coccidioides immitis,* and *Histoplasma capsulatum*. *Sporothrix schenckii* fungal infections may be seen, especially in gardeners. More unusual infections occur in immunocompromised patients, including *Aspergillus, Candida, Cryptococcus,* and *Nocardia.* The reader is referred to the specific chapters regarding these organisms for up-to-date antimicrobial recommendations.

LYME ARTHRITIS

Lyme disease (Chapter 321) usually causes oligoarticular arthritis, most commonly affecting the knee. Antibiotic treatment, as outlined in Chapter 321, is effective. Polyarticular disease affecting the small joints has been associated with HLA-DR4, which is found in greater frequency in patients with rheumatoid arthritis.

MYCOPLASMA ARTHRITIS

Mycoplasma hominis (Chapter 317) causes an oligoarticular or monoarticular arthritis. Risk factors include an immunocompromised state and hypogammaglobulinemia. The treatment of choice is tetracyclines, usually doxycycline; alternatively, clindamycin or fluoroquinolones can be used.

TUBERCULOUS ARTHRITIS

Most cases of tuberculosis (TB; Chapter 324) in Canada, the United States, Western Europe, Australia, and New Zealand occur in immigrants. The arthritis is usually monoarticular or oligoarticular, affecting larger joints, and TB should be suspected in patients who have refractory monoarticular or pauciarticular arthritis thought to be secondary to another bacterial infection or to a systemic inflammatory disease such as rheumatoid arthritis. TB screening is mandatory for all patients before beginning treatment with immunosuppressive drugs or biologic response modifiers.

The diagnosis of TB may be delayed because of a lack of suspicion because patients may not have pulmonary disease. Atypical mycobacterial infection may occur in fishermen and immunocompromised patients. Appropriate treatment for septic arthritis due to TB is based on guidelines and in vitro susceptibility testing, but it often includes isoniazid, ethambutol, or rifampin

and pyrazinamide as empirical therapy (Chapter 324). Atypical mycobacteria are often not susceptible to traditional antituberculous agents, and infectious disease consultation is recommended. Patients with a history of TB in whom anti-TNF therapies are being considered should be appropriately treated for TB before these drugs are started. Patients with a positive purified protein derivative (PPD) test or QuantIFERON assay for TB without a history of diagnosed tuberculosis should be treated prophylactically for several months before starting anti-TNF therapy. Clinical suspicion and culture of synovial fluid or synovial membrane obtained at biopsy are essential to the diagnosis.

SYPHILIS

Musculoskeletal involvement by syphilis (Chapter 319) is manifold in its manifestations and includes monoarticular or oligoarticular arthritis, polyarthralgias, tenosynovitis, sacroiliitis, spondylitis, chondritis, osteitis, and periostitis. Charcot's joints, osteitis, and chronic arthritis are typical of tertiary syphilis. Most patients with syphilis-related arthritis can be treated successfully. Arthritis may complicate congenital, secondary, and tertiary syphilis.

PROSTHETIC JOINT INFECTION

More than 1 million joint replacements (Chapter 276) are done each year in the United States, and this number continues to increase. Infection occurs in 0.3 to 1.7% of hip arthroplasties and 0.8 to 1.9% of knee arthroplasties, and the infection risk is two- to three-fold higher in patients with rheumatoid arthritis. Prosthetic joint infections are classified as (1) early infections, occurring within 3 months of joint replacement; (2) delayed infections, occurring 3 months to about 1 year after joint replacement; and (3) late infections, occurring more than 1 to 2 years after joint replacement.[5-7] Infections occurring within the first year are usually related to the implantation surgery itself, and late infections are usually due to hematogenous spread.

The development of a bacterial biofilm on the prosthetic joint is characteristic of prosthetic joint infection, increasing the susceptibility to infection in experimental animal models with as few as 100 colony-forming units. These biofilms are formed by bacterial glycocalyx, which increases the organisms' resistance to antimicrobial agents and likely accounts for the difficulty in obtaining viable organisms from the infected joint. More than half of all prosthetic joint infections of hips and knees are caused by staphylococci. Other organisms, including gram-negative bacilli, anaerobes, and *Candida* species, may also cause infection. In particular, *Propionibacterium* species are associated with infected shoulder arthroplasties. About 20% of cases are polymicrobial, and in 7%, cultures are negative.

Risk factors associated with the development of prosthetic joint infection include wound healing complications, prior superficial surgical site infection, prior infection of the joint, previous surgery on the joint, rheumatoid arthritis, advanced age, obesity, smoking, cancer, and diabetes mellitus. Other risk factors include simultaneous bilateral arthroplasty, prolonged operative time, requirement for blood transfusion, and infection occurring elsewhere in the body that can hematogenously seed the prosthesis.

Patients with early-onset infection may have classic symptoms and signs of septic arthritis, including joint pain, effusion, erythema, and fever. Patients with delayed infection may have only joint pain, with or without implant loosening, requiring a high degree of suspicion for the presence of infection.

The definitive diagnosis of prosthetic joint infection is based on the recovery of organisms from multiple specimens of synovial fluid and periprosthetic tissue, sonication of the prosthesis itself, acute inflammation suggestive of infection on pathologic examination of periprosthetic tissue obtained at surgery, or the presence of a sinus track communicating with the prosthesis, even in the absence of microorganisms.

An elevated sedimentation rate or C-reactive protein without another obvious cause, such as inflammatory arthritis or recent surgery, is very suggestive of infection in a patient with a painful, loose prosthesis. Plain radiographs may show loosening, new bone formation, and lucencies along the implant margin but are often nonspecific. Technetium-based scintigraphy combined with indium-labeled white blood cell scanning is suggestive of established infection but is often not performed owing to the expense. MRI and CT have low utility in diagnosing prosthetic joint infection.

Surgical treatment of prosthetic joint infection typically consists of débridement with retention of the prosthesis for acute infection, resection arthroplasty with or without staged reimplantation for chronic infection, or amputation in a few limited instances. Systemic antibiotic therapy in a patient with a prosthetic joint infection is pathogen directed and driven by the surgical therapy used to manage the infection. Following an attempt at salvage of the prosthesis with 2 to 6 weeks of effective intravenous antibiotic therapy, chronic suppressive therapy with oral antimicrobial agents is often used. In rifampin-susceptible staphylococcal infections, its addition to a companion intravenous or oral antimicrobial is recommended to avoid the emergence of resistance, to treat biofilm organisms, and to improve the chance of salvaging the prosthesis. After resection arthroplasty, 4 to 6 weeks of pathogen-directed intravenous therapy is typical before an attempt at reimplantation several weeks later. The use of depot local antimicrobial therapy with antibiotic-impregnated polymethylmethacrylate spacers following resection arthroplasty is also very common. The reader is referred to recently released guidelines for more specific information on the diagnosis and management of prosthetic joint infection (Infectious Diseases Society of America guidelines).

PREVENTION

In addition to optimizing comorbidities such as diabetes mellitus and discontinuing tobacco use preoperatively, careful screening for infection, including asymptomatic urinary tract infection, is prudent when considering joint surgery. Perioperative antibiotic treatment with cephalosporin in patients undergoing prosthetic joint replacement reduces the risk for infection by approximately three-fold. Antimicrobial therapy should be given within 60 minutes of the initial incision, ideally before tourniquet application. Cefazolin or cefuroxime can be given to patients with normal renal function, and vancomycin can be used in patients who are allergic to penicillin.

Whether an antirheumatic agent should be stopped before joint replacement surgery is unclear. The usual practice is to hold drugs such as methotrexate, anti-TNF agents, and other biologics including abatacept and tocilizumab for one to four half-lives before and after surgery. No guidelines exist for tofacitinib or anakinra, but similar suggestions may be helpful. It may be prudent to wait at least 8 to 12 weeks after rituximab therapy for rheumatoid arthritis before performing elective joint replacement; it is unclear whether B-cell reconstitution plays a role in surgical infection risk. The impact of these strategies on reducing prosthetic joint infections is unknown.

OSTEOMYELITIS

DEFINITION

Osteomyelitis is a bacterial infection of bone that causes destruction and can occur through a variety of mechanisms.[8,9]

EPIDEMIOLOGY

Osteomyelitis of the bones of the foot in adult patients with diabetes, neuropathy, and arterial insufficiency is very common. Management of osteomyelitis in diabetic feet is discussed in updates for Chapter 229. Hematogenous seeding of the spine also occurs but less frequently. The incidence of osteomyelitis due to trauma and surgery is increasing.

PATHOBIOLOGY

Osteomyelitis can develop from (1) hematogenous seeding from a distant infection, (2) contiguous spread from nearby skin and joints, and (3) penetration of microorganisms into bone at the time of trauma or surgery. Unless there is trauma or the presence of a foreign body, bone is typically very resistant to infection. Organisms such as *S. aureus* cause disease more frequently because they colonize the skin in up to 30 to 40% of individuals, frequently cause cellulitis and bacteremia, and have the ability to bind to bone through the expression of receptors for fibronectin and collagen.

Hematogenous causes of osteomyelitis typically present in elderly people; it usually involves two or more vertebrae and their intervening disc spaces. Bacteria gain access to these structures through the arterial and venous systems (Batson's venous plexus). Bacteremia from any source can cause osteomyelitis of the spine, but cellulitis, urinary tract infection, and pneumonia are the most common sources.

Contiguous focus osteomyelitis is common in adults, typically occurring in elderly people. It results from the spread of infection from nearby skin, often in the feet of patients with diabetes, neuropathy, or vascular insufficiency, or in pelvic bones in patients with decubitus due to impaired sensation from spinal cord injury or disease. Alternatively, it can occur at the time of orthopedic surgery, from contamination at the time of an open fracture, or from a human or animal bite.

Acute osteomyelitis has a duration of less than 10 days, whereas chronic infection has a duration of more than 10 days. *S. aureus* is the most common cause of hematogenous and contiguous osteomyelitis in adults.

Osteomyelitis due to β-hemolytic streptococci and aerobic gram-negative bacilli is much less common, but it can occur if infections due to these organisms result in hematogenous seeding, if nosocomial contiguous osteomyelitis occurs due to surgical site infection, or if contamination occurs at the time of traumatic open fracture. Polymicrobial infection, including infection due to anaerobes, is very common in osteomyelitis of the bones of the feet associated with diabetes and vascular insufficiency. Coagulase-negative staphylococci can be pathogenic in patients with orthopedic implants.

CLINICAL MANIFESTATIONS

Localized pain over the affected bones is a hallmark of osteomyelitis. A sinus tract or swelling and erythema due to concomitant soft tissue infection or abscess may be present in osteomyelitis due to contiguous infection. Constitutional symptoms, including fever, are present in the minority of cases and more often in hematogenous osteomyelitis. If neurologic structures are involved, neurologic signs and symptoms may be present. Signs and symptoms due to a coexisting infection that has caused hematogenous osteomyelitis may be present as well. The differential diagnosis of osteomyelitis includes diseases that can cause acute and chronic bone pain in adults, including osteoarthritis, metastatic malignancy, fractures, and SAPHO (synovitis, acne, pustulosis, hyperostosis, and osteitis) syndrome, as well as postoperative pain and soft tissue infection without concomitant osteomyelitis.

DIAGNOSIS

The WBC is often elevated in hematogenous and acute osteomyelitis. Serum inflammatory markers such as the sedimentation rate and C-reactive protein are often abnormal, particularly in cases of hematogenous infection, but may be normal in chronic contiguous osteomyelitis. Blood cultures are positive in 25 to 50% of cases of hematogenous infection but are almost always negative in chronic osteomyelitis unless concomitant soft tissue infection is present. In the setting of chronic contiguous osteomyelitis, plain radiographs often show specific abnormalities; in vertebral osteomyelitis, they are often not helpful in confirming the diagnosis of infection.

The ability to percutaneously probe or palpate bone with a probe is a simple, effective diagnostic test in patients with diabetes mellitus and possible contiguous osteomyelitis of the feet. In one prospective study, the ability to palpate bone through a contiguous ulcer had a sensitivity of 66% and a specificity of 85% for osteomyelitis.

MRI is the most sensitive and diagnostic imaging technique to identify osteomyelitis, except when orthopedic implants are present. Gallium scans are more sensitive and specific than three-phase technetium (^{99m}Tc) bone scans or indium-labeled leukocyte scans for the diagnosis of vertebral osteomyelitis. Gallium scans are used when spinal hardware is present that degrades the magnetic resonance images and in cases of skull bone osteomyelitis due to malignant external otitis.

Multiple specimens of involved bone, contiguous soft tissue, and purulence should be sent for Gram stain, aerobic and anaerobic culture, and pathologic examination at the time of bone biopsy or surgical débridement. If the history, examination, or imaging is suggestive of atypical infection, culture for fungi and mycobacteria or other unusual organisms should be performed.

TREATMENT

Rx

There are no large randomized studies comparing antimicrobial therapy for osteomyelitis.[A1] Antimicrobials for specific pathogens based on in vitro susceptibility testing are recommended, and examples of antimicrobials used to treat common pathogens causing osteomyelitis and septic arthritis are shown in Table 272-2. Oral antibiotics can achieve adequate levels in bone, and oral and parenteral therapies may achieve similar cure rates in some cases.

The duration of antimicrobial therapy is almost always dictated by surgical therapy in chronic osteomyelitis. For example, if an amputation is performed, a short course of antimicrobial therapy may be required, whereas if an extensive débridement of chronic osteomyelitis is performed, prolonged intravenous antimicrobial therapy for 4 to 6 weeks is typically recommended. If the surgical therapy could lead to a worse outcome than no surgery, chronic oral antimicrobial suppression may be recommended. Acute hematogenous vertebral osteomyelitis in adults is typically treated with 6 weeks of intravenous antimicrobial therapy, without surgical intervention, after identification of the pathogen through percutaneous or open biopsy. Hyperbaric oxygen therapy for chronic osteomyelitis is controversial.

TABLE 272-2 ANTIMICROBIAL THERAPY FOR SELECTED MICROORGANISMS IN OSTEOMYELITIS OR SEPTIC ARTHRITIS IN ADULTS

MICROORGANISM	FIRST CHOICE*	ALTERNATIVE CHOICE
Methicillin/oxacillin/nafcillin-sensitive staphylococci	Nafcillin sodium or oxacillin sodium 1.5-2 g IV q4-6h for 4-6 wk *or* cefazolin 1-2 g IV q8h	Vancomycin 15 mg/kg IV q12h for 4-6 wk
Methicillin/oxacillin/nafcillin-resistant staphylococci (MRSA)	Vancomycin† 15 mg/kg IV q12h *or* daptomycin 6 mg/kg IV q24h	Linezolid 600 mg PO/IV q12h *or* levofloxacin† 500-750 mg PO/IV daily
Penicillin-sensitive streptococci	Aqueous penicillin G 20 × 10^6 U/24 hr IV either continuously or in 6 equally divided daily doses *or* ceftriaxone 1-2 g IV q24h *or* cefazolin 1-2 g IV q8h	Vancomycin 15 mg/kg IV q12h
Enterococci	Aqueous crystalline penicillin G 20 × 10^6 U/24 hr IV either continuously or in 6 equally divided daily doses *or* ampicillin sodium 12 g/24 hr IV either continuously or in 6 equally divided daily doses; the addition of gentamicin sulfate 1 mg/kg IV or IM q8h for 1-2 wk is *optional*	Vancomycin† 15 mg/kg IV q12h; the addition of gentamicin sulfate 1 mg/kg IV or IM q8h for 1-2 wk is *optional*
Enterobacteriaceae	Ceftriaxone 2 g IV q24h	Ciprofloxacin† 500-750 mg PO q12h
Pseudomonas aeruginosa	Cefepime 2 g IV q8-12h	Ciprofloxacin† 750 mg PO q12h or ceftazidime 2 g IV q8h

*Antimicrobial selection should be based on in vitro sensitivity data, as well as allergies, intolerances, and drug interactions in individual patients.
†Doses shown are based on normal renal and hepatic function and may need to be adjusted or serum levels monitored (vancomycin).
MRSA = methicillin-resistant *Staphylococcus aureus.*
Adapted from Berbari EF, Steckelberg JM, Osmon DR. Osteomyelitis. In: Mandell GL, Bennett JE, Dolin R, eds. *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases,* 7th ed. Philadelphia: Churchill Livingstone/Elsevier; 2010:1457-1467.

PREVENTION

Improving the control of diabetes and decreasing the incidence of peripheral vascular disease will reduce the incidence of diabetic foot bone infection. Optimal strategies to prevent surgical site infection after orthopedic procedures will prevent orthopedic implant infection after surgery and open fractures.

PROGNOSIS

The success of osteomyelitis management depends on the medical and surgical therapy employed and the ability to improve comorbidities such as arterial insufficiency. The ability of orthopedic surgeons to perform more extensive reconstructive surgery has allowed more extensive débridement and higher success rates, as well as restoration of function. Treatment failure can lead to relapse of infection or progression of infection to involve more of the affected bone. Long-standing osteomyelitis can be complicated by amyloidosis, squamous cell carcinoma of the skin in a chronic sinus tract, or primary bone malignancy.

REVIEW QUESTIONS

1. A 55-year-old man with a history of diabetes has had a chronic ulcer over the fifth metatarsal head with some swelling and pain for the past 5 weeks, following what he though was a minor trauma. On examination, bone can be palpated with a probe. Which of the following is most likely?

A. The white blood cell count is elevated.
B. There is a high probability that the patient has osteomyelitis.
C. The best imaging test to define the cause of the pain is a gallium scan.
D. The best imaging test to define the cause if the pain is plain bone radiography.
E. The most likely cause of a possible infection is *Fusobacterium* species infection.

Answer: B The ability to palpate bone by probing the overlying ulcer is highly suggestive of osteomyelitis. Patients with contiguous chronic osteomyelitis often have normal white blood cell counts and are often afebrile. Magnetic resonance imaging is the best (most sensitive) radiographic technique for demonstrating bone damage consistent with osteomyelitis. Overall, *Staphylococcus aureus* is the most common cause of osteomyelitis, but in patients with diabetic foot bone osteomyelitis, the infection is often polymicrobial (see Table 280-1).

2. A 32-year-old carpet layer presents with a 3-day history of swelling of the right knee. The father and grandfather of the patient developed gout as young men. The patient had a single episode of right toe pain and swelling 3 months earlier, which he attributed to "kicking carpet into place." He has a temperature of 38.7° C. Examination of the right knee reveals erythema and swelling, most prominently over the anterior aspect of the knee, but extending around the soft tissues about the knee. With some pain, he is able to completely extend the knee, although he cannot comfortably flex it beyond 80 degrees. The prepatellar bursa is aspirated. The white blood cell count is 750. Which of the following is correct?

A. The knee joint should also be aspirated and joint fluid sent for culture and sensitivity.
B. The low white blood cell count in the bursal fluid makes it unlikely that the bursa is infected.
C. Gram stain examination of the bursal fluid will almost always guide therapy.
D. Urate crystals will not be found on microscopic examination.
E. A magnetic resonance imaging (MRI) study must be obtained to rule out osteomyelitis.

Answer: B This patient has prepatellar bursitis, which is usually due to direct tissue invasion, in this case likely related to local tissue invasion in the setting of chronic soft tissue trauma associated with kneeling and local friction of the overlying skin. Bursal fluid is often unobtainable, but if it can be obtained, the white blood cell count in the aspirated bursal fluid in the setting of septic bursitis is generally low compared with the WBC count in septic arthritis, on average 13,500 cells in the bursal fluid. Gram stain is positive in only about 15% of cases of septic bursitis. Urate crystals may be seen in cases of gouty bursitis, which can occur concomitantly, but should not distract from the possibility of septic bursitis. MRI is the most sensitive imaging technique to evaluate osteomyelitis in routine clinical practice, but there is nothing in this case to cause suspicion of bone infection.

3. Which of the following is true regarding septic arthritis?

A. Most cases are due to direct inoculation of the joint from trauma or surgical procedures such as arthrocentesis.
B. Gonococcal arthritis is the most common form of septic arthritis in persons aged 20 to 40 years.
C. Hematogenous spread of tuberculosis is the most common cause of septic arthritis in persons from developing countries immigrating to Western countries of Europe, North American, and Australia.
D. Blood cultures are frequently positive in septic arthritis.
E. Intravenous vancomycin and daptomycin are the mainstays of treatment for most cases of septic arthritis in the immunocompetent host in the current era of multiple antibiotic resistance.

Answer: D About 75% of cases of septic arthritis are due to hematogenous spread, including surgical instrumentation. Although gonococcal arthritis must be considered in sexually active patients, 50 to 70% of cases of septic arthritis are due to *Staphylococcus aureus.* Although almost all cases of septic tuberculous arthritis in Western countries occur in immigrants from developing countries, most cases of septic arthritis in these patients are still due to nontuberculous bacteria. Blood cultures should always be obtained in persons with septic arthritis. They are positive in up to 50% of cases, even in cases when the joint aspirate fails to microscopically reveal the causative organism. Although multiple antimicrobial resistance is a serious problem, most cases of uncomplicated septic arthritis in the otherwise healthy host can be managed with an oral antistaphylococcal penicillin or first-generation cephalosporin.

4. A 76-year-old man with a history of osteoarthritis arthritis and total joint replacement of the right hip at the age of 70 years presents with a 2-day history of right groin pain and temperature to 39.5° C 3 days after finishing a 1-week course of levofloxacin for an infected ingrown toenail. He is allergic to penicillins. Empirical antibiotic therapy with vancomycin for presumed staphylococcal prosthetic joint infection is started. The synovial fluid aspirate from the prosthetic right hip is negative, but blood cultures reveal *S. aureus*, methicillin resistant. His prosthesis was not loose on plain-film examination. Which of the following is true regarding prosthetic infections in this patient?

A. A biofilm with polymicrobial bacterial colony-forming units is frequently present, complicating eradication of the organism. Explantation of the prosthesis is always needed in such cases.
B. The most appropriate antimicrobial therapy in this case would be linezolid 600 mg PO/IV every 12 hours.
C. Risk factors for prosthetic joint infection *include* wound healing complications, prior superficial surgical site infection, prior infection of the joint, osteoarthritis, and diabetes mellitus.
D. Because of the occurrence of prosthetic infection in this patient following hematogenous spread of the causative bacterium, the best course of action would be explantation of the prosthesis at this time, followed by 4 to 6 weeks of antibiotic therapy without reimplantation.
E. The best course of action would be to attempt salvage of the prosthesis with débridement and retention and 2 to 6 weeks of effective intravenous antibiotic therapy and rifampin based on the recently published Infectious Diseases Society of America Prosthetic Joint Infection guidelines (Osmon DR. Berbari EF, Berendt AR. et al. Infectious Diseases Society of America. Diagnosis and management of prosthetic joint infection: clinical practice guidelines by the Infectious Diseases Society of America. *Clin Infect Dis.* 2013;56:e1-e25), followed by chronic suppressive therapy with oral antimicrobial agents.

Answer: E Biofilms are often found in explanted infected prosthesis and complicate successful antimicrobial therapy. These biofilms are polymicrobial in about 20% of cases. Risk factors for prosthesis infection include rheumatoid arthritis, but not osteoarthritis. In most cases of acute infection, management efforts are directed toward treating the infection and attempting to salvage the prosthesis. When resection arthroplasty is needed, 4 to 6 weeks of pathogen-directed intravenous therapy is typical before an attempt at reimplantation several weeks later.

5. A 68-year-old woman with a history of chronic atrial fibrillation and diabetic neuropathy presents with a 5-day history of subacute swelling and pain in the left ankle. She reports that she "turned" her ankle while gardening about a week ago. Her temperature is 36.7° C. Inspection of the ankle reveals moderate erythema and swelling. The skin is intact; sensation to touch is diminished in both feet. The remaining history and physical examination are unrevealing, including examination of the oral cavity. The sedimentation rate is 42 mm/hour; white blood cell count is 9800 mm^3, and INR is 3.2. Which of the following strategies should be pursued in management of this patient?

A. Blood cultures and empirical therapy with vancomycin 15 mg/kg every 12 hours or daptomycin 6 mg/kg/IV every 24 hours for presumed methicillin-resistant *Staphylococcus aureus* (MRSA). Avoid arthrocentesis because of the elevated INR and risk for worsening joint damage due to hemarthrosis and the danger of hematogenous spread of the infection.

B. Blood cultures, empirical therapy with vancomycin 15 mg/kg every 12 hours or daptomycin 6 mg/kg/IV every 24 hours for presumed MRSA, and arthrocentesis for examination of synovial fluid Gram stain and culture

C. Blood cultures, empirical therapy with aqueous crystalline penicillin G 20×10^6 U every 24 hours IV either continuously or in six equally divided daily doses *or* ampicillin sodium 12 g every 24 hours IV either continuously or in six equally divided daily doses. Avoid arthrocentesis because of the elevated INR and risk for worsening joint damage due to hemarthrosis and the danger of hematogenous spread of the infection.

D. Blood cultures, empirical therapy with aqueous crystalline penicillin G 20×10^6 U every 24 hours IV either continuously or in six equally divided daily doses *or* ampicillin sodium 12 g every 24 hours IV either continuously or in six equally divided daily doses, and arthrocentesis for examination of synovial fluid Gram stain and culture

Answer: B A source of infection was not identified in this patient, who has risk factors for septic arthritis of diabetes mellitus and diabetic neuropathy. Because even in these cases the most common cause of septic arthritis is gram-positive cocci, particularly *Staphylococcus aureus*, initial treatment directed at this organism is appropriate. It is not unreasonable to initiate therapy with an MRSA-appropriate regimen. Arthrocentesis should always be performed if there is suspicion of septic arthritis; bleeding complications, even in patients on anticoagulation, are rare, and the information potentially gained generally justifies the risk for the procedure.

273 CRYSTAL DEPOSITION DISEASES

N. LAWRENCE EDWARDS

The destructive potential of intrasynovial crystals has been recognized for more than a century. The mechanisms by which certain crystals induce inflammation and joint destruction have become much better clarified over the past several decades. The three most common crystal-induced arthropathies are caused by precipitation of monosodium urate monohydrate (MSU), calcium pyrophosphate dehydrate (CPPD), and basic calcium phosphate (BCP) and are termed *gout, CPPD arthropathy,* and *basic calcium arthropathy*, respectively.

At the turn of the 20th century, Wilhelm His and Max Freudweiler at the University of Leipzig proved that MSU crystals could induce inflammation when injected into normal joints. In 1961, Daniel McCarty and Joseph Hollander developed a way of identifying MSU crystals in synovial fluid using compensated polarized light microscopy. This technique also allowed for distinguishing MSU crystals from the other "phlogystic" crystals such as CPPD and BCP.

The role of calcium-containing crystals in cartilage pathology and joint disease was first suggested in serial radiographs by Zitnan and Sitaj that showed accretion of calcific deposits in articular cartilage leading to accelerated joint destruction. The nature and structure of CPPD crystals in inflamed synovial fluid was first described by McCarty and collaborators in 1962. This group also established the term *pseudogout* to describe this common crystalline arthropathy.

Basic calcium crystals are ultra-microscopic in size and are not detected by the compensated polarized microscopy used to identify MSU and CPPD crystals. Paul Dieppe and Ralph Schumacher independently identified these very small crystals in synovial fluid using electron microscopy in the mid-1970s. Like MSU and CPPD crystals, BCP crystals are biologically active and can accelerate atrophic changes in bone and cartilage. This chapter defines these separate crystalline arthropathies and describes their different pathogeneses and treatments.

GOUT AND HYPERURICEMIA

DEFINITION

Gout is an inflammatory arthritis of metabolic origin that is caused by crystallization of MSU crystals within joints. It is the most common inflammatory joint disease in men and in older women. Its incidence and prevalence are increasing worldwide. The metabolic derangement responsible for gout is the supersaturation of blood and body fluids with the urate ion to the point that crystal formation is possible. At physiologic pH and at normal body temperature, urate is considered to be supersaturated at concentrations of 6.8 mg/dL or greater. Therefore, from a biologic perspective, hyperuricemia is any serum urate level greater than 6.8 mg/dL in both men and women. Although hyperuricemia is a necessary prerequisite for developing gout, only 20% of all hyperuricemic subjects will ultimately develop gout.

The natural course of gout progresses from an intermittent monoarthritis or oligoarthritis in the lower extremities to a chronic, destructive, and debilitating polyarthritis involving almost any peripheral joint in the body. Also considered within the definition of gout is the spectrum of clinical conditions resulting from the deposition of MSU crystals in the subcutaneous tissues and kidney manifesting as tophaceous deposits, inflammatory cellulitis, urate nephropathy, and kidney stones.

EPIDEMIOLOGY

Hyperuricemia is very common in Western cultures, with prevalence as high as 15 to 20% being reported in some more recent population-based studies.[1] This rate of hyperuricemia is more than twice that observed just three decades earlier. A number of factors have been proposed to explain this dramatic rise. These include the overall increase in longevity; the increased prevalence of hypertension, metabolic syndrome, and obesity; the ubiquitous use of thiazide diuretics and low-dose aspirin; changes in dietary trends, including the greater use of high-fructose corn syrup as a sweetener; and finally, the increase in survival of patients end-stage renal disease and organ transplantation.

There is a direct correlation between the degree of serum urate elevation and the likelihood of developing gout. The reported annual incidence of gout in subjects with baseline serum urate levels greater than or equal to 9 mg/dL is 4.9%, compared with only 0.5% in people with serum urate levels of 7.0 to 8.9 mg/dL.

Epidemiologic surveys since the 1970s demonstrate a continuous increase in the prevalence of gout. According to the most recent National Health and Nutrition Examination Survey (NHANES 2007-2009), 8.3 million adults in the United States are followed by a health care provider for gout, a prevalence of 3.9%. Men continue to make up the majority of the gout population (73%). The prevalence of gout in women has been rising at a disproportionately higher rate.

PATHOBIOLOGY

Uric acid is the end product of purine metabolism in humans. In most mammals, purine catabolism is taken one step further through the enzyme uric acid oxidase or uricase, with the purine end product in these species being the very soluble allantoin. Humans and most other hominoids lost the ability to produce the enzyme uricase nearly 18 million years ago. As a result, uric acid accumulation is possible. Whether caused by overproduction of uric acid or its underexcretion by the kidneys, this accumulation leads to supersaturation of urate ion in blood and the precipitation of MSU crystals in synovial fluid, soft tissues, and organs. Urate is produced by the conversion of a very soluble molecule, hypoxanthine, to the less soluble xanthine, which, in turn, is converted to the very insoluble uric acid by progressive purine ring oxidations catalyzed by the enzyme xanthine oxidase. Xanthine oxidase is present in several organs, but most activity in the body is found in the liver and intestines. Because of its potential for causing disease, urate elimination is very important. The total daily accumulation of uric acid from de novo synthesis, nucleotide degradation, and dietary consumption is between 800 and 1200 mg/day and is balanced by renal excretion of approximately two thirds of the total amount and intestinal elimination by the remaining one third.

Simply put, hyperuricemia occurs when urate production is not balanced by renal excretion. In 90% of all gout patients, the cause of this imbalance is renal underexcretion. The remaining 10% of gout cases are caused by purine overproduction or a combination of overproduction and underexcretion. The nongenetic causes of hyperuricemia include other medical conditions, dietary components, and medications (Table 273-1). These factors may result in either overproduction or diminished renal clearance of uric acid. Similarly, the genetic causes of hyperuricemia (Table 273-2) may affect either production or elimination of uric acid.[2]

TABLE 273-1 NONGENETIC CAUSES OF HYPERURICEMIA

IMPAIRED URIC ACID EXCRETION
Clinical Conditions
Reduced glomerular filtration rate
Hypertension
Obesity
Systemic sclerosis
Lead nephropathy
Drugs
Diuretics
Ethanol
Low-dose salicylates (0.06-3.0 g/day)
Cyclosporine
Tacrolimus
Levodopa
EXCESSIVE URIC ACID PRODUCTION
Clinical Conditions
Myeloproliferative and lymphoproliferative neoplasms
Obesity
Psoriasis
Diet and Drugs
Alcoholic beverages (especially beer)
Red meat, organ meat, shellfish
High fructose corn syrup
Cytotoxic drugs
Nicotinic acid
Pancreatic extract

Renal Urate Underexcretion

Because uric acid is small and not protein bound, it is completely filtered by the glomerulus. In normal persons, approximately 8 to 10% of the filtered load is ultimately cleared in the urine. The various renal tubular transporters that are responsible for determining how much of the filtered uric acid is actually excreted are located in the proximal convoluted tubules and are referred to collectively as the *transportasome* (Fig. 273-1). Both reabsorption and secretion occur in this segment through the actions of several organic acid transporters (OATs), with the net effect being the reabsorption of nearly 90% of the uric acid filtered at the glomerulus. These OATs are also responsible for eliminating organic acids other than uric acid as well as many commonly used medications. The most important tubular transporter of uric acid is URAT1. This transporter swaps urate ions for other monocarboxylate organic ions in both directions across the luminal membrane of proximal tubular cells. This system can be driven to reabsorb more uric acid from the tubular lumen by raising tubular epithelial concentrations of lactate, pyruvate, or the ketoacids acetoacetate and β-hydroxybutyrate. Certain drugs, when present in the tubular lumen, can displace uric acid from the transporter, causing more uric acid to be lost in the urine. These compounds include probenecid, losartan, and high-dose aspirin and are considered uricosuric.

When renal clearance of uric acid is compared between normal adult men and gouty men, the gouty subjects excrete only 70% as much uric acid as normal individuals at any given serum urate concentration. In general, gouty subjects required a serum urate concentration to be 1.7 mg/dL higher to obtain the same level of excretion as seen in normal subjects.

Most genetic polymorphisms associated with gout in genome-wide association studies encode for the various components of the uric acid transportasome. Polymorphisms in the glucose transporter GLUT-9 (encoded by the *SLC2A9* gene) are statistically the most significant determinants of serum urate. ABCG2 is a multifunctional transporter that belongs to the adenosine triphosphate (ATP)-binding cassette family found in the proximal tubule of the kidney as well as in the small intestine and liver. Polymorphisms in the *ABCG2* gene have a larger effect on urate levels in men than in women. Polymorphisms in the gene encoding URAT1 may lead to either hypouricemia or hyperuricemia. A loss-of-function mutation results in familial renal hypouricemia. Other mutations have been detected that lead to hyperuricemia and gout in Mexican, Asian, and African American populations.

The serum urate variance explained by these common genetic variants is only about 6% of the total variance observed between gouty and nongouty subjects. Similar risk-stratifying techniques demonstrate that 67% of the variance is caused by nongenetic factors such as serum creatinine, ethanol consumption, and the components of the metabolic syndrome.

TABLE 273-2 GENETIC CAUSES OF HYPERURICEMIA

SYNDROME	PHENOTYPE
INBORN ERRORS OF PURINE METABOLISM	
Hypoxanthine-guanine phosphoribosyl transferase deficiency	Neurologic dysfunction, renal stones, early-onset gout
Phosphoribosyl pyrophosphatase synthetase overactivity	Neurologic dysfunction, early-onset gout
EXCESSIVE CELL DEATH AND URATE GENERATION	
Glycogen storage disease I	Growth restriction, lactic acidosis, early-onset gout
Glycogen storage disease III	Early-onset gout
Glycogen storage disease V	Early-onset gout
Glycogen storage disease VII	Early-onset gout
Fructose-1-phosphate aldolase deficiency	Growth restriction, liver failure, early-onset gout
Myoadenylate deaminase deficiency	Myopathy, gout
Carnitine palmitoyltransferase II deficiency (late onset)	Rhabdomyolysis, gout
REDUCED RENAL EXCRETION OF URIC ACID	
Medullary cystic kidney disease	Renal dysfunction, early-onset gout
Familial juvenile hyperuricemic nephropathy	Renal dysfunction, early-onset gout
Uric acid transportasome mutations	
GLUT-9	Familial gout
ABCG2	Familial gout
URAT1	Familial gout

Urate Overproduction

In approximately 10% of gouty subjects, hyperuricemia is caused by uric acid overproduction rather than reduced renal excretion. In most of these people,

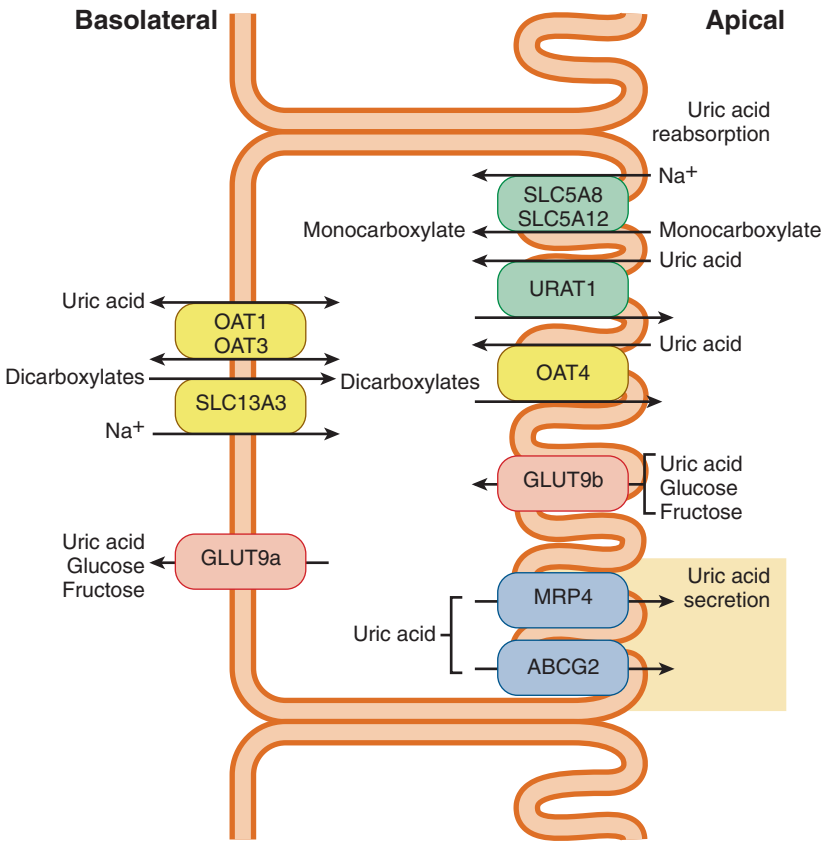

FIGURE 273-1. Renal transport of urate in proximal tubule of kidney. Serum urate reaches the tubule lumen by glomerular filtration and by secretion through the proximal tubular epithelium. Secretion of urate is facilitated in the luminal direction by MRP4, UAT, ABCG2, and NTP1, and at the basolateral membrane by OAT1 and OAT3. Reabsorption of urate from the tubular lumen is facilitated by URAT1, OAT4, OAT10, and the short isoform of GLUT (GLUT9b), and at the basolateral membrane by the long isoform (GLUT9a). ABCG2 = adenosine-triphosphate-binding cassette transporter; GLUT = glucose transporter; MRP = multidrug-resistance-related protein; NTP = sodium phosphate transport protein; OAT = organic acid transporters; URAT = uric acid transporter.

the hyperuricemia reflects accelerated cell turnover (e.g., lymphoproliferative and myeloproliferative diseases, psoriasis, chronic hemolytic states, polycythemia vera, and certain muscle glycogenoses) or other causes of enhanced purine nucleotide breakdown as seen with alcohol abuse or fructose ingestion. In addition to these secondary causes of urate overproduction, there are primary disease processes that are also responsible for urate overproduction. These are inborn errors of metabolism that result in increased de novo purine synthesis, as seen in PRPP synthetase overactivity or decreased purine salvage as seen in the complete and partial HPRT deficiencies (Lesch-Nyhan syndrome and Kelley-Seegmiller syndrome, respectively). Regardless of the cause, urate overproduction is determined by a 24-hour urine collection showing greater than 1000 mg of uric acid while eating a standard Western diet.

Pathogenesis of Monosodium Urate Monohydrate Crystals and Inflammation

MSU crystals in joints, soft tissues, and organs are the cause of pain and destruction in gout. Urate crystals will form only when physiologic conditions permit. In plasma, urate becomes insoluble at concentrations of 6.8 mg/dL (408 µmol/L) with a pH of 7.40 and normal body temperature. A reduction in pH or temperature will lower the solubility threshold even further. Not all people who are hyperuricemic will form crystals, however. There appears to be an additional requirement of a "nucleation factor" that is still poorly defined for gout and other local factors that either promote or inhibit further crystal growth.

MSU crystals form in joints and soft tissues of individuals long before they have any symptoms of gout. They deposit in small lattice structures called *microtophi* on the surface of cartilage and synovial lining. These microtophi slowly grow but are generally stable as long as the environment surrounding them does not change drastically with regard to pH, urate concentration, or temperature. At the time of the first and subsequent flares, something does change in the joint environment to cause these crystal lattice structures to break apart and shed a massive number of crystals into the joint space. These newly released and nonopsonized crystals activate receptors on synovial macrophages and are then phagocytized by monocytes and macrophages, leading to interaction with the NALP3 inflammasome. This results in the rapid production of interleukin-1 (IL-1), which is responsible for all the cardinal features of the severe inflammation associated with acute gout. The gout flare is self-limited probably as a result of a physical change in the MSU crystals after they have been repeatedly phagocytized and partially digested. A maturation of the resident monocytes in the inflamed joint also appears to help terminate the gouty flare. Even after the acute attack subsides, low-grade inflammation persists in the asymptomatic joint. It is this persistent, ongoing inflammatory process that will eventually lead to bony erosion, cartilage destruction, and synovial hypertrophy if the hyperuricemia is not treated and the MSU crystals dissolved.

CLINICAL MANIFESTATIONS

Classic Gout

The natural course of classic gout passes through three stages: asymptomatic hyperuricemia, acute intermittent gout, and chronic advanced gout.[3] The rate of progression from asymptomatic hyperuricemia to chronic advanced gout varies considerably from one person to another and is dependent on numerous factors, the most important being the degree of increase in serum urate levels.

Asymptomatic hyperuricemia[4] refers to a state in which serum urate exceeds the level of solubility (6.8 mg/dL), but symptoms of crystalline deposition have not occurred. Only 15 to 20% of all hyperuricemic people are prone to develop MSU crystals, and for this group, the period of asymptomatic hyperuricemia begins a stage of subclinical structural changes. In men, asymptomatic hyperuricemia frequently begins at puberty, whereas in women, it is usually delayed until menopause.

The initial episode of acute gout usually follows decades of asymptomatic hyperuricemia. In men, the first attack usually occurs between the fourth and sixth decades of life. In women, the age of onset is older and varies with several factors, most importantly the age of menopause. The classic acute gout attack is hallmarked by the rapid development of warmth, swelling, erythema, and exquisite pain in one or occasionally two joints. The characteristically severe pain evolves from its faintest twinge to its most intense level over an 8- to 12-hour period. Initial attacks are usually monoarticular and involve lower extremity joints. The most common joint involved is the first metatarsal phalangeal joint (termed *podagra*), followed by the ankle, midfoot, and knee (Fig. 273-2). After years of acute intermittent attacks, upper extremity joints, including the wrists, elbows, and small joints of the hands, can also become involved. Systemic symptoms of fever, chills, and malaise may accompany acute attacks, along with an intense erythema extending beyond the area of the involved joint. This may lead to confusion with a septic process.

Factors capable of provoking episodes of acute gout are those that cause fluctuations in serum urate levels, including trauma, surgery, starvation, overindulgence in certain high-purine foods, and the ingestion of any medication that raises or lowers serum urate.

The other characteristic of classic gout flares is the self-remitting nature. For the first several acute flares, the duration of the attack is 5 to 8 days. The resolution of symptoms is gradual but complete, even if no anti-inflammatory therapy is administered. The periods between the acute attacks are devoid of articular pain, although synovial fluid aspirates during this stage continue to show low-grade inflammation and the presence of MSU crystals.

Eventually, the untreated patient will progress to chronic polyarticular gout, also referred to as *advanced gout*. This stage usually develops after 10 or more years of acute intermittent gout and is evident when the pain-free intercritical periods have disappeared. Gouty flares can continue to occur against this constantly painful background. The intensity of the chronic pain is not nearly as severe as that experienced with the acute flares.

The subcutaneous tophus is the most characteristic lesion of advanced gout. The development of tophaceous deposits of MSU is a function of the duration and severity of hyperuricemia. Subcutaneous tophi may occur anywhere over the body but most commonly in the fingers, wrists, ears, knees, and olecranon bursa and at pressure points under the ulnar aspect of the forearm and Achilles tendon (Fig. 273-3). Gout at this stage can be confused with rheumatoid arthritis, especially if tophi are confused with rheumatoid nodules.

Atypical Gout Presentations

Approximately 5% of patients with gout exhibit the onset of symptoms before age 25 years. Early-onset gout represents a special subset of patients who generally have a genetic component (see Table 273-2), with a more

FIGURE 273-2. The intense inflammation of acute gouty arthritis. A, The marked swelling of the first metatarsophalangeal joint (podagra) is demonstrated. A dusky blue hue over an intense erythema is characteristic. **B,** Ankle swelling is shown with erythema extending beyond the area of the tibiotalar joint.

FIGURE 273-3. Characteristic locations of gouty tophi. A, At the elbow, tophi present as hard nodules along the ulnar ridge or as multiple nodules within the olecranon bursa. **B,** Ear tophi are uncommon but may be an easy source of crystal confirmation of gout when present. **C,** Small subcutaneous tophi can occur along the ventral creases of fingers. **D,** Tophi over the proximal interphalangeal or distal interphalangeal joints may be confused with Bouchard or Heberden nodes, respectively.

accelerated clinical course, requiring more aggressive antihyperuricemic therapy.

Gout develops in approximately 15% of heart transplant recipients who are taking cyclosporine to prevent allograft rejection. A slightly lower frequency of gout is seen in kidney and liver transplant recipients. Cyclosporine-induced gout has a marked shortening of the asymptomatic and acute intermittent stages, with a rapid appearance of tophi in 1 to 4 years.

In most large reviews, women account for no more than 5% of all gout subjects. This demographic is changing, with gout in older women becoming more common. Most women with gout are postmenopausal. Women who have premenopausal gout usually have renal insufficiency and hypertension and are taking thiazide diuretics, or they have a strong genetic predilection. Gout in older women may differ from classic gout in its propensity to occur in joints previously damaged by osteoarthritis such as the knees or the distal interphalangeal joints with Heberden nodes.

Saturnine gout is the term used to describe gout caused by chronic lead exposure. In the middle of the last century, this was most commonly observed in consumers of "moonshine" whiskey. Occupational exposure as seen in plumbers and environmental exposure from lead-based paints are other potential causes of this unusual form of gout.

DIAGNOSIS

Hyperuricemia is a critical risk factor for developing gout, but it is not a reliable diagnostic test because many people with elevated serum urate levels will never develop gout. Serum urate levels during an acute flare of gout are also unreliable because they may be suppressed by as much as 1.5 to 2.0 mg/dL from baseline values. The definitive diagnosis of gout is made by polarized compensated microscopy of a synovial fluid aspirate from the affected joint. The presence of intracellular needle-shaped crystals with strong negative birefringence is the diagnostic "gold standard." Similar microscopic results from a tophus aspirate or spontaneously draining fluid would also confirm the diagnosis of gout.

Synovial fluid confirmation is obtained in as few as 10% of patients said to have gout. The presumptive diagnosis of gout is based on a pattern of acute joint symptoms coupled with the patient's own medical history or a family history. The patient's medical history may reveal comorbidities frequently associated with gout or the use of medications associated with urate retention.

The characteristic clinical presentation is the rapid onset (over 8 to 12 hours) of severe pain in one or several lower extremity joints (especially the great toe, midfoot, and ankle). The presumptive diagnosis is given much greater credence if there have been similar previous attacks that spontaneously resolved to a symptom-free state.

Radiographic evaluation is not helpful in early attacks of gout except to rule out fracture. In advanced gout, affected joints may show punched-out periarticular erosions with classic overhanging edges. Ultrasonography can detect MSU crystals layered over articular cartilage in early disease and may be diagnostic. Magnetic resonance imaging is not part of a standard evaluation but will reveal soft tissue and intra-articular tophi long before they become clinically evident.

The differential diagnosis of acute gout includes bacterial infection, trauma, sarcoidosis, and CPPD arthropathy (pseudogout). Diseases occasionally confused with advanced gout include rheumatoid arthritis, reactive arthritis, and CPPD arthropathy.

TREATMENT AND PREVENTION

In 2012, the American College of Rheumatology (ACR) published its first guidelines on the management of gout.[5,6] Subsequent developments have been systematically reviewed.[7] There were several components of these guidelines that are applicable to all subjects with recurrent gouty flares. First, and foremost, is a heavy emphasis on patient education in order to obtain an optimal treatment outcome. Not only should patients be informed about dietary and other lifestyle changes that will lower their serum uric acid and lessen flares (Table 273-3), but they should also know that their disease is caused by an excessive burden of MSU crystals already present in their joints and soft tissues. This understanding of the disease process underlying gouty arthritis will help shift the focus from symptoms to "urate burden" as the real target of treatment.

Acute Gout

The treatment goal for acute gout flare is to relieve pain and terminate the flare as quickly as possible. Resting the painful joint and applying ice are generally helpful, but pharmacologic intervention is usually necessary to alter the excruciatingly painful course that may last for several days to more than a week. The therapeutic options include nonsteroidal anti-inflammatory drugs (NSAIDs),[■] oral colchicine,[■] and corticosteroids. NSAIDs are widely used but

TABLE 273-3 SPECIFIC AMERICAN COLLEGE OF RHEUMATOLOGY RECOMMENDATIONS ON LIFESTYLE AND DIET FOR GOUTY PATIENTS

Weight loss for obese patients	Avoid: Organ meats High fructose corn syrup–sweetened drinks Alcohol overuse
Healthy overall diet	Limit: Beef, pork, lamb, shellfish Beer
Exercise to achieve fitness	Encourage: Low-fat dairy
Smoking cessation	
Stay well hydrated	

may be inappropriate for patients with renal insufficiency or peptic ulcer disease. Oral colchicine administered as 1.2 mg (two tablets) at the time of flare onset followed in 1 hour by a third 0.6-mg tablet is the recommended dosing for the first 24 hours. This is followed by 7 to 10 days of once-daily or twice-daily colchicine depending on renal function. Corticosteroids can be administered orally, intramuscularly, or intra-articularly for acute gout symptoms and is a valuable option in patients with poor renal function or intolerance to colchicine. Issues critical to treatment success for a gouty flare are the early initiation of treatment, ensuring adequate dosing of anti-inflammatory therapy, and continuing the treatment until the flare has completely resolved (usually 6 to 10 days). During the acute flare, subjects already taking urate-lowering therapy (ULT) should continue the drug, whereas those not receiving this therapy should not be started.

Recurrent and Advanced Gout

The principal goal of treating gout is to lower the serum uric acid below its saturation point so that the process of crystallization will cease and the accumulated urate burden will be gradually diminished. The 2012 ACR guidelines recommend a target serum urate of less than 6 mg/dL in all subjects, with an even lower target (<5 mg/dL) for patients with advanced gout. ULT is recommended for all patients with two or more gouty flares per year, patients with advanced disease, and those with kidney stones. Allopurinol and febuxostat are both xanthine oxidase inhibitors and are considered first-line ULT. The ACR guidelines recommend that allopurinol starting dose be no greater than 100 mg/day. The dose is gradually escalated by 100 mg daily every 2 to 5 weeks, with serum urate monitoring until the target serum urate is achieved. The maximal U.S. Food and Drug Administration (FDA)-approved dose of allopurinol is 800 mg daily. In subjects with advanced chronic kidney disease, the initial dose should be reduced to 50 mg daily, with incremental dose escalations of 50 mg. Febuxostat is an alternative ULT and should be used in patients who have failed allopurinol treatment or have demonstrated sensitivity or intolerance to allopurinol.[8] The initial febuxostat dose of 40 mg daily can be increased to 80 mg daily after 2 weeks of therapy if the serum urate target is not achieved.

In patients with gout who have not attained the target serum urate despite maximal doses of either allopurinol or febuxostat, the uricosuric agent probenecid can be added to the xanthine oxidase inhibitor. Pegloticase is an intravenously administered monomethoxypoly (ethylene glycol)-conjugated recombinant uricase that dramatically lowers serum urate levels. It is approved by the FDA for the treatment of gout in patients for whom conventional therapy has been ineffective and who still have signs and symptoms of gout.

Before the initiation of any form of ULT, the patient should be placed on maintenance anti-inflammatory therapy. This is to prevent or minimize the anticipated increase in flare activity that is associated with starting ULT. Typically, this anti-inflammatory prophylaxis is in the form of colchicine once or twice daily or low-dose NSAIDs. Anti-inflammatory prophylaxis should be continued until the subject has been free of gout flares for 6 months or more.

CALCIUM PYROPHOSPHATE DIHYDRATE CRYSTAL DEPOSITION DISEASE

DEFINITIONS

The heterogeneous group of clinical conditions associated with CPPD crystals are collectively called *CPPD crystal deposition disease*. Within this spectrum is the common radiographic finding of chondrocalcinosis (CC) that is frequently asymptomatic. The acute synovitis associated with intra-articular CPPD crystals can closely mimic the findings of gout and is hence referred to as *pseudogout*. The more chronic changes associated with CPPD-induced bone and cartilage destruction is referred to as *pyrophosphate arthropathy*. These conditions are further classified as familial (genetic), metabolic, and sporadic.

EPIDEMIOLOGY

The true prevalence of CPPD crystal deposition disease is unknown, but it is generally thought to be underdiagnosed because of its confusion with other forms of arthritis.[9] The prevalence of radiographically appearing chondrocalcinosis has been studied extensively and is clearly an age-related phenomenon. Chondrocalcinosis of the meniscal and articular cartilage of the knee is seen in 4% of people between the ages of 55 and 59 years; in 18% of those 80 to 84 years; and in approximately 27% of those older than 85 years.

PATHOBIOLOGY

Clinical CPPD disease is divided into three categories based on the etiology of altered inorganic pyrophosphate (PPi) metabolism. The categories are hereditary (familial), sporadic (idiopathic), and metabolic. All three types of CPPD disease are associated with extracellular PPi accumulation around chondrocytes, and extracellular PPi is necessary for the formation of CPPD crystals. Intracellular PPi is a common byproduct of many synthetic reactions, and if allowed to accumulate intracellularly, it impedes the further synthesis of proteins, nucleotides, and lipids. Therefore, there are multiple mechanisms for removing PPi from the cellular cytoplasm, including specific and nonspecific membrane transporters and both intracellular and extracellular (ecto-) pyrophosphate hydrolysis.

Hereditary forms of CPPD crystal deposition disease may be caused by increased transmembrane transport of chondrocyte intracellular PPi to its extracellular matrix by diminished activity of the protective pyrophosphate hydrolases, or because of altered influences of factors that lead to increased extracellular PPi, including transforming growth factor-β, bone morphogenic protein-2 and -4, ascorbic acid, and osteopontin. The best characterized of the hereditary causes is a gain of function mutation of the ANK anion transporter on the chondrocyte plasma membrane.

These types of mutations are rarely observed in the sporadic form of CPPD disease. Aging chondrocytes in culture produce considerably more PPi than do younger chondrocytes, although the exact mechanism for this is unclear.

The metabolic diseases that predispose to CPPD crystal deposition disease include hemochromatosis, hyperparathyroidism, hypomagnesemia (as in Gitelman syndrome), and hypophosphatasia. All of these metabolic conditions result in increased extracellular PPi or other alterations in the cartilage matrix that are permissive for CCPD crystal formation.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

CPPD crystal deposition disease presents in a variety of fashions. It is frequently asymptomatic (lanthanic) and recognized only by the appearance of chondrocalcinosis on radiographs. The most common clinical manifestation accounting for approximately 60% of CPPD disease is a polyarticular, noninflammatory arthritis affecting joints not typically involved in primary osteoarthritis, including the wrists, shoulders, and metacarpophalangeal joints (particularly the second and third metacarpophalangeals). This form of CPPD disease is called *pseudo-osteoarthritis* and may be associated with occasional inflammatory attacks. The acute monoarticular presentation is known as pseudogout. The pain and swelling of pseudogout can be similar to that seen in gout. The onset is usually not as abrupt as with gout, and the attacks tend to last longer—frequently months. Pseudogout occurs more often in the large joints than in small joints. CPPD crystal deposition disease can occasionally present as a chronic polyarticular inflammatory disease that may mimic rheumatoid arthritis or polymyalgia rheumatica.

CPPD disease is diagnosed by identifying chondrocalcinosis by radiography in a patient with a clinical history suggestive of the disease (Fig. 273-4). Definitive diagnosis is made by the finding of CPPD crystals by compensated polarized light microscopic examination of aspirated synovial fluid.[10]

PREVENTION AND TREATMENT

Rx

There are no specific therapies for CPPD crystal deposition disease.[11] In patients with metabolic disease–associated CPPD disease, treatment and control of the metabolic disease can afford some improvement in the arthritis, although this is not the case for phlebotomy-treated hereditary hemochromatosis. For both the acute and chronic forms of CPPD crystal deposition disease, therapy is directed at symptoms. NSAIDs are the mainstay of

FIGURE 273-4. Calcium pyrophosphate dehydrate arthropathy of the knee. Radiographic evidence of chondrocalcinosis showing fibrocartilage calcification as thick, linear deposits parallel to and separate from subchondral bone.

treatment. Low-dose oral colchicine can be used in both acute and chronic settings. Intra-articular steroids have also been proved to be beneficial for symptomatic CPPD crystal deposition disease. The IL-1 inhibitor, anakinra, has been effectively used "off-label" for treating CPPD disease flares. On the other hand, intra-articular viscosupplementation (hyaluronic acid) may exacerbate joint symptoms.

APATITE (BASIC CALCIUM PHOSPHATE)-ASSOCIATED ARTHROPATHY

BCP crystals include several different crystal species. The most common of these is hydroxyapatite. The BCP crystals are unlike MSU or CPPD crystals in that they are not identifiable by polarized microscopy. These very tiny crystals are responsible for several important clinical conditions. Although BCP crystals are found in 50% of osteoarthritic synovial fluids, the incidence and prevalence of the individual apatite-associated clinical manifestations have not been established. This is especially true of the most severe and destructive apatite syndromes such as Milwaukee shoulder and tumoral calcinosis. The prevalence of the most common apatite-associated conditions, calcific periarthritis of the shoulder, was 3% in a large North American study.

PATHOBIOLOGY

Like MSU and CPPD crystals, BCP crystals exert their pro-inflammatory effects by being phagocytized by resident synoviocytes and influxing leukocytes. Unlike MSU and CPPD crystals, apatite crystals apparently do not act through the NALP3 inflammasome. Rather, BCP crystals are dissolved in the acidic phagosome and raise intracellular calcium levels and then activate the calcium-dependent signaling pathways. The synoviocytes are stimulated by these pathways to increase production of tumor necrosis factor-α and IL-6, and influxing neutrophils are stimulated to increase pro-inflammatory oxygen radicals. The fibroblasts in the joint lining and surrounding soft tissues are stimulated to increase production of many of the matrix metalloproteinases, such as collagenase 1, collagenase 3, and stromolysin 1.

CLINICAL MANIFESTATIONS OF BASIC CALCIUM PHOSPHATE DEPOSITION

The clinical manifestations of BCP deposition can be acute or chronic, and their cause can be idiopathic, hereditary, or secondary to other diseases that cause hypercalcemia (Table 273-4). BCP crystals can be found in 50% of synovial fluids from osteoarthritic knees. The presence of BCP crystals correlates with more severe radiographic changes secondary to more rapid deterioration in these osteoarthritic knees. Acute inflammatory arthritis associated with BCP deposition is similar in many ways to that of gout and pseudogout and has been referred to as *pseudo-pseudogout*. The patients tend to be younger and usually have evidence of soft tissue BCP deposition elsewhere in the body. Periarticular calcifications are often asymptomatic. However, BCP deposition can cause an acute and severe inflammation of the ligaments, tendons, and bursae surrounding a joint, termed *acute calcific periarthritis*. This frequently occurs around the shoulders and hips but can also occur in fingers, toes, wrists, and ankles.

TABLE 273-4 CLINICAL MANIFESTATIONS OF BASIC CALCIUM PHOSPHATE DEPOSITION DISEASE

Osteoarthritis and basic calcium phosphate deposition
Acute inflammatory arthritis
Acute calcific periarthritis
Chronic noninflammatory arthropathy
Diffuse idiopathic skeletal hyperostosis (DISH)
Tumoral calcinosis
Calcifications associated with hypercalcemic states
Hyperparathyroidism
Hypervitaminosis D
Sarcoidosis
Metastatic cancer
Myeloma
Leukemia

The most destructive BCP-associated arthropathy is Milwaukee shoulder, which is characterized by large noninflammatory effusions containing BCP crystals with or without CPPD crystals. The process results in the destruction of the rotator cuff leading to marked instability and glenohumeral cartilage dissolution. This process can also affect knees. Like the acute calcific periarthritis discussed previously, Milwaukee shoulder is observed in women four times more frequently than in men.

Diffuse idiopathic skeletal hyperostosis (DISH) predominates in men and elderly people. The radiographic appearance of this condition is flowing ossifications along the anterolateral aspect of spinal vertebrae, especially in the thoracic spine. DISH is usually asymptomatic, but very large bridging osteophytes can cause pain; in the cervical spine, it can even result in dysphagia.

Idiopathic tumoral calcinosis is rare but most prevalent in young patients of African descent. These subjects have large irregular calcifying masses in the soft tissue surrounding the shoulders, hips, and elbows. Some cases show a familial occurrence and medical conditions associated with hyperphosphatemia.

Finally, metastatic calcifications can arise in any medical condition associated with hypercalcemia such as hyperparathyroidism, hypervitaminosis D, sarcoidosis, metastatic cancer, multiple myeloma, and leukemia.

TREATMENT AND PREVENTION

Rx

The treatment of most BCP-associated syndromes is conservative. In acute inflammatory arthritis and periarthritis, low-dose oral colchicine and NSAIDs are the mainstay of a symptomatic therapy. The persistent large effusion seen in Milwaukee shoulder should be serially aspirated to decrease intracapsular pressure. The added effectiveness of corticosteroid injections in this setting is unproved. The calcinosis associated with abnormal calcium and phosphate metabolism is best managed by treating the underlying metabolic process.

REVIEW QUESTIONS

1. The prevalence of hyperuricemia in the United States has been rising dramatically over the past three decades because of all of the following *except* which one?

A. Increased longevity of the population
B. Increased use of low-dose aspirin and thiazide diuretics
C. Greater consumption of low-fat dairy products
D. Greater consumption of high-fructose corn syrup
E. Increased prevalence of the metabolic syndrome

Answer: C The aging population, the increasing prevalence of the metabolic syndrome, and increased consumption of medications and diets that increase blood uric acid levels by either inhibiting its excretion (low-dose aspirin and thiazide diuretics) or increasing its production (high-fructose corn syrup) are all factors leading to the increased prevalence of hyperuricemia and gout in the United States. Increased consumption of low-fat dairy products does not cause hyperuricemia.

2. Which one of the following is true regarding renal clearance of uric acid?

A. Comparable in gouty and nongouty subjects
B. Reduced in gouty subjects by 70%
C. Proportional to the serum urate levels in both gouty and nongouty subjects
D. Controlled by components of the "transportasome" in the distal nephron
E. Reduced by the angiotensin II receptor blocker losartan

Answer: C Gouty subjects have reduced renal clearance of uric acid, and their excretion of uric acid is reduced by only 30% (not 70%). The renal tubular transporters (collectively called the *transportasome*) that are responsible for determining how much of the filtered uric acid is actually excreted are located in the proximal convoluted tubules, not the distal nephron. Renal clearance of uric acid is not reduced by losartan.

3. Factors that may provoke flares of gout include all of the following *except* which one?

A. Initiation of allopurinol
B. Overindulgence in shellfish
C. Starvation
D. Initiation of colchicine
E. Surgery

Answer: D Initiation of colchicine can actually block flares of gout. In contrast, allopurinol or any other drug or factor that alters blood uric acid levels (either up or down) can provoke an acute gouty attack.

4. According to the American College of Rheumatology (ACR) 2012 treatment guidelines for urate-lowering therapy, which one of the following is true?

A. Prophylactic anti-inflammatory therapy should be initiated before starting allopurinol or febuxostat.
B. Patients with chronic kidney disease should not be treated with more than 300 mg of allopurinol daily.
C. Serum urate levels should be reduced to less than 5 mg/dL in all patients with gout.
D. The initial starting dose of allopurinol is 300 mg daily in most patients.
E. Probenecid is first-line therapy for patients with chronic kidney disease stage 3 or 4.

Answer: A Prophylactic anti-inflammatory drugs should be initiated before starting allopurinol or febuxostat because any acute change in uric acid levels (including acute changes that actually reduce the levels, as these drugs would do, as well as increase the levels) can precipitate an acute gout attack. The ACR guidelines recommend starting allopurinol at doses of 100 mg daily in those without kidney disease or 50 mg daily in those who do have advanced chronic kidney disease, followed by dose escalations of 100 mg or 50 mg in these situations, respectively. ACR guidelines recommend a target serum uric acid of less than 6 mg/dL, except in those with advanced gout, whose levels should be lowered to less than 5 mg/dL. The uricosuric agent, probenecid, is recommended only as addition to a first-line xanthine oxidase inhibitor if target urate levels cannot be attained with maximum doses of the latter.

5. The laboratory investigation for underlying metabolic causes of calcium pyrophosphate dehydrate (CPPD) deposition disease would include all of the following, *except* which one?

A. Serum ferritin
B. Serum calcium and phosphate
C. Serum alkaline phosphatase
D. Serum magnesium
E. Serum lead

Answer: E Metabolic diseases that predispose to CPPD crystal deposition disease include hemochromatosis, hyperparathyroidism, hypomagnesemia states, and hypophosphatasia. *Saturnine gout* is the term used to describe gout (not CPPD crystal deposition disease) caused by chronic lead exposure (e.g., by occupational exposure or drinking "moonshine" whiskey).

6. The basic calcium crystal arthropathy referred to as *Milwaukee shoulder* is characterized by which one of the following?

A. Bilateral involvement in men
B. Destruction of the glenohumeral joint
C. Markedly inflammatory synovial fluid
D. Birefringent crystals in the synovial fluid
E. Slow progression

Answer: B The form of BCP arthropathy known as Milwaukee shoulder has a predilection for elderly women, is usually unilateral but can involve the knees, and has non-inflammatory synovial fluid (WBC <1,000 per cubic mm) that is usually bloody in appearance. Despite non-inflammatory fluid the condition can be rapidly destructive.

274 FIBROMYALGIA, CHRONIC FATIGUE SYNDROME, AND MYOFASCIAL PAIN

ROBERT M. BENNETT

Fibromyalgia (FM) and chronic fatigue syndrome (CFS) are multisymptomatic syndromes defined respectively by the core features of chronic widespread pain and chronic unexplained fatigue. Although there is a significant overlap in symptomatology between FM and CFS, they are generally considered to be separate disorders. Myofascial pain is a universal experience that is usually self-limited; when it becomes persistent, it may accentuate and perpetuate the experience of chronic fatigue and FM.

FIBROMYALGIA

EPIDEMIOLOGY

Chronic musculoskeletal pain is commonly encountered in the general population with an estimated prevalence of about 20%. It is subdivided into chronic regional pain, with a prevalence of about 25%, and chronic widespread pain, with a prevalence of about 10%.

FM is considered to be a subset of chronic widespread pain and has a prevalence of about 2% in women and 0.5% in men. There is a steady increase in FM with age, with about 12% of women in their 60s being affected. Chronic musculoskeletal pain is associated with a reduction in overall health status, and FM patients have more impairment than do patients with chronic widespread pain or chronic regional pain. The prevalence of FM in the medical setting is much greater, with about 20 to 30% of the rheumatology visits in the United States made for FM.

PATHOBIOLOGY

There is persuasive evidence that FM pain results from abnormal sensory processing within the central nervous system (Fig. 274-1).[1] This is commonly referred to as *central sensitization* and results from an amplification of peripheral sensory stimuli and a deficit of descending inhibitory control from the midbrain.[2] The magnification of peripheral sensory input is readily visualized as increased activity in somatosensory areas of the brain on magnetic resonance imaging (MRI) in FM subjects versus healthy controls. Central sensitization is the result of a persistent neuronal hyperexcitability that continues long after the original sensitizing input has waned. The pathophysiology of this phenomenon is based, in part, on temporal summation of neural impulses. This occurs when pain fibers (unmyelinated C) are repetitively stimulated at a rate greater than one impulse every 3 seconds. At a biochemical level, such stimulation results in depolarization of *N*-methyl-D-aspartate (NMDA) receptors, which causes transcriptional changes that affect pain processing. Thus, persistent pain input may eventually give rise to central sensitization in some individuals, probably based, in part, on a genetic predisposition.[3]

The frequent development of FM from focal pain states, such as in rheumatoid arthritis, post-traumatic injuries, and endometriosis, is thought to be a result of chronic nociceptive input stimulating central neuroplastic changes.

The descending pain system, originating in the periaqueductal gray nucleus of the midbrain and terminating in the dorsal horn, is important in modulating the transmission of nerve impulses to the brain. This inhibitory system is defective in FM patients. Activation of the nuclei in the midbrain involved in this system occurs in response to opioids, endorphins, emotions, and the placebo response. This modulation may upregulate or downregulate sensory processing, and in part, it underlies the influence of the psyche on the pain experience.

Understanding the biologic basis for central sensitization has provided an explanation for the common association of FM with other conditions such as irritable bowel syndrome, overactive bladder, multiple chemical hypersensitivity, and chronic daily headaches.

CLINICAL MANIFESTATIONS

FM patients always have the core symptom of widespread pain but also report a wide array of other symptoms (Table 274-1).[4]

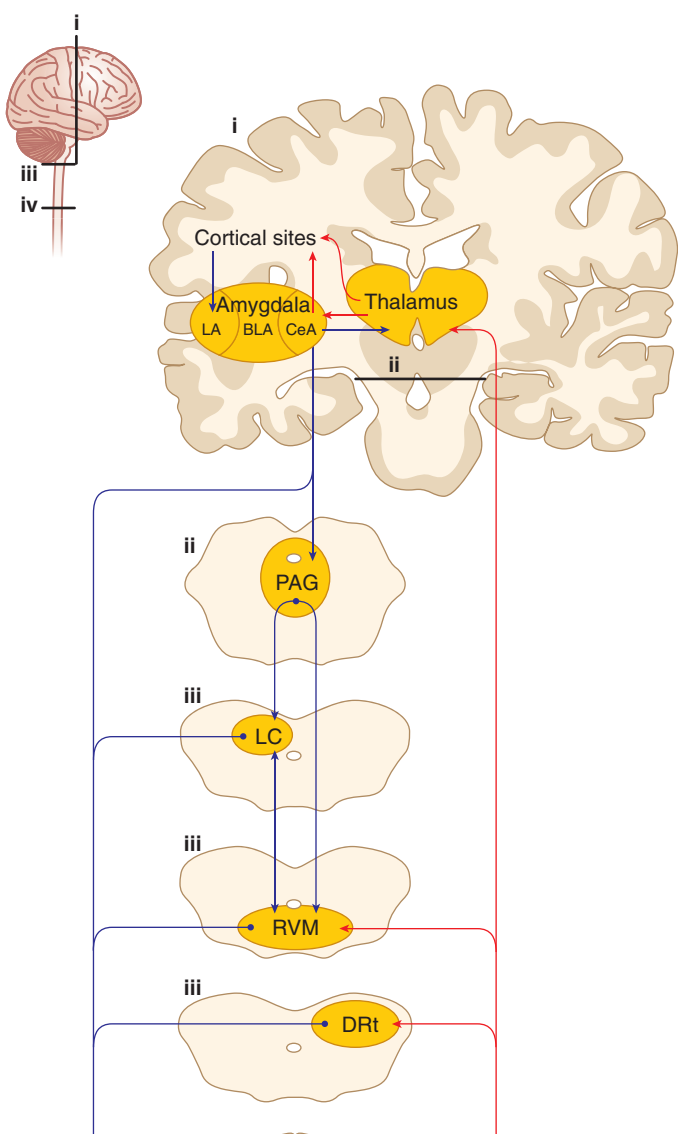

FIGURE 274-1. Neuroanatomy of pain pathways. Nociceptive inputs enter the spinal dorsal horn through primary afferent fibers that synapse onto transmission neurons. The projection fibers ascend through the contralateral spinothalamic tract. Ascending projections target the thalamus, and collateral projections also target mesencephalic nuclei, including the DRt, the RVM, and the midbrain PAG. Descending projections from the DRt are a critical component of the DNIC pathway. Rostral projections from the thalamus target areas that include cortical sites and the amygdala. The lateral capsular part of the CeA ("nociceptive amygdala") receives nociceptive inputs from the brain stem and spinal cord. Inputs from the thalamus and cortex enter through the lateral (LA) and basolateral (BLA) amygdala. The CeA sends outputs to cortical sites and the thalamus, in which cognitive and conscious perceptions of pain are integrated. Descending pain modulation is mediated through projections to the PAG, which also receives inputs from other sites, including the hypothalamus, and communicates with the RVM as well as other medullary nuclei that send descending projections to the spinal dorsal horn through the DLF. The noradrenergic locus coeruleus (LC) receives inputs from the PAG, communicates with the RVM, and sends descending noradrenergic inhibitory projections to the spinal cord. Antinociceptive and pronociceptive spinopetal projections from the RVM positively and negatively modulate nociceptive inputs and provide for an endogenous pain regulatory system. Ascending (red) and descending (blue) tracts are shown schematically. Areas labeled "i-iv" in the small diagram correspond with labeled details of the larger diagram. (From Ossipov MH, Dussor GO, Porreca F. Central modulation of pain. *J Clin Invest* 2010;120[11]:3779-3787.)

From Bennett RM, Jones J, Turk DC, et al. An internet survey of 2,596 people with fibromyalgia. *BMC Musculoskelet Disord.* 2007;8:27.

Pain
The core symptom of FM is chronic widespread pain and stiffness. Characteristically, the pain is described as a constant dull ache that is worsened by muscle overactivity. FM-related pain is usually perceived as arising from muscle; however, many patients also report joint pain but have no objective evidence of arthritis.

Fatigue
Easy fatigability from physical exertion, mental exertion, and psychological stressors is typical of FM. Patients with CFS have many similarities with FM patients; about 75% of patients meeting the diagnostic criteria for CFS also meet criteria for the diagnosis of FM.

Disordered Sleep
FM patients characteristically have nonrestorative sleep. Even if they sleep continuously for 8 to 10 hours, they awake feeling tired. Many exhibit an alpha-delta electroencephalographic pattern that would explain their never achieving the restorative stages of non–rapid eye movement sleep. A poor night's sleep is often followed by worsening of FM symptoms the next day. Restless legs syndrome and the associated periodic limb movement disorder occur in up to 60% of FM patients. A thorough evaluation for sleep disorders, such as sleep apnea, is warranted in all FM patients.

Cognitive Dysfunction
Cognitive dysfunction is a prominent complaint of many FM patients. They commonly describe difficulties with working memory, semantic memory, concentration, logical analysis, and motivation. It has been estimated that the working memory deficit in FM is comparable to 20 years of aging. Recent studies have documented that these neurocognitive deficits correlate with local brain morphology in the frontal lobe and anterior cingulate gyrus.

Psychological Distress
Having a chronic painful disorder for which there is currently no generally accepted cure often produces an existential crisis. Approximately 30% of FM patients have significant depression at any given time, and about 60% have a lifetime prevalence of depressive illness. Although psychiatric disorders are common in FM patients, they do not seem to be intrinsically related to the pathophysiology of FM; effective treatment of depression with a selective serotonin re-uptake inhibitor (SSRI) does not eliminate FM pain. FM patients are at an increased risk for suicide and suicide ideation.[5] Fibromyalgia and depression show familial clustering, suggestive of an underlying genetic susceptibility.

Associated Problems
Fibromyalgia patients often have a spectrum of other pain disorders that share similar features, such as not having a well-defined etiology, having an association with mood disorders, and having no definitive cure. These accompanying disorders are often referred to as *central sensitivity syndromes* and include irritable bowel syndrome, overactive bladder syndrome, temporomandibular pain disorder, chronic pelvic pain, chronic daily headaches, and chemical hypersensitivity syndrome.

History
Initiation and Maintenance of Fibromyalgia
FM seldom emerges "out of the blue." Many patients relate an onset following an acute injury, repetitive workload, persistent stress, infections, and toxin exposure. It is not uncommon for a regional pain state to evolve into FM. FM is commonly found as an accompaniment of other painful disorders, such as rheumatoid arthritis, migraine, low back pain, systemic lupus erythematosus, Sjögren syndrome, inflammatory bowel disease, endometriosis, and osteoarthritis. There is increasing evidence that FM is a common occurrence in victims of post-traumatic stress disorder; for instance, both FM and CFS were common diagnoses after Operation Desert Storm in 1991. Childhood abuse and sexual trauma are often elicited during a careful and empathetic history.

DIAGNOSIS
The current "gold standard" for diagnosis of FM is based on the classification criteria of the American College of Rheumatology.[6] These criteria require persistent symptoms of at least 3 months' duration and widespread pain accompanied by tenderness at 11 or more of 18 tender point locations.

The following are the locations of the nine paired tender points:

Occiput: bilateral, at the suboccipital muscle insertions
Low cervical: bilateral, at the anterior aspects of the intertransverse spaces at C5-C7
Trapezius: bilateral, at the midpoint of the upper border
Supraspinatus: bilateral, at the origins, above the scapular spine near the medial border
Second rib: bilateral, at the second costochondral junctions just lateral to the junctions on the upper surfaces
Lateral epicondyle: bilateral, 2 cm distal to the epicondyles
Gluteal: bilateral, in the upper outer quadrants of the buttocks in the anterior fold of muscle
Greater trochanter: bilateral, posterior to the trochanteric prominence
Knee: bilateral, at the medial fat pad proximal to the joint line

Because the fibromyalgia tender point evaluation is seldom performed in clinical practice, more recent criteria have proscribed a diagnosis based on the combination of common symptoms and pain locations. Figure 274-2 is one example of such criteria that has an 80% diagnostic accuracy.

FM is not a diagnosis of exclusion; thus, laboratory tests and imaging studies play no role in establishing the diagnosis, although they are often indicated in the evaluation of concomitant peripheral pain generators and accompanying symptoms.

TREATMENT Rx

Successful management of FM requires a thorough analysis in terms of the biopsychosocial model of disease. The major management issues that require attention are listed in Figure 274-3.[7]

Education
There is evidence that higher educational attainment is associated with a better prognosis in many chronic disorders, such as FM. Education has a positive effect through cognitive behavioral strategies, such as goal setting and reassessment of priorities. Educated patients are more likely to take an active role in self-management.

Pain
In considering the management of pain in FM, it is logical to focus on the major sites of pain processing, namely, peripheral pain generation and central pain pathways. There is no specific tissue pathology, at least in peripheral tissues, that is characteristic of FM. However, once the central nervous system

Pain location inventory (PLI):

Directions: For each of the following 28 sites, select those locations where you have experienced persistent pain during the past 7 days. The score will be between 0 and 28.

Neck	Left upper back	Right wrist	Left thigh
Right jaw	Right lower back	Left wrist	Right knee
Left jaw	Left lower back	Right hand	Left knee
Mid–upper back	Right shoulder	Left hand	Right ankle
Front of chest	Left shoulder	Right hip	Left ankle
Mid–lower back	Right arm	Left hip	Right foot
Right upper back	Left arm	Right thigh	Left foot

10–item Symptom Impact Questionnaire (SIQR):

Directions: For each of the following 10 questions, check the one box that best indicates the intensity of the following common symptoms over the last 7 days. Divide the total symptom score (0–100) by 2 (i.e., the range will be 0 to 50).

Criteria:

A patient fulfilling the following guidelines has a high likelihood of having FM:*

1. **The symptoms and pain locations have been persistent for at least the last 3 months**
2. **Pain location score is ≥ 17**
3. **SIQR symptom score is ≥ 21**

* • *Fibromyalgia patients have a continuum of symptoms; a diagnosis based on a strict numerical cutoff is subject to error.*
• *The presence of another pain disorder or related symptoms does not rule out a diagnosis of fibromyalgia.*
• *A careful clinical evaluation is always required in order to identify any condition that could fully account for the patient's symptoms and/or contribute to the severity of the symptoms.*

FIGURE 274-2. Alternative diagnostic criteria for fibromyalgia.[4] (From Bennett RM, Friend R, Marcus D, et al. Criteria for the diagnosis of fibromyalgia: validation of the modified 2010 preliminary American College of Rheumatology criteria and the development of alternative criteria. *Arthritis Care Res (Hoboken)*. 2014;66:1364-1373.)

is sensitized, not only are peripheral pain generators perceived as being more painful, but they also prolong and amplify the central neuroplastic changes. Thus, a critical first component of treating FM pain is to identify and effectively treat all peripheral pain generators, which commonly include peripheral arthritis, axial arthritis, spinal stenosis, myofascial trigger points, neuropathic pain, vascular headaches, visceral pain (e.g., irritable bowel syndrome, overactive bladder), postsurgical pain, and pelvic pain syndromes (e.g., endometriosis).

Management of central sensitization is typically initiated with heterocyclic antidepressant (HCA) medications such as amitriptyline, trazodone, cyclobenzaprine, or nortriptyline. (Chapter 397) There is evidence that antidepressant medications with both re-uptake inhibition of serotonin and norepinephrine (e.g., venlafaxine, duloxetine, milnacipran) are more effective in treating FM pain. Both duloxetine and milnacipran have U.S. Food and Drug Administration (FDA) approval for use in FM. Importantly, the mechanism of action of these drugs is independent of any antidepressant effect and results from upregulation of the descending pain system that originates in the brain stem and uses serotonin and norepinephrine as neurotransmitters at dorsal horn synapses. Anticonvulsant medications such as gabapentin, pregabalin, and topiramate are increasingly being used in FM and other chronic pain states; they inhibit the presynaptic release of glutamate and thus modulate the activation of NMDA receptors. Pregabalin has been beneficial in randomized trials and has FDA approval for use in FM. Sedative hypnotics such as zolpidem and zopiclone often help the nonrestorative sleep, but not pain. On the other hand, sodium oxybate, an FDA-approved drug for narcolepsy, has been shown to improve not only sleep but also pain, stiffness, and fatigue; it has not been approved for use in fibromyalgia.

Opioids are often used in the treatment of FM, but long-term trials are lacking. Opioids should not be the first choice for analgesia; however, they should not be withheld if less powerful analgesics have failed. Tramadol (both Ultram and Ultracet) has proved useful in reducing FM pain in two controlled trials. Tramadol is a weak opioid agonist that also inhibits the re-uptake of serotonin and norepinephrine at the level of the dorsal horn. It is metabolized by CYP2D6, as are many antidepressant medications. FM patients who are taking tramadol or any of several antidepressants that are eliminated by CYP2D6 are at risk for the development of a serotonin syndrome (Chapter 434). A careful review of concomitant medications is an important prerequisite in the prescription of any new medication, especially in difficult-to-treat patients who are often taking multiple medications.

Fatigue

A search for a treatable cause of fatigue is always indicated (E-Table 274-1). Common treatable causes of chronic fatigue in FM patients are inappropriate dosing of medications, depression, aerobic deconditioning, primary sleep disorder (e.g., sleep apnea), non-restorative sleep, a coexisting inflammatory disorder, and neurally mediated hypotension. As in CFS, the underlying cause of *primary* fatigue in FM is not known. Sodium oxybate, methyl phenidate, and modafinil have provided worthwhile improvement in fatigue in some FM patients.

Sleep

Low-dose HCAs, particularly trazodone and cyclobenzaprine, are the mainstay of sleep pharmacotherapy in FM patients. Some patients cannot tolerate HCAs because of unacceptable levels of daytime drowsiness or weight gain.

E-TABLE 274-1 DIFFERENTIAL DIAGNOSIS OF CHRONIC FATIGUE

CHRONIC INFECTIONS	**CHRONIC INFLAMMATION**
Hepatitis C Lyme disease Parasitic and fungal infections Chronic pulmonary infections Human immunodeficiency virus Tropical diseases	Rheumatoid arthritis Systemic lupus erythematosus Sjögren syndrome Polymyositis/dermatomyositis Vasculitis Sarcoidosis
SLEEP DISORDERS	**CARDIOPULMONARY**
Obstructive sleep apnea Restless leg syndrome Circadian rhythm disorder Upper airway resistance syndrome Narcolepsy/parasomnias Alpha-delta sleep disorder	Congestive heart failure Neurally mediated hypotension Postural orthostatic tachycardia syndrome Pulmonary hypertension Chronic obstructive pulmonary disease Mitral valve prolapse

Mood disorders (depression/anxiety/bipolar) Schizophrenia Post-traumatic stress disorder Anorexia nervosa/bulimia Childhood abuse and/or neglect	Chronic overwork Persistent unresolved stress Inadequate exercise Morbid obesity (body mass index >40) Alcoholism/drug abuse

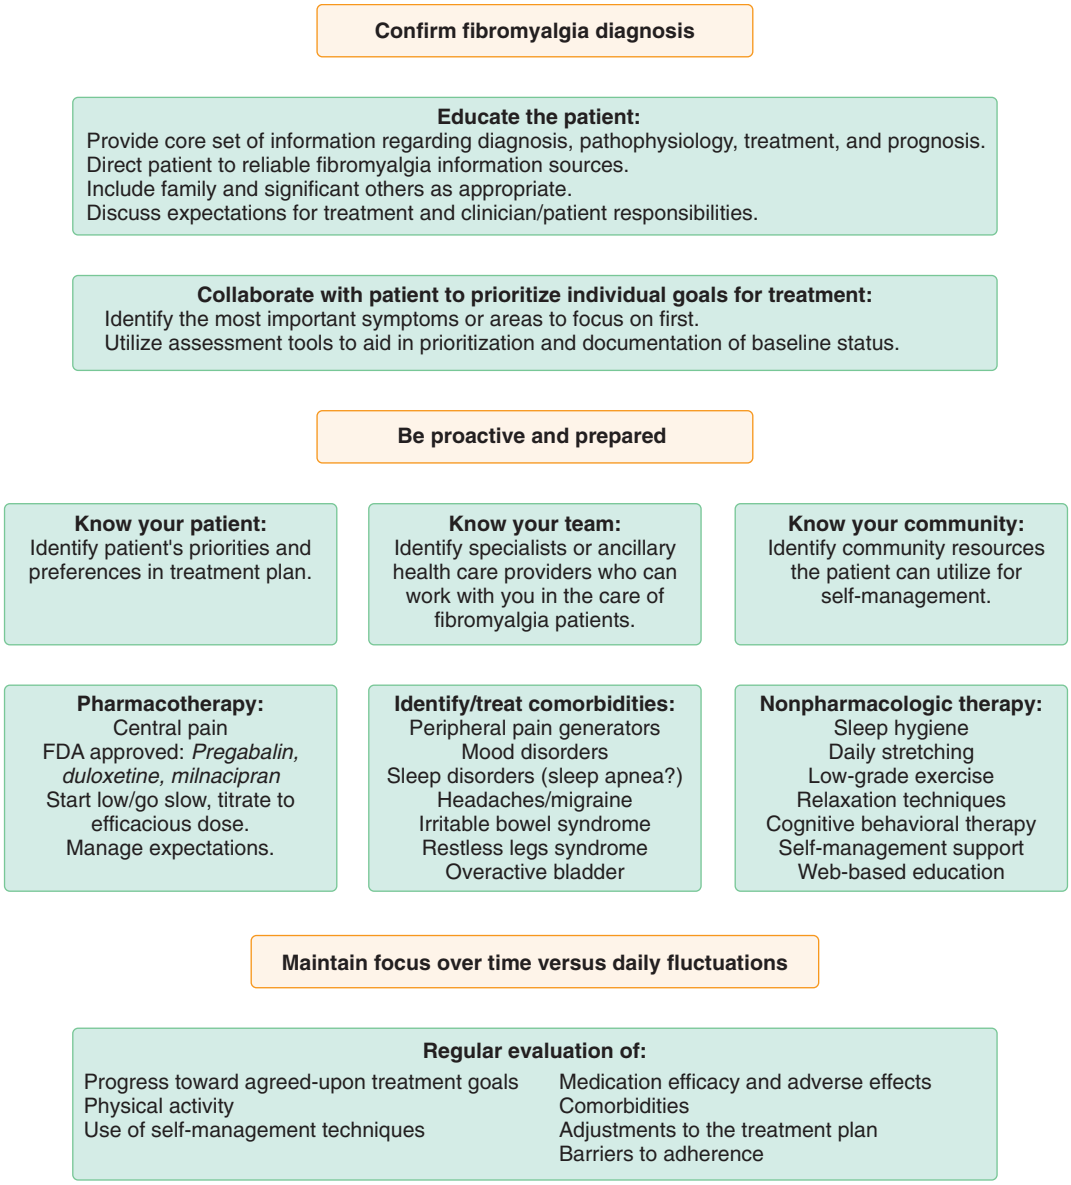

FIGURE 274-3. Management algorithm for treatment of fibromyalgia. (Adapted from Arnold LM, Clauw DJ, Dunegan LJ, Turk DC. A framework for fibromyalgia management for primary care providers. *Mayo Clin Proc.* 2012;87[5]:488-496.)

In these patients, short-acting benzodiazepine-like medications such as zolpidem, zapelon, and eszopiclone may be beneficial. Sodium oxybate is proving to be a useful medication in improving the nonrestorative sleep of FM. About 25% of male and 15% of female FM patients have sleep apnea (Chapter 405), which usually requires treatment with continuous positive airway pressure or surgery. By far the most common sleep disorder in FM patients is restless legs syndrome or periodic limb movement disorder. Treatment is with dopamine agonists such as L-dopa/carbidopa, pramipexole, or ropinirole.

Psychological Distress

Stressors related to psychosocial/economic and health issues often develop in FM patients. Psychological intervention in terms of improving the internal locus of control and more effective problem solving is important in such patients. Cognitive-behavioral therapy is particularly well suited to effect these changes, although it does not affect pain. Although antidepressant medications are commonly used in the treatment of pain and disordered sleep in FM patients, the doses are often suboptimal for treating depressive illness.

Deconditioning

FM is invariably aggravated by excessive exertion. However, a carefully graded program of aerobic conditioning and stretching is a critical component of an effective FM treatment program. Daily stretching, progressive walking, and simple strength training have been shown to be an important component of FM treatment. In general, exercise needs to be incrementally added to the program *after* some control of pain, sleep, and depression has been achieved.

Endocrine Dysfunction

There is no good evidence that FM is primarily due to an endocrine disorder. However, common problems such as hypothyroidism and menopausal symptoms often aggravate pain and fatigue, and appropriate replacement therapy is frequently worth a trial. A subset of fibromyalgia patients have adult growth hormone deficiency and show a worthwhile response to growth hormone therapy.

PROGNOSIS

FM symptoms usually persist for many years. A 5-year longitudinal study of 1550 FM patients undergoing standard treatment by U.S. rheumatologists reported substantial improvement in 10%, moderate improvement in 15%, and a worsening of symptoms in 39%. The majority of patients continued with high levels of self-reported symptoms and distress, with about 25% having a trend toward improvement.[8] In general, recommended medications can be expected to effect a 30% improvement in about 30% of patients. Difficulty in accepting an FM diagnosis, hypervigilance, high levels of psychological distress, and poor social support are poor prognostic factors. The consequences of pain, fatigue, and cognitive dysfunction negatively influence the sustained performance of physical and mental tasks. Everyday activities

From Nacul LC, Lacerda EM, Pheby D, et al. Prevalence of myalgic encephalomyelitis/chronic fatigue syndrome (ME/CFS) in three regions of England: a repeated cross-sectional study in primary care. *BMC Med.* 2011;9:91.

take longer for FM patients, who need more time to get started in the morning and often require extra rest periods during the day.

CHRONIC FATIGUE SYNDROME

CFS, also referred to as myalgic encephalomyelitis (ME), is a poorly understood disorder characterized by a subacute onset of disabling fatigue and other defining symptoms (Table 274-2).[9] There are no conclusive diagnostic tests or generally effective treatments.

EPIDEMIOLOGY

Fatigue is a common symptom; indeed, some 50% of individuals report "feeling fatigued" in population surveys. Fatigue is one of the most common problems reported to primary care doctors. In a series of 1000 consecutive patients seen in primary care, 8.5% reported debilitating fatigue lasting 6 months or longer without apparent cause; only 15% satisfied the clinical definition for CFS shown in Table 274-3. In many cases, fatigue is self-limited, or the causes are self-evident (e.g., insufficient rest, a medical illness, depression, or insomnia). On the other hand, well-documented CFS is relatively rare, with a frequency of 0.006 to 3.0% in various population surveys. CFS is diagnosed predominantly in women aged 30 to 55 years. They are typically highly functional before the onset of the illness.

PATHOBIOLOGY

The cause of CFS remains poorly defined. There are many reports linking CFS with chronic infections; most have not stood up to careful scrutiny. Although many CFS patients complain of nonrestorative sleep, polysomnographic studies have been inconclusive (Chapter 405). The similarity between CFS and early Addison disease has prompted numerous neuroendocrine studies. They have failed to show a clinically treatable endocrine deficiency. About 30% of CFS patients have abnormal results on tilt-table testing with evidence of autonomic dysfunction in terms of neurally mediated hypotension or postural orthostatic tachycardia syndrome. This may be of relevance

TABLE 274-3 1994 CFS INTERNATIONAL STUDY GROUP CRITERIA

A diagnosis of CFS requires the following features:

1. Persistent chronic fatigue (at least 6 months) or intermittent, unexplained chronic fatigue, which relapses, or with a definite start, and is not the result of recent exertions. The fatigue is not improved by rest and results in a significant reduction in the patient's previous level of activity.
2. Exclusion of other diseases that may cause chronic fatigue *plus* four of the following eight minor criteria that have been present concurrently for 6 months or longer, after the onset of fatigue:
   - A. Recently impaired memory or concentration.
   - B. Pain on swallowing
   - C. Painful axillary or cervical lymph nodes
   - D. Muscle pains
   - E. Joint pain without swelling
   - F. Headache with a new pattern or increased severity
   - G. Sleep that does not improve after rest
   - H. Postexertional discomfort lasting more than 24 hours

From Morris G, Maes M. Case definitions and diagnostic criteria for myalgic encephalomyelitis and chronic fatigue syndrome: from clinical-consensus to evidence-based case definitions. *Neuro Endocrinol Lett.* 2013;34(3):185-199.

in a subpopulation of patients, but treatment with fludrocortisone was of no benefit in one large placebo-controlled study. Many studies have suggested a low level of immune stimulation in CFS, the most common abnormalities being reduced natural killer cell function and increased numbers of cytotoxic T cells. However, these findings are not diagnostically useful, and clinical improvement has not been associated with any significant change in immune markers. Extensive psychological testing in CFS patients has failed to reveal a common psychiatric denominator. MRI studies[10] have reported significant reductions in gray-matter volume, which are consistent with the complaint of impaired memory; they also suggest subtle abnormalities in visual processing and discrepancies between intended actions and consequent movements (E-Fig. 274-1).[11]

CLINICAL MANIFESTATIONS

The chief complaint is an abrupt onset of debilitating fatigue that causes significant impairment in daily activities, work ability, and social relationships. Typically, these patients report excellent health status just before the onset of fatigue, which is often preceded by a flulike prodrome. Symptoms suggestive of an infectious etiology include low-grade fever, night sweats, tender cervical lymph nodes, sore throat, myalgias, and headaches. As in FM, many CFS patients complain of generalized musculoskeletal pain, cognitive dysfunction, irritable bowel syndrome, temporomandibular pain disorders, nonrestorative sleep, and multiple chemical sensitivities (see Table 274-2).

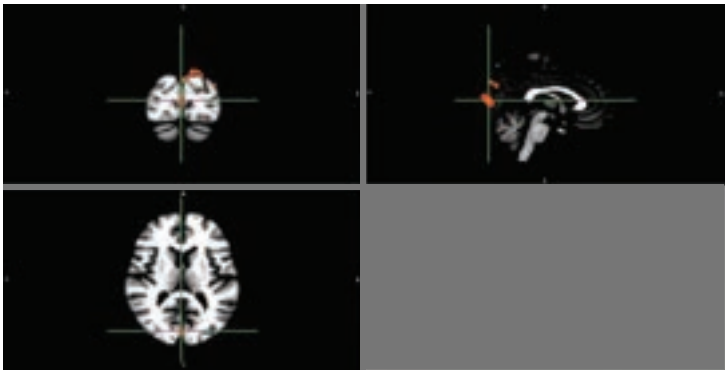
DIAGNOSIS

There are several definitions of CFS; this has led to different clinical descriptions depending on the criteria used. The most widely used criteria are the 1994 CFS International Study Group Criteria.[12] Whereas the definition of FM contains no exclusionary criteria, the definition of CFS excludes patients with fatiguing medical disorders such as melancholic depression, psychotic disorders, substance abuse, and severe obesity (body mass index >40). Because CFS is not a diagnosis of exclusion, it is important to systematically evaluate the patient for treatable causes of fatigue (see E-Table 274-1).

TREATMENT

Rx

Currently, there is no generally accepted pharmacologic intervention for patients with CFS. Antidepressants (HCAs and SSRIs) are of minimal benefit, although two studies have reported modest benefit with the use of monoamine oxidase inhibitors in patients with significant vegetative symptoms. Patients with presumed CFS should have a general medical work-up to exclude treatable causes of fatigue (e.g., sleep apnea, hypothyroidism, chronic infection, anemia, orthostatic hypotension). Patients with poorly defined chronic illnesses require affirmation that they have a real illness and that the clinician will provide them with ongoing empathetic care. Education is a critical component in managing CFS; acceptance of having a chronic disorder, avoidance of catastrophizing, and adoption of activity pacing are important facets of



E-FIGURE 274-1. Regional gray- and white-matter volumetric changes in chronic fatigue syndrome. High-resolution structural 3T cerebral magnetic resonance images depicting voxel volume in the gray matter in chronic fatigue syndrome patients compared with healthy controls. Significantly reduced gray-matter volume *(P* < .05) was noted in the occipital lobes; left lateral occipital cortex, superior division; left primary visual cortex; right angular gyrus; and left parahippocampal gyrus. This figure shows *P*-value maps depicting clusters of gray matter volume reduction (red areas). (From Puri BK, Jakeman PM, Agour M, et al. Regional grey and white matter volumetric changes in myalgic encephalomyelitis [chronic fatigue syndrome]: a voxel-based morphometry 3 T MRI study. *Br J Radiol.* 2012;85[1015]:e270-e273.)

living with CFS[13]; such problems are often helped by cognitive behavioral therapy.[14] The mainstay of treatment is to engage the patient in a gently graded program of aerobic exercise.

PROGNOSIS

The prognosis for a full recovery varies between 0 and 37%; substantial improvement rates vary between 6 and 62%. Younger patients and those without a significant psychiatric overlay or catastrophizing have the best prognosis.

MYOFASCIAL PAIN

Pain arising from muscle is a universal human experience. In most instances, it is due to muscle *macrotrauma* (i.e., a muscle tear or sprain) or muscle *microtrauma* (i.e., injury at the sarcomere level resulting from repetitive muscle use or overexertion). After appropriate rest, the pain usually dissipates over a period of a few days to weeks. In some cases, a persistent pain focus develops that has the characteristics of a myofascial trigger point. This diagnosis should be considered if the patient complains of focal pain that is aggravated by muscle use or psychological stressors that cause increased muscle tension. Myofascial trigger points often play a role in poorly characterized focal pain syndromes such as low back pain, jaw pain, pelvic pain, and headache.[15]

A myofascial trigger point is a well-defined point of focal tenderness within a muscle (Fig. 274-4). Palpation usually reveals a ropelike induration referred to as a "taut band." In many instances, firm palpation of this area causes pain in a referred distribution that reproduces the patient's symptoms. Importantly, referred pain from a trigger point does not follow a nerve root distribution (i.e., it is not dermatomal). Trigger points frequently cause dysfunction in terms of a restriction in range of movement and weakness; the involved muscle or muscles often demonstrate easy fatigability (Table 274-4).

Electromyographic recordings from trigger points show spontaneous low-voltage activity resembling end-plate spike potentials. In normal muscle, depolarization of the motor end plate initiates the release of calcium ions from the sarcoplasmic reticulum, which in turn results in activation of the myosin-actin contractile elements ("contraction coupling"). It is thought that the areas of electrical hyperexcitability in trigger points result from a nonphysiologic focal contraction caused by an influx of calcium ions into the damaged sarcomeres. If this process is not "switched off," excessive utilization of adenosine triphosphate may result in a focal energy crisis in the injured muscle and thus perpetuate the problem. Functional MRI studies have confirmed the hyperalgesic features of myofascial trigger points in terms of increased activity of brain regions involved in processing stimulus intensity and negative affect. Microdialysis of trigger point foci have shown, compared with adjacent muscle, a more acidic pH and an increase of inflammatory cytokines, bradykinin, substance P, and calcitonin gene–related peptide.

Factors commonly cited as predisposing to trigger point formation include deconditioning, poor posture, repetitive mechanical stress, mechanical imbalance (e.g., leg length inequality), joint disorders, and nonrestorative sleep. The muscle pain experienced by FM patients is often the result of pain originating from myofascial trigger points and amplified by central sensitization.[16] It is hypothesized that myofascial pain is an important "peripheral pain generator" that may, in some FM patients, perpetuate and accentuate the process of central sensitization. The characteristic tender points used in FM diagnosis are in fact myofascial trigger points.

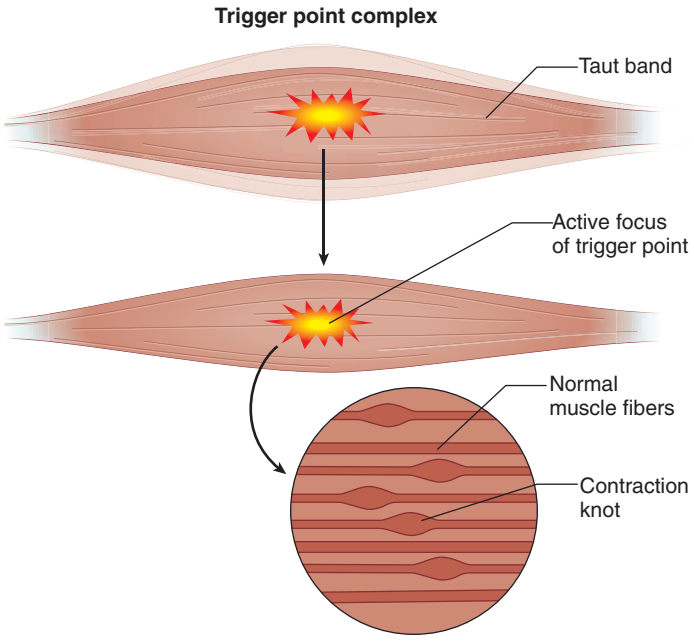


FIGURE 274-4. Schematic depiction of a myofascial trigger point. Depiction of a trigger point complex as seen in a longitudinal section of muscle. The top component represents a muscle with a taut band. The middle component represents a magnified view of the taut band containing an active trigger point focus. The lower component represents further magnification of the taut band and trigger point focus showing contraction knots (contracted sarcomere units). It is envisaged that these contraction knots are responsible for the nodularity of the taut band. Effective needling of myofascial trigger point requires piercing each contraction knot within the taut band. (From Bennett R. Myofascial pain syndromes and their evaluation. *Best Pract Res Clin Rheumatol.* 2007;21:427-445.)

TREATMENT

Rx

Management of myofascial trigger points is based on the following principles:

Postural and Ergonomic

An important issue in the effective management of myofascial pain syndromes is correction of predisposing factors (see earlier). These factors interfere with the ability of the muscle to fully recover and are the most common reason for treatment failure.

Stretching

Restoration of a muscle to its full stretch length breaks the link between the energy crisis and contraction of injured sarcomeres (see earlier). Commonly used stretching techniques include spray and stretch with ethyl chloride, acupressure, post-isometric relaxation, and deep stroking massage.

Strengthening

Muscles harboring trigger points usually become weak because of the inhibitory effects of pain. A program of slowly progressive strengthening is essential to restore full function and minimize the risk for recurrence and perpetuation of satellite trigger points.

Trigger Point Injections

Needling the myofascial trigger point with a "peppering technique" often provides a worthwhile and long-lasting benefit. Although dry needling is effective, the use of a local anesthetic (1% lidocaine or 1% procaine) helps confirm the accuracy of the injection and provides immediate relief. Validation of the accuracy of the injection is suggested by the patient's report that the pain is reproduced on entry of the needle into the trigger point; in superficial muscles a local twitch response may be observed, and this provides further evidence of an accurate injection.

Medications

Treatment of myofascial trigger points is mainly nonpharmacologic. Nonsteroidal anti-inflammatory drugs and other analgesics often provide moderate symptomatic relief. As in FM, drugs that modulate pain at the central level are a useful adjunct in difficult-to-treat patients, especially if central sensitization is suspected.

FUTURE DIRECTIONS

Both FM and CFS represent a major challenge to modern medicine in understanding a constellation of common, often disabling symptoms that originate

TABLE 274-4 DIAGNOSTIC FEATURES OF A MYOFASCIAL TRIGGER POINT

- Focal point of tenderness on palpation of the muscle involved
- Reproduction of pain complaint by trigger-point palpation (about 3-kg pressure)
- Palpation reveals an induration of the adjacent muscle (the "taut band")
- Often pseudo-weakness of the muscle involved (no atrophy)
- Often referred pain on continued (at least 5 seconds' duration) pressure over trigger point

within the central nervous system but cannot be explained in terms of a classic psychological disorder. The central sensitization demonstrated in FM patients has provided important insight into the physiologic basis for the complaint of widespread pain, but no such breakthrough has occurred in the comprehensive understanding of fatigue in either FM or CFS. Current research suggests that both these conditions have a genetic predisposition that interacts with environmental insults such as infections, trauma, myofascial foci, and psychological stressors. In the next few years, epigenetic studies should start to unravel the complex interaction of environment and genes. Both these disorders are prime examples of the need to integrate the classic biomedical model of disease with psychosocial influences (i.e., the biopsychosocial model of disease).

REVIEW QUESTIONS

1. A 45-year-old woman presents with a 2-year history of pain and swelling in her hands and aching muscles. Which of the following is the most likely diagnosis?

A. Rheumatoid arthritis
B. Fibromyalgia
C. Systemic lupus erythematosus
D. Hand osteoarthritis with concomitant fibromyalgia
E. Dercum disease

Answer: D Hand osteoarthritis is especially common in women, as is fibromyalgia. Although fibromyalgia patients often complain of joint swelling, this is never observed clinically. Thus, the most likely diagnosis is a combination of fibromyalgia and hand osteoarthritis. Early rheumatoid arthritis can have this presentation, but after 2 years, other joints, especially the feet, would be symptomatic. Dercum disease is a rare disorder characterized by multiple painful lipomas.

2. A 47-year-old woman presents with a 2-year history of pain and stiffness in her right shoulder without swelling. She has a full range of motion in the shoulder but has pain when stretching forward. She reports that she feels a "bump" in the upper shoulder muscles. Which of the following is the most likely diagnosis?

A. Polyarteritis nodosa
B. Fibromyalgia
C. A focal myofascial trigger point
D. Fibrosarcoma of the trapezius muscle
E. Polymyositis

Answer: C This is the typical presentation of a myofascial trigger point in the shoulder girdle muscles. The pain associated with myofascial trigger points is aggravated by full range of motion. Most patients with myofascial pain problems are aware of a "tight knot" in the involved muscles. Polymyositis is a generalized autoimmune disorder of muscle that usually presents as proximal muscle weakness; pain is seldom a major symptom.

3. Chronic fatigue syndrome (CFS) has a population prevalence of which of the following?

A. 2%
B. 8 to 10%
C. Less than 1%
D. 0.001% to 0.003%
E. 4 to 8%

Answer: C CFS is less prevalent than fibromyalgia, which has a prevalence of about 2% in the general population. However, most population studies in CFS report a prevalence of 0.006 to 3.0%. This is in contradistinction to a complaint of fatigue, which is one of the most common symptoms seen by family doctors.

4. The clinical features of myofascial trigger points often include all *except* which of the following?

A. Pain referred distally when the trigger point is palpated for 1 second
B. Pain referred distally when the trigger point is palpated for between 5 and 10 seconds
C. Restricted movement in involved muscle
D. A tight "knot" in the involved muscle
E. Pseudo-weakness of the involved muscle

Answer: A A critical clinical feature of a myofascial trigger point is distally referred pain after about 5 or more seconds of steady pressure over the tight knot. A common mistake in evaluating myofascial trigger points is to just prod them without exerting prolonged pressure. The patient needs to be asked to report pain or discomfort occurring in an area outside the tight knot during palpation; this referred pain is usually distal to the trigger point. This feature is even more marked when a trigger point is needled.

275

SYSTEMIC DISEASES IN WHICH ARTHRITIS IS A FEATURE

STERLING G. WEST

Arthritis, arthralgias, and myalgias can be significant features of several systemic diseases and may be the presenting symptoms for some of these disorders (Table 275-1). Appropriate evaluation of these musculoskeletal symptoms, including selected laboratory tests and radiographs, can provide clues to the early diagnosis of these diseases. Synovial biopsies are rarely necessary but can be diagnostic. Brief descriptions of the arthritic manifestations of some of these systemic disorders follow; a more detailed discussion of each entity is found in the chapters devoted to these diseases. Because of the rarity of many of these diseases, evidence-based treatments with U.S. Food and Drug Administration–approved medications are lacking.

TABLE 275-1 SYSTEMIC DISEASES ASSOCIATED WITH ARTHRITIS

DISEASE	TEST*
GASTROINTESTINAL DISEASES	
Autoimmune hepatitis	Liver-associated enzymes, *ASMA*
Primary biliary cirrhosis	Alkaline phosphatase, *antimitochondrial Ab*
Pancreatitis-arthritis syndrome	Lipase, amylase, *abdominal CT scan*
Whipple's disease	*Tissue biopsy, tissue immunohistochemical stain for Tropheryma whippelii, PCR for T. whippeli DNA*
Gluten-sensitive enteropathy	*Antitransglutaminase antibody, small bowel biopsy*
Inflammatory bowel disease	Stool guaiac, *colonoscopy*
Hepatitis B/hepatitis C	Liver-associated enzymes, *hepatitis serology, cryoglobulins*
Intestinal bypass arthritis	*Cryoglobulins*
HEMATOLOGIC DISORDERS	
Hemophilia	PTT, *factor VIII and IX levels*
Hemoglobinopathies	CBC, *hemoglobin electrophoresis*
Hypogammaglobulinemia	Low total protein, *SPEP, immunoglobulins*
Plasma cell dyscrasias	High total protein, *SPEP, UPEP, IEF*
ENDOCRINE DISORDERS	
Diabetes mellitus	Glucose, *hemoglobin* A_{1c}
Thyroid disorders	TSH, *thyroxine*
Parathyroid disorders	Calcium, phosphorus, *PTH*
Acromegaly	Radiographs, *growth hormone, IGF-1*
Hyperlipoproteinemia	Lipid panel
Paget's disease	Bone-specific alkaline phosphatase, radiographs, *bone scan*
MALIGNANT DISORDERS	
Hypertrophic osteoarthropathy	Radiographs (hands, wrists, chest)
Leukemia and lymphoma	CBC, LDH, *bone marrow/tissue biopsy*
Carcinomatous polyarthritis	*Cancer screen*
Palmar fasciitis and arthritis	*CA-125, pelvic CT scan, cancer screen*
OTHER DISEASES	
Hemochromatosis	Iron studies, radiographs, *HFE gene*
Multicentric reticulohistiocytosis	Radiographs, *skin/synovial biopsy*
Sarcoidosis	Chest radiograph, *ACE level, tissue biopsy*
IgG4-related disease	Serum IgG4 level, *histopathology of biopsy specimens including IgG4 immunostaining*
Alkaptonuria	Radiographs, *urine homogentisic acid level*
Fabry's disease	Angiokeratomas, *α-galactosidase A level or gene mutation*
Relapsing polychondritis	*Cartilage biopsy*
Cystic fibrosis	Chest radiograph, *sweat chloride, CFTR gene mutation*
Tenosynovial giant cell tumor: diffuse type (diffuse pigmented villonodular synovitis)	Synovial fluid analysis, *MRI, synovial biopsy*
Systemic infections	Cultures, serologies (RPR, HIV, EBV, parvovirus)

*Tests listed are common laboratory tests and radiographs that are frequently ordered; this information should provide a clue that a systemic disease is a possible cause of the patient's musculoskeletal symptoms. These tests, coupled with the history and physical examination, should be followed by more specific tests and biopsies (listed in italics) to confirm the diagnosis.
Ab = antibody; ACE = angiotensin-converting enzyme; ASMA = anti–smooth muscle antibody; CBC = complete blood cell count; CFTR = cystic fibrosis transmembrane conductance regulator; CT = computed tomography; EBV= Epstein Barr virus; HIV = human immunodeficiency virus; IEF = immunoelectrophoresis; IGF-1= insulin-like growth factor-1; IgG4 = immunoglobulin G4; LDH = lactate dehydrogenase; MRI = magnetic resonance imaging; PCR = polymerase chain reaction; PTH = parathyroid hormone; PTT = partial thromboplastin time; RPR = rapid plasmin reagin; SPEP = serum protein electrophoresis; TSH = thyroid-stimulating hormone; UPEP = urine protein electrophoresis.

AUTOIMMUNE HEPATITIS

Patients with type I autoimmune hepatitis (Chapter 149) may present with a syndrome resembling systemic lupus erythematosus (SLE; Chapter 266). Patients with the early-onset subset are frequently young and female, with complaints of polyarthralgia and occasionally fever. Laboratory examination may show leukopenia, a positive antinuclear antibody (70 to 90%), elevated erythrocyte sedimentation rate, polyclonal gammopathy, and elevated liver-associated enzymes. Antibodies against double-stranded DNA are usually not seen, whereas antibodies against the smooth muscle antigen (F1 actin) support the diagnosis. Joint radiographs show soft tissue swelling without erosions or deformity. Joint pain resolves with corticosteroid therapy for the liver disease. Patients with autoimmune hepatitis have an increased risk for having a concurrent autoimmune disease.[1]

PRIMARY BILIARY CIRRHOSIS

Up to 50% of patients with primary biliary cirrhosis (Chapter 155) have other autoimmune disorders, including rheumatoid arthritis (RA), Sjögren's syndrome, limited scleroderma, and autoimmune thyroiditis.[2] In addition to antimitochondrial antibodies, rheumatoid factor, antinuclear antibodies, and anticentromere antibodies are often present. More than 10% of patients with primary biliary cirrhosis have a symmetrical or asymmetrical small joint inflammatory arthritis. Unlike RA, it can involve distal interphalangeal joints and is rarely erosive or deforming. Other musculoskeletal manifestations include osteomalacia related to vitamin D deficiency, osteoporosis related to renal tubular acidosis, and hypertrophic osteoarthropathy associated with liver disease.

WHIPPLE'S DISEASE

An inflammatory arthritis occurs in 60 to 90% of patients with Whipple's disease (Chapter 140) and may precede other clinical manifestations by years.[3] The joint involvement is typically an intermittent, migratory oligoarthritis affecting large joints more than small joints or the spine, lasting from several hours to days. The synovial fluid is inflammatory, with a

predominance of mononuclear cells. Subcutaneous nodules are occasionally seen, contributing to an erroneous diagnosis of rheumatic fever or RA. However, patients consistently test negative for rheumatoid factor and antinuclear antibodies. Synovial biopsies show rod-shaped bacilli on electron microscopy, which have been identified as *Tropheryma whipplei*. Diagnosis is suspected when duodenal, synovial, or lymph node biopsies show periodic acid–Schiff–positive macrophages. Infection is confirmed by demonstration of the organism in tissue by immunohistochemical staining with antisera specific for *T. whipplei*. Quantitative polymerase chain reaction to detect *T. whipplei* DNA is used as a confirmatory test performed on tissue and body fluids. Typically, the arthritis does not cause radiographic changes or deformities. Prolonged antibiotic therapy results in resolution of musculoskeletal as well as other symptoms of this disease. Relapses, especially neurologic, can occur in up to 35% of patients after cessation of antibiotic therapy.

GLUTEN-SENSITIVE ENTEROPATHY (CELIAC DISEASE)

An asymmetrical oligoarthritis or symmetrical polyarthritis occurs in up to 25% of adults with celiac disease (Chapter 140). It may precede the enteropathic symptoms by months to years. Large joints such as knees and ankles, more than hips and shoulders, are most commonly involved. Axial involvement is reported. The arthritis does not cause deformities or radiographic changes and resolves with a gluten-free diet in 40 to 50% of cases. Another musculoskeletal manifestation is osteomalacia related to vitamin D malabsorption, which may mimic diffuse fibromyalgia.

PANCREATITIS-ARTHRITIS SYNDROME

Pancreatic panniculitis is a systemic syndrome occurring in some patients with pancreatic acinar cell carcinoma and less commonly in patients with pancreatitis or hematologic malignancies. This syndrome is characterized by tender red nodules, usually on the extremities; these are frequently misdiagnosed as erythema nodosum, but biopsy shows areas of lobular panniculitis with fat necrosis. Arthritis occurs in 60% of patients and usually involves the ankles and knees. Synovial fluid is typically noninflammatory and creamy in color. It contains multiple lipid droplets because of necrosis of fat in the synovial membrane. Other manifestations include osteolytic lesions (10%) from bone marrow fat necrosis, pleuropericarditis, fever, and eosinophilia. The prominent fat necrosis is due to the release of lipase, amylase, and trypsin from the diseased pancreas. Another musculoskeletal manifestation resulting from pancreatic disease is osteomalacia from vitamin D deficiency related to malabsorption.

HEMOPHILIA

Hemophilia A (factor VIII deficiency) and hemophilia B (factor IX deficiency) (Chapter 174) are associated with hemarthrosis.[4] Almost all patients with factor levels less than 1% of normal experience recurrent hemarthroses spontaneously or after minor trauma. Large joints (knees, elbows, ankles) are most commonly involved. Intramuscular hemorrhage can also occur. Recurrent hemarthrosis can lead to proliferative synovitis and cartilage degradation, resulting in both erosive and degenerative changes on radiographs. Physical examination shows bone enlargement, crepitus, atrophic muscles, and joint contractures. Treatment of acute monoarthritis consists of factor replacement to achieve a level of 30% or greater, given at the first sign of joint swelling. Patients with fever (temperature >38° C) or who fail to respond to factor replacement need joint aspiration to rule out septic arthritis, which occurs with an increased incidence in hemophilia. Chronic arthritis is treated with nonsteroidal anti-inflammatory drugs (NSAIDs), which do not inhibit platelet function; arthroscopic or radiation synovectomy for chronic synovitis; and total joint arthroplasty for end-stage joint disease. The regular prophylactic administration of factor replacement has reduced the risk for developing chronic arthropathy. Acute and chronic arthritis is less frequent and less severe in patients with hemophilia B compared with hemophilia A.

HEMOGLOBINOPATHIES

Patients with sickle cell anemia (Chapter 163) or the heterozygous states of sickle β-thalassemia and sickle–hemoglobin C disease frequently experience polyarthralgia. Local sickling of cells leads to obstruction of the microcirculation and to bone infarctions. Patients most commonly experience painful crises causing chest, back, and joint pain. A painful large joint arthritis (usually in the knees), often with noninflammatory synovial effusions, lasting days to 2 to 3 weeks can also occur. Infarcts in the metaphyses of bones are commonly found on joint radiographs. Vertebral bodies have a characteristic "Lincoln log" appearance or a central cuplike indentation ("codfish vertebrae"). Femoral and humeral head osteonecrosis can occur in up to 33% of sickle cell anemia and sickle–hemoglobin C disease cases. Because of splenic autoinfarction, septic arthritis (*Staphylococcus aureus*) and osteomyelitis (50% caused by *Salmonella*) have been associated with sickle cell disease. In adults, gout has been reported, whereas in children younger than 2 years, an acute, painful, nonpitting swelling of the hands and feet (hand-foot syndrome) associated with fever and leukocytosis may be the first manifestation of sickle cell anemia. Treatment includes intravenous hydration, oxygen, and analgesics. Hydroxyurea can reduce the frequency of painful crises. In patients with β-thalassemia major (Cooley's anemia; Chapter 162), significant expansion of bone marrow develops as a result of increased erythroid precursors, leading to osteoporosis and microfractures that affect primarily the lower extremities. Chelation therapy with deferiprone (to reduce iron overload from transfusions) can cause arthralgias in 20% of patients.

HYPOGAMMAGLOBULINEMIA

Patients with congenital X-linked hypogammaglobulinemia (Bruton's disease) or acquired common variable immunodeficiency (CVID; Chapter 250) can develop a nonerosive, noninfectious large joint oligoarthritis that responds to intravenous gamma globulin therapy. However, septic arthritis caused by common pathogens or *Mycoplasma* can also occur and must be rigorously excluded. In adults with acquired CVID, autoimmune conditions are also common (22%), including autoimmune cytopenias and pernicious anemia. Selective immunoglobulin A (IgA) deficiency (Chapter 250) is associated with various rheumatic manifestations, including positive autoantibodies, in the absence of clinical disease. Systemic autoimmune disorders, including SLE, juvenile idiopathic arthritis, and others, as well as organ-specific autoimmune disorders such as type 1 diabetes mellitus and myasthenia gravis, also occur in IgA-deficient individuals.

DIABETES MELLITUS

Diabetic stiff hand syndrome of limited joint mobility (diabetic cheiroarthropathy) occurs in more than 30% of patients with long-standing, poorly controlled type 1 or type 2 diabetes mellitus (Chapter 229).[5] Patients present with the insidious development of flexion contractures and thickened skin of the fingers, which may be confused with scleroderma. These changes may be due to excess glycosylation of tendinous structures and accumulation of sugar alcohols, producing excess water content in the tissues and leading to increased stiffness. As a result of the inability to extend the fingers fully, the "prayer sign" is observed on physical examination. Unlike diabetic stiff hand syndrome, Dupuytren's contractures are due to a chronic thickening of the palmar aponeurosis, causing flexion deformities of the third and fourth digits. It is a frequent musculoskeletal complication, occurring in more than 20% of type 2 diabetic patients. A less common manifestation is Charcot's, or neuropathic, joints, occurring in less than 1% of all patients with long-standing diabetes. All patients have a diabetic peripheral neuropathy and typically present with painless swelling of the feet caused, most commonly, by destruction of the tarsometatarsal joints. Deformities can occur with midtarsal collapse ("rocker bottom" feet), predisposing to ulceration and infection of the skin over desensate bony prominences. Radiographs are diagnostic, and treatment should include supportive footwear and protected weight bearing.

Unlike Charcot's joint, diabetic osteolysis and diabetic amyotrophy are unique to diabetes. The osteolysis is characterized by resorption of the distal metatarsal bone and proximal phalanges of the feet, giving radiographs a characteristic "licked candy" appearance. Pain is variable, and treatment is conservative because the process may terminate on its own. Diabetic amyotrophy is a lumbar polyradiculopathy (L2 to L4) that arises with severe pain, dysesthesias, and rapid atrophy of the proximal muscles of one or both thighs. Carpal tunnel syndrome (25%), adhesive capsulitis of the shoulder (frozen shoulder), flexor tenosynovitis (trigger finger) of the hands, diffuse idiopathic skeletal hyperostosis (type 2 diabetes), osteopenia (type 1 diabetes), diabetic muscle infarction (usually of the thigh), osteomyelitis of the foot, and septic joints are all musculoskeletal conditions that occur with increased frequency in diabetic patients. Aggressive control of blood glucose helps prevent some of these musculoskeletal complications.

THYROID DISORDERS

Musculoskeletal symptoms occur in 33% of patients with clinical hypothyroidism (thyroid-stimulating hormone levels >20 μU/mL) (Chapter 226). Patients can present with carpal tunnel syndrome, Raynaud's phenomenon, or muscle aching and stiffness similar to fibromyalgia and polymyalgia

rheumatica. Patients with severe hypothyroidism can experience a noninflammatory myopathy with proximal muscle weakness and elevated creatine kinase, which may be confused clinically with polymyositis. Similarly, myxedematous patients can develop a symmetrical arthropathy of the large joints, especially the knees, associated with noninflammatory synovial fluid with increased viscosity. The association of hypothyroidism with chondrocalcinosis is controversial, but clearly patients beginning thyroid replacement therapy can experience an acute attack of pseudogout. Patients with hyperthyroidism can develop proximal myopathy (70%), adhesive capsulitis of the shoulder (10%), osteoporosis, or thyroid acropachy. Thyroid acropachy occurs in less than 1% of patients with Graves' disease and consists of soft tissue swelling of the hands, digital clubbing, and periostitis, particularly involving the metacarpal and phalangeal bone shafts. Pain is usually mild, radiographs are characteristic, and there is no effective therapy. Patients with autoimmune thyroid disease have an increased prevalence of positive antinuclear antibodies and an increased association with systemic connective tissue diseases such as Sjögren's syndrome.

PARATHYROID DISORDERS

Primary hyperparathyroidism (Chapter 245) can develop with osteoporosis and fractures or with chondrocalcinosis and episodes of acute pseudogout.[5] In severe hyperparathyroidism, which is rare, vague myalgias and arthralgias resembling fibromyalgia; a reversible, painless, proximal myopathy with normal creatine kinase; and osteitis fibrosa cystica with bone pain can be seen. Osteitis fibrosa cystica occurs primarily in patients with secondary hyperparathyroidism associated with renal failure and has a characteristic radiographic appearance, with subperiosteal resorption on the radial side of the phalanges, small erosions in the hands and distal clavicles, and discrete lytic bone lesions (brown tumors). Ectopic calcifications, joint laxity, and tendon ruptures have been reported in patients with severe hyperparathyroidism. Hypoparathyroidism has also been associated with myopathy and ectopic calcifications. Patients with type Ia pseudohypoparathyroidism and pseudo-pseudohypoparathyroidism have a shortened fourth metacarpal bone bilaterally.

ACROMEGALY

Up to 75% of patients with acromegaly (Chapter 224) develop an atypical form of osteoarthritis. The knees, shoulders, hips, and lumbosacral and cervical spine are the most frequently symptomatic areas, although the hands reveal the most characteristic radiographic changes, with widened joint spaces due to cartilage hypertrophy. Carpal tunnel syndrome (50%), Raynaud's phenomenon (33%), and proximal muscle weakness with normal creatine kinase can also occur.

HYPERLIPOPROTEINEMIA

Type IIa familial hyperlipidemia (Chapter 206) is associated with tendinous and tuberous-osseous xanthomas as well as episodic Achilles tendinitis. An acute migratory, inflammatory arthritis persisting up to a month and resembling rheumatic fever occurs in up to 50% of patients. Predominantly large joints are affected. In addition, a self-limited, acute monoarticular or oligoarticular arthritis involving the knee or ankle can occur. Patients with type III familial hyperlipoproteinemia can develop tendon and bone xanthomas. Patients with human immunodeficiency virus (HIV) infection taking protease inhibitor drugs can develop dyslipidemia leading to tendon xanthomas. In all hyperlipidemias, gout must be excluded before ascribing the symptoms to hyperlipoproteinemia. Therapy with NSAIDs and treatment of the underlying lipid disorder should be pursued. Notably, some of the therapies used to treat hyperlipidemia can cause musculoskeletal symptoms, including hyperuricemia and gout from nicotinic acid and myalgias (with or without elevated creatine kinase) from statin therapy.

PAGET'S DISEASE

Paget's disease (Chapter 247) can cause bone pain and deformity. An elevated bone-specific alkaline phosphatase and characteristic radiographic changes can help make the diagnosis. Joint pain caused by secondary osteoarthritis in areas of bone involvement by Paget's disease most commonly occurs in the hips, knees, or vertebrae. Spinal stenosis from Paget's disease of the spine has been reported. Bisphosphonate therapy is highly effective.

HYPERTROPHIC OSTEOARTHROPATHY

Hypertrophic osteoarthropathy is a syndrome that includes clubbing of the fingers and toes, periostitis of long bones (distal tibia, femur, radius), and arthritis (Fig. 275-1). Hypertrophic osteoarthropathy is classified into primary (hereditary) and secondary forms. Between 80 and 90% of secondary hypertrophic osteoarthropathy is associated with intrathoracic neoplasms, especially non–small cell lung cancer.[6] Other causes include other neoplasms, chronic pulmonary infections, congenital heart disease, cirrhosis, HIV infection, medications (voriconazole), and inflammatory bowel disease. Patients with secondary hypertrophic osteoarthropathy can present with acute, severe, burning bone pain and a noninflammatory arthritis caused by periarticular periostitis. Pain is accentuated by dependency of the limbs. Pitting edema, warmth, and tenderness of the legs and forearms can be seen. Radiographs show diagnostic changes of periosteal elevation, new bone formation, or both along the distal ends of long bones. Therapy is symptomatic, and hypertrophic osteoarthropathy improves with successful treatment of the underlying primary disease. In resistant cases, treatment with intravenous bisphosphonate has been effective in modulating symptoms.

LEUKEMIA AND LYMPHOMA

Leukemia can arise as an asymmetrical or migratory polyarthritis, monoarthritis (rare), back pain (10%), or nocturnal bone pain. Articular manifestations occur in 14 to 50% of children and 4 to 16% of adults with acute leukemia and can precede the diagnosis by months. Joint pain is attributed to leukemic synovial infiltration and usually involves the ankle or knee, but it can be polyarticular, resembling juvenile or adult RA. The joint pain is disproportionately more severe than the clinical findings. Synovial effusions are uncommon, and evidence of leukemic cells in the synovial fluid is rare. Bone pain due to subperiosteal leukemic cell infiltration occurs in up to 50% of patients, with long bone pain (lower extremities) more common in children and back pain more common in adults. Radiographs are normal in 50%

FIGURE 275-1. Hypertrophic osteoarthropathy. A, Severe clubbing of the nails. **B,** Radiograph demonstrating periosteal elevation of the distal radius and ulna.

of cases. The musculoskeletal symptoms are poorly responsive to NSAIDs but can resolve with successful therapy of the leukemia. Musculoskeletal symptoms occur in 25% of patients with non-Hodgkin's lymphoma. Nocturnal bone pain is the most common presenting musculoskeletal complaint. A seronegative monoarthritis or polyarthritis can occur and should be suspected in patients with severe constitutional symptoms or lymphadenopathy out of proportion to the degree of arthritis. Patients with angioimmunoblastic T-cell lymphoma (Chapter 185) may occasionally develop a chronic, nonerosive polyarthritis with erythroderma.

CARCINOMATOUS POLYARTHRITIS

Polyarthritis can rarely (<2%) be the presenting manifestation of an occult malignancy; it may precede the discovery of the malignancy by several months.[7] Breast, colon, lung, ovarian, and lymphoproliferative malignancies are the most commonly associated cancers. Clinical features suggesting carcinomatous polyarthritis include the explosive onset of a rheumatoid factor–negative, asymmetrical polyarthritis involving predominantly the lower extremities and sparing the hands and wrists in a patient older than 60 years. Polymyalgia rheumatica and RA must be excluded. Treatment of the underlying malignancy results in improvement of the arthritis.

PALMAR FASCIITIS AND ARTHRITIS SYNDROME

Ovarian carcinoma (Chapter 199) is the most common malignancy found in patients with palmar fasciitis and arthritis. This musculoskeletal manifestation can also be seen in patients with breast, gastric, or pancreatic cancer. Patients present with a severe, painful, symmetrical inflammatory polyarthritis and fasciitis causing contractures primarily of the hands and, less commonly, the feet. Patients may have vasomotor instability, causing diagnostic confusion with complex regional pain syndrome or RA. This syndrome portends a poor prognosis because it typically manifests after tumor metastasis. Response to treatment is poor, although clinical improvement can occur with successful eradication of the underlying tumor.

HEMOCHROMATOSIS

Joint involvement occurs in 40 to 75% of patients with hereditary hemochromatosis (Chapter 212) and may be the presenting symptom (Fig. 275-2).[8] The metacarpophalangeal (MCP) joints (especially the second and third MCP joints), wrists, knees, hips, shoulders, and ankles are most often involved in a symmetrical pattern. The arthropathy resembles osteoarthritis, with joint swelling resulting from bone enlargement, but it is distinguished clinically by the involvement of atypical joints, such as MCP joints, wrists, and ankles. Radiographs show joint space narrowing, subchondral cysts, sclerosis, and osteophytes that are hooklike at the MCP joints. Chondrocalcinosis is present in up to 50% of patients. It is typically asymptomatic, but in some patients it leads to attacks of acute inflammatory synovitis (pseudogout), which may result in the misdiagnosis of RA. The prevalence of overt arthritis increases with age, and it may be only minimally symptomatic when the disease arises in other organs. However, it is not uncommon for articular pain to be the initial presenting complaint (33%). Consequently, all patients (especially male) presenting with premature osteoarthritis occurring in atypical joints, especially MCP joints and wrists, should be screened for hereditary hemochromatosis with iron studies. The mechanism whereby iron causes arthritis is unclear, but it may be related to hemosiderin deposits in the synovial membrane and chondrocytes activating degradative enzymes. Treatment is symptomatic with NSAIDs and, when severe, total joint arthroplasties. Phlebotomy for iron removal does not alter the course of the arthritis. Additional rheumatic manifestations in patients with hemochromatosis include osteoporosis related to hypogonadotropic hypogonadism, osteomalacia related to vitamin D deficiency when liver disease is severe, and an increased susceptibility to *Yersinia* septic arthritis.

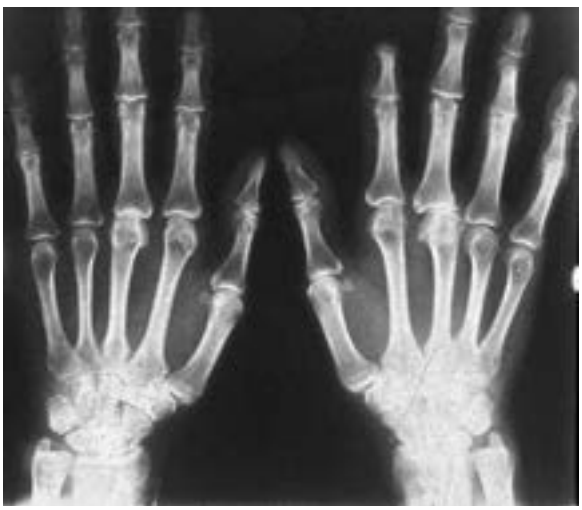

FIGURE 275-2. Hemochromatotic arthropathy. Radiograph demonstrating degenerative changes, with hooklike osteophytes of the second and third metacarpophalangeal joints bilaterally.

MULTICENTRIC RETICULOHISTIOCYTOSIS

Multicentric reticulohistiocytosis (MRH) is a chronic, symmetrical, inflammatory polyarthritis most commonly affecting the hands and cervical spine.[9] It may resemble RA but can be differentiated by its prominent distal interphalangeal joint synovitis. Joint involvement remits and relapses initially, but in 50% of cases it worsens into a severely deforming arthritis mutilans. Firm, nonpruritic, reddish brown or yellow papulonodular lesions ("coral beads") that wax and wane occur around the nail beds and on the face, hands, ears, and other areas predominantly above the waist. The skin lesions have a diagnostic histology. In 50 to 66% of patients, these diagnostic nodules follow the onset of arthritis by months to years. Additional associations include xanthelasma (33%) and malignancies of various types (25%), which may precede or follow the onset of MRH. MRH usually remits spontaneously in 8 to 10 years but often leaves permanent cutaneous and joint damage. Treatment may include methotrexate or cytotoxic therapy if the arthritis is aggressive. Anti–tumor necrosis factor-α (anti-TNF-α) therapy is reportedly beneficial in resistant cases.

SARCOIDOSIS

Joint manifestations including arthritis, periarthritis, and arthralgias occur in 4 to 38% of patients with sarcoidosis (Chapter 95).[10] Rheumatic involvement is divided into acute and chronic types. The first consists of the triad of arthritis, erythema nodosum, and hilar adenopathy on chest radiographs (Löfgren's syndrome), which may be accompanied by fever. Arthritis arises most often in the knees and ankles, and periarticular pain can be severe. Treatment is with NSAIDs, colchicine, or both, and symptoms usually remit spontaneously over several weeks. The less common type of joint involvement in sarcoidosis consists of synovitis that accompanies the slower onset, more chronic, systemic form of sarcoidosis. Polyarthritis, oligoarthritis, or monoarthritis can affect the small or large joints; it is typically nondestructive but in some cases can be aggressive. Dactylitis resulting from sarcoid bone and soft tissue involvement can occur (Fig. 275-3). In contrast to the acute type, chronic sarcoid arthropathy is characterized by mildly inflammatory synovial fluid and histologic granulomas on synovial biopsy. Treatment consists of NSAIDs, low-dose corticosteroids, hydroxychloroquine, and methotrexate or azathioprine. In refractory cases, anti-TNF-α therapy has been successful. Other musculoskeletal manifestations of sarcoidosis include lytic or sclerotic bone lesions (3 to 13%) and symptomatic acute or chronic myopathy (3%). Notably, asymptomatic lesions involving bone and muscle are much more common on magnetic resonance imaging and tissue biopsies.

IMMUNOGLOBULIN G4–RELATED DISEASE

Patients with IgG4-related disease are typically men (70 to 75%) older than 50 years. Patients present with a variety of local and systemic manifestations, some of which can resemble several rheumatic diseases (Chapter 256).[11] For example, tumefactive lesions of the salivary glands can mimic Sjögren's syndrome. Destructive sinus and middle ear lesions or periorbital masses can suggest granulomatous polyangiitis (GPA) (formerly Wegener's granulomatosis). Furthermore, patients with IgG4-related disease frequently (40%) have allergic manifestations including chronic sinusitis and pulmonary symptoms, which may add to the diagnostic confusion with GPA. IgG4-related disease can also cause an inflammatory aortitis with aneurysm formation that can be mistaken for giant cell arteritis. A fibrosclerotic presentation in the abdomen can mimic retroperitoneal fibrosis. Other organs that can be involved include the pancreas, biliary tree, kidneys, lymph nodes, meninges, thyroid, breast, prostate, pericardium, and skin. Although up to 70% of patients will have an elevated serum IgG4 level, histopathologic analysis of biopsy specimens is the "gold standard" for diagnosis. The key pathologic features are a dense lymphoplasmacytic infiltrate organized in a storiform

FIGURE 275-3. Sarcoid bone involvement. Punched-out lytic lesions of the middle phalanx, with soft tissue swelling.

pattern, obliterative phlebitis, and a mild or moderate eosinophilic infiltrate. The plasma cell infiltrate will show more than 30 IgG4-positive cells per high-power field and a ratio of IgG4 to IgG positive cells that is higher than 50%. Glucocorticoids are effective in most patients. Several medications (azathioprine, mycophenolate mofetil, methotrexate) have been used as steroid-sparing agents to maintain remission. For refractory disease, B-cell depletion therapy with rituximab is effective.

ALKAPTONURIA (OCHRONOSIS)

Although an inherited disorder, alkaptonuria is usually not diagnosed until the patient presents with progressive premature osteoarthritis as a young adult (before age 30 to 35 years). The spine is initially involved, followed by the knees, shoulders, and hips. Small peripheral joints are spared. Radiographs show multiple vacuum discs, disc space ossification, and osteoarthritic changes in the spine. Nonarticular features include bluish brown discoloration of ear pinna, sclera, and nasal cartilage. Deposition of ochronotic pigment onto collagen fibers causes the articular cartilage to become brittle and fragmented. The noninflammatory synovial fluid may show tiny shards of pigmented cartilage ("ground pepper"). The diagnosis of alkaptonuria is suspected when fresh urine turns dark brown or black on standing or with alkalinization. The diagnosis is confirmed by quantitative measurement of increased homogentisic acid in urine. A specific enzyme assay for homogentisic acid dioxygenase can also be performed. There is no effective therapy for alkaptonuria, although nitisinone is currently under investigation. The arthritis is treated symptomatically with analgesics.

FABRY'S DISEASE

Most patients with hereditary lysosomal storage diseases present and are diagnosed during childhood (Chapter 208). However, female heterozygotes and atypical variants of Fabry's disease may have a milder and later-onset phenotype. Fabry's disease is an X-linked lipid storage disease caused by a deficiency of lysosomal α-galactosidase A. Males with classic Fabry's disease usually develop neuromuscular symptoms in childhood, including painful crises with burning paresthesias of the distal extremities, often accompanied by fever. However, in female heterozygotes and males with low residual α-galactosidase A levels, disease manifestations may occur for the first time in adulthood. Neuromuscular manifestations can range from painful acroparesthesias to fibromyalgia. Progressive or isolated cardiac, cerebrovascular, and renal disease can develop later. Fabry's disease should be suspected in any patient with a paternal family history of early-onset renal failure. Patients should be examined for characteristic ocular stigmata (cornea verticillata) and dermal signs (angiokeratomas). The diagnosis is confirmed in males by determining α-galactosidase A activity in plasma or peripheral leukocytes. In contrast, female carriers must be tested for one of the specific gene mutations. Early diagnosis is important because enzyme replacement therapy can prevent irreversible organ damage.

RELAPSING POLYCHONDRITIS

Relapsing polychondritis is an uncommon multisystem disorder characterized by recurrent episodes of inflammation of cartilaginous tissues.[12] Patients with relapsing polychondritis typically present with the sudden onset of pain and erythema involving the cartilage of the external ear, larynx, trachea, or nose. A nonerosive, seronegative polyarthritis or oligoarthritis affecting small, large, or parasternal joints (23 to 47%); ocular inflammation, including episcleritis or scleritis; and audiovestibular disturbances may also be presenting symptoms. The arthritis is typically acute, migratory, and episodic and resolves spontaneously over days to weeks. Rarely, it can become chronic. Tenosynovitis is also common. Relapsing polychondritis is presumably due to a cell-mediated and humoral immune response against cartilage components; biopsies showing acute and chronic inflammation destroying cartilage support the diagnosis. Late sequelae of relapsing polychondritis include deformity of the pinnae or nose, reduced vision or hearing, tracheal narrowing or collapse, and aortic insufficiency resulting from aortic ring dilation as well as other cardiovascular abnormalities. Patients with relapsing polychondritis frequently have associated coexisting diseases, such as systemic vasculitis, various connective tissue diseases (e.g., RA), myelodysplastic syndromes and other cancers, and thyroid disease. Treatment depends on the severity of the presentation and whether major organs are involved. Mild episodes of inflammation are treated with NSAIDs, colchicine, dapsone, and low-dose corticosteroids. Life-threatening or organ-threatening complications are treated with high-dose corticosteroids and immunosuppressive agents such as methotrexate or cyclophosphamide. Infliximab and tocilizumab have been anecdotally effective in treatment-resistant cases.

CYSTIC FIBROSIS

In up to 10% of patients with cystic fibrosis (Chapter 89), an episodic, nondestructive, inflammatory oligoarthritis develops, most commonly involving the fingers and lower extremity joints. This arthritis is thought to be due to immune complex deposition caused by chronic lung infections. Attacks last for a few days and may be associated with fever and painful nodular skin lesions and purpura. Other musculoskeletal manifestations include osteoporosis (30-75%) and osteomalacia related to malabsorption and, more rarely, hypertrophic osteoarthropathy (5%) and a small vessel vasculitis.

TENOSYNOVIAL GIANT CELL TUMOR: DIFFUSE TYPE

The diffuse type of tenosynovial giant cell tumor (TGCT) (also called diffuse pigmented villonodular synovitis) occurs most commonly in the third and fourth decades of life. It is characterized by the onset of unilateral pain and swelling of a joint, typically the knee (80%). Unusually, a tendon, bursa, or another joint can be involved. The synovial fluid is characteristically brown or hemorrhagic, and radiographs may show soft tissue swelling, osteolysis, subchondral cysts, and bone erosions. TGCT is a nonmalignant condition due to a translocation between chromosomes 1p13 and 2q35 in which the gene coding for colony-stimulating factor-1 (CSF-1) is fused to the collagen VI alpha-3 gene. Up to 15% of cells in the TGCT overexpress CSF-1. The remaining cells in the tumor are inflammatory cells recruited into the tumor because they contain the receptor for CSF-1. TGCT is best diagnosed by synovial biopsy. Microscopic examination reveals a characteristic histology, including marked synovial cell hyperplasia and subsynovial invasion by masses of polygonal cells, multinucleated giant cells, and lipid-filled macrophages. Hemosiderin deposits are between and within cells and have a characteristic appearance on magnetic resonance imaging, with nodular foci of decreased signal on both T1- and T2-weighted images. The treatment for pigmented villonodular synovitis is synovectomy with or without postoperative radiotherapy.[13]

FUTURE DIRECTIONS

With the advances being made in immunology and genetics, there will be an increased understanding of the pathogenesis of many of these diseases. Treatments such as immunomodulating biologic agents or cartilage-preserving therapies will be developed on the basis of new discoveries elucidating the etiology of these unusual disorders. Because of the rarity of many of these diseases, the establishment of registries and international databases detailing clinical characteristics and response to therapies would be a valuable resource.

REVIEW QUESTIONS

1. A 30-year-old man complains of a several-months history of joint pain involving his hands, wrists, knees, and ankles. He reports chronic swelling but no acute attacks of synovitis. He has been taking up to eight acetaminophen tablets a day to control the pain. He denies rashes, nodules, pleuritic chest pain, or dyspnea. He reports no family history of arthritis. His father died of liver cancer. Physical examination is remarkable for synovial thickening over his metacarpophalangeal joints (MCPs), wrists, and ankles. He has small effusions in both knees. His skin examination shows darkened skin but no nodules. Radiographs show joint space narrowing, sclerosis, and osteophytes of his MCPs and radiocarpal joints. Which one of the following tests is most likely to support this patient's diagnosis?

A. Iron studies
B. Anti–cyclic citrullinated peptide (CCP) antibodies
C. Liver-associated enzymes
D. Urine homogentisic acid
E. Morning serum cortisol

Answer: A This patient has hemochromatotic arthropathy, which would be supported by abnormal iron studies (elevated iron, % transferrin saturation, and ferritin). Up to 33% of patients with hemochromatosis present with arthritis as their initial manifestation. Osteoarthritic involvement of MCPs, wrists, and ankles, coupled with dark skin demonstrating a grayish hue, are characteristic. The osteoarthritic changes on radiographs excludes rheumatoid arthritis, so an anti-CCP antibody would not be helpful. Although liver-associated enzymes may be elevated, other stigmata of liver disease are absent early in the course of hemochromatosis. However, the early diagnosis and treatment of this patient and affected family members will help prevent cirrhosis and possible liver cancer, which developed in his father. A urinary homogentisic acid level will be normal. Ochronosis can cause dark skin, but the arthritis presents in the lumbar spine with osteoarthritis and calcified vertebral discs. Addison's disease (primary adrenal insufficiency) likewise causes hyperpigmentation, but it is not typically associated with rheumatic manifestations.

2. A 32-year-old woman complains of painful lower extremity nodules and bilateral ankle arthritis over the past 5 days. She denies fever, sore throat, cough, chest or abdominal pain, or dysuria. Past history is significant for two urinary tract infections and one episode of pelvic inflammatory disease. She has a family history of a mother who died with ovarian cancer. Her only medication is birth control pills. Physical examination shows normal vital signs. She has bilateral swelling and tenderness of her ankles. Several 2- to 3-cm erythematous, tender nodules are on the extensor surfaces of both lower legs. The remainder of the examination is unremarkable. Which one of the following tests should be ordered now to support this patient's clinical diagnosis?

A. Nodule biopsy
B. Ankle joint synovial fluid analysis
C. Cervical culture for *Neisseria gonorrhoeae*
D. Chest radiograph

Answer: D This patient has a presentation consistent with acute sarcoidosis manifested by erythema nodosum and bilateral ankle arthritis (Sweiss NJ, Patterson K, Sawaqed R, et al. Rheumatologic manifestations of sarcoidosis. *Semin Respir Crit Care Med*. 2010;31:463-473). A person with bilateral ankle arthritis should always be investigated for possible sarcoidosis. Despite negative pulmonary symptoms, a chest radiograph will show bilateral hilar adenopathy supporting the clinical diagnosis of Lofgren's syndrome. A nodule biopsy would show a septal panniculitis consistent with erythema nodosum, which could be from a cause other than sarcoidosis such as birth control pills. Synovial fluid aspiration is usually unsuccessful and always nondiagnostic in a patient with an acute sarcoidosis presentation. A cervical culture in an asymptomatic patient is unlikely to be useful, and disseminated gonococcemia typically presents with fever, arthritis, and a vesiculopustular rash, but not nodules.

3. A 72-year-old woman complains of a 3-week history of bilateral progressive hand pain unresponsive to naproxen, prednisone, and oxycodone. She denies fever, rash, or Raynaud's phenomenon. She has had a 10-pound weight loss and lower abdominal pain that she attributes to constipation and lack of appetite owing to taking narcotics. Physical examination shows normal vital signs. She has bilateral metacarpophalangeal and proximal interphalangeal joint swelling and tenderness. She has diffuse swelling, erythema, and tenderness that follow the track of the flexor tendons of the digits. Straightening the fingers causes intense pain. Shoulder examination shows decreased internal rotation bilaterally. The remainder of the joint, heart, and lung examinations were normal. Tests obtained in the emergency room last week showed normal hand radiographs except for soft tissue swelling and chondrocalcinosis of the wrists. Rheumatoid factor and antinuclear antibody were negative. Which one of the following tests would be most important to obtain next?

A. Magnetic resonance imaging (MRI) of the hands
B. Anti–CCP antibody
C. Bimanual pelvis examination
D. Synovial fluid aspiration and crystal examination

Answer: C This patient is presenting with the palmar fasciitis and polyarthritis syndrome (PFPAS). This presentation is highly associated with ovarian cancer when it occurs in an elderly woman (Shah A, Jack A, Liu H, Hopkins RS. Neoplastic/paraneoplastic dermatitis, fasciitis, and panniculitis. *Rheum Dis Clin North Am*. 2011;37:573-592). Therefore, a bimanual pelvic examination would be the most important test to obtain. MRI of the hands will show palmar fasciitis, which was diagnosed on the clinical examination. Although rheumatoid arthritis can have an acute onset, the lack of response to nonsteroidal anti-inflammatory drugs (NSAIDs) and prednisone makes this diagnosis unlikely. In addition, the rheumatoid factor was negative, so an anti-CCP antibody is unlikely to be positive. Chondrocalcinosis is a common incidental radiographic finding in elderly patients. The multijoint presentation and lack of response to prednisone make acute pseudogout unlikely, and therefore putting the patient through a difficult aspiration of a finger joint looking for crystals is not indicated.

4. A 52-year-old man is admitted to the hospital for joint pain, diarrhea, and weight loss. He reports a 3-year history of palindromic, inflammatory polyarthritis that tends to affect large joints, including the knees, ankles, and wrists. He also has increased lower back pain that is worse at the end of the day. Previous evaluation showed a negative rheumatoid factor, negative antinuclear antibody, and normal hand and wrist radiographs. He states the arthritis lasts several weeks before resolving. NSAIDs, hydroxychloroquine, and methotrexate have been ineffective in reducing the frequency of attacks that occur every few months. Over the past 6 months, he has noted diarrhea and a 20-pound weight loss. He has had mild abdominal discomfort and a decreased appetite. Evaluation showed a normal colonoscopy 4 months ago. An abdominal computed tomography scan showed hepatomegaly and several enlarged periaortic lymph nodes. A 24-hour stool collection revealed steatorrhea. An antitransglutaminase antibody was negative. Physical examination shows a thin male with normal vital signs except a pulse of 100 beats per minute. He has mild hepatomegaly. He has a few enlarged axillary lymph nodes. His right wrist and left knee are swollen. Synovial fluid aspiration from his knee yesterday showed a cell count of 22,100/mm^3 with 80% neutrophils. Gram stain and crystal examinations were negative. Laboratory evaluation included the following:

Complete blood count: hematocrit 33%, white blood cell count 7800/mm^3, platelets normal
Chemistries: normal
Albumin: 2.7 g/dL
Aspartate transaminase: 51 U/L (normal, 0 to 40)
Urinalysis: normal
Erythrocyte sedimentation rate: 48 mm/hour

Which one of the following tests is most likely to confirm your clinical diagnosis?

A. Hepatitis C serologies
B. Esophagogastroduodenoscopy with small bowel biopsy
C. Anti–*Saccharomyces cerevisiae* antibody
D. HLA-B27 and sacroiliac joint radiograph
E. Blood culture

Answer: B This patient has Whipple's disease, which would be diagnosed by a small bowel biopsy (Puechal X. Whipple's disease. *Ann Rheum Dis.* 2013;72:797-803). Patients with Whipple's disease frequently have an intermittent inflammatory arthritis that precedes other manifestations of Whipple's disease by a few years. The patient's more recent weight loss, diarrhea with steatorrhea, hepatomegaly, and lymphadenopathy are other manifestations of Whipple's disease. The small bowel biopsy showing periodic acid–Schiff–positive macrophages and immunohistochemical staining with antisera specific for *Tropheryma whipplei* will confirm the diagnosis. A lymph node or synovial biopsy would show similar diagnostic findings. The recent normal colonoscopy rules out inflammatory bowel disease, so an anti–*Saccharomyces cerevisiae* antibody will not be helpful. Despite an enlarged liver and mild transaminitis, which are also seen in Whipple's disease, hepatitis C would not explain his steatorrhea. The patient's back pain is mechanical because it is worse at the end of the day. Therefore, an HLA-B27 test and sacroiliac joint radiographs will not confirm his diagnosis, nor will these tests explain his diarrhea. Although the patient has an inflammatory synovial fluid, septic arthritis would not follow this clinical course.

5. You are asked to consult on a 64-year-old man hospitalized for aortitis. He was emergently admitted 3 days ago with chest pain from a 6-cm descending thoracic aortic aneurysm and dissection. Pathologic examination of the surgically removed diseased aorta revealed a nongranulomatous aortitis with fibrosis. His past history includes diet-controlled diabetes mellitus and hypertension controlled with lisinopril. One year ago, he had an orbital pseudotumor successfully treated with 3 months of prednisone. He denies fever, headaches, or visual problems. Physical examination was limited because of his recent surgery. Temporal artery pulses were normal. He had atelectatic crackles in both bases. He has 1^+ pedal edema. No abdominal bruits or masses. Preoperative laboratories include the following:

Complete blood count: hematocrit 35%, white blood cell count 10,400/mm^3, platelets 280,000
Chemistries: normal
Rapid plasma reagin: negative

Aorta histology showed lymphoplasmacytic infiltrate without granulomas or giant cells. Adventitial phlebitis and fibrosis were present. Stains for spirochetes and fungal elements were negative. Which one of the following is most likely to help confirm this patient's diagnosis?

A. Genetic testing for transforming growth factor-β (TGF-β) receptor mutations
B. Antineutrophil cytoplasmic antibody
C. Immunohistochemical staining of tissue for immunoglobulin G4 (IgG4)-positive plasma cells
D. Temporal artery biopsy

Answer: C This patient has IgG4-related disease (Stone JH, Zen Y, Deshpande V. IgG4-related disease. *N Engl J Med.* 2012;366:539-551). The nongranulomatous, lymphoplasmacytic infiltrate in the aorta is consistent with this. The past history of an orbital pseudotumor is also compatible with this condition. Serum IgG4 level is typically elevated. Immunohistochemical studies would show that the aortic infiltrate was primarily IgG4-producing plasma cells. Genetic testing for TGF-β receptor mutations would not be helpful because this is not the histology seen in patients with Loeys-Dietz syndrome. Antineutrophil cytoplasmic antibody–related vasculitis does not cause aortitis. A temporal artery biopsy would offer no further information not already shown by the aortic histology.

276 SURGICAL TREATMENT OF JOINT DISEASES

C. RONALD MACKENZIE AND EDWIN P. SU

Estimates of the prevalence of arthritis and other rheumatic diseases demonstrate the enormous impact that these conditions have on the U.S. populace and the health care system in general. More than 21% of U.S. adults (46 million people) currently report physician-diagnosed arthritis. Although the majority of this health burden arises as a consequence of osteoarthritis, the full span of the rheumatic diseases contributes to the impact of this class of conditions. Already the leading cause of disability in the nation, the number of people with arthritis and arthritis-attributable limitation in activity is anticipated to approach 67 million affected adults by the year 2030. Ultimately, surgical intervention is required in many of these individuals. Factors such as an increased patient awareness of the benefits of surgery, the desire for higher activity levels, and improvements in surgical techniques have, in concert with the increasing prevalence of chronic arthritis, fueled the growth in utilization of orthopedic surgery. In 2010, it was estimated that about 300,000 primary total hip replacements and about 650,000 primary total knee replacements were performed in the United States. By the year 2020, it is predicted that about 500,000 hip replacements and 1.5 million knee replacements will be performed each year.[1]

PATHOBIOLOGY

The pathobiology of joint arthritis leading to surgical intervention is essentially that of articular cartilage damage resulting in the loss of mechanical properties, accompanied by inflammation of the joint lining. With continued cartilage deterioration, stiffness and pain ensue. Without the protective layer of articular cartilage, the nociceptive and proprioceptive receptors in the periosteum are activated, leading to unremitting pain.

Osteoarthritis is the most common cause of end-stage arthritis (Chapter 262). Osteoarthritis may be primary, due to biochemical changes in the cartilage, or secondary to systemic disease affecting the cartilage, joint damage from preexisting inflammatory joint disease, or trauma. Mechanical overload and imbalances lead to further cartilage degradation. Important adaptive processes such as subchondral sclerosis and osteophyte formation occur in response to joint overload, and, if chronically present, cyst formation in the subarticular bone may also result. Over time, the osteophytes or bone spurs will lead to restricted range of motion (Fig. 276-1).

Inflammatory arthritis, by contrast, is a constellation of diseases involving the synovium. Included in this class of disorders are such important conditions as rheumatoid arthritis (Chapter 264), psoriatic arthritis, and the seronegative spondyloarthropathies (Chapter 265). On a pathologic level, all involve the release of inflammatory mediators in the adjacent synovium, leading secondarily to cartilage destruction. In contrast to osteoarthritis, there is no mechanical overload as a primary mechanism, and no bone sclerosis or osteophyte formation are seen. Rather, the inflammatory synovitis leads to characteristic loss of cartilage matrix, marginal bony erosions, and osteopenia (Fig. 276-2)

Trauma is another important cause of joint destruction. Post-traumatic arthritis is initiated by cartilage damage at the time of injury or by secondary mechanical imbalances that result from fractures of juxta-articular bone. Abnormal loading conditions will subsequently lead to a wear-and-tear form of cartilage damage.

Osteonecrosis is another entity that may lead to joint arthritis. In this process, the blood supply to the bone is compromised, leading to necrosis of the bone supporting the articular surface. The most commonly affected joints are the hip, shoulder, and knee. As the disease progresses, the necrotic bone may collapse, leading to the loss of articular integrity and progressive cartilage deterioration.

FIGURE 276-1. Radiograph of an osteoarthritic left hip. Note the asymmetrical joint space narrowing and subchondral sclerosis that are characteristic of a wear-and-tear pattern of joint deterioration.

FIGURE 276-2. Radiograph of a left hip with end-stage inflammatory arthritis. Note the symmetrical pattern of cartilage loss and presence of osteopenia.

Other causes of arthritis that may lead to joint damage include metabolic disorders (chondrocalcinosis, gout), tumor (synovial chondromatosis), infections (post-septic), and bleeding disorders (hemophilia).

PREOPERATIVE CONSIDERATIONS

The indications for orthopedic surgery are refractory joint pain and disability. Ultimately, the patient and physicians need to agree that the possible benefits of surgery outweigh the risks (Chapter 431). The decision to proceed with surgery therefore reflects the outcome of a partnership among the patient, the orthopedic surgeon, and the patient's primary physician or rheumatologist (Chapter 430). Achieving the necessary decision-making balance may be complicated, especially given the increasing burden of comorbidity that accompanies the aging patient.

In the elective setting, joint replacement and spine surgery are the most common procedures under consideration. With the former, severe pain and functional limitation unrelieved by conservative treatment are the most common indications for surgical intervention. In the case of spinal surgery, severe radiculopathy, nerve dysfunction (e.g., acute foot drop), and myelopathy are additional considerations. In contrast to elective surgery, there are circumstances when a deliberative approach is not possible because of the

development of more urgent, occasionally life-threatening clinical problems. Examples include hip fracture, acute myelopathy, or the patient with an infected native or prosthetic joint. Because the patient's general health is at risk in these settings, the medical-surgical team must stabilize the patient quickly in order to optimize the outcome. Owing to the coupling of medical advances with increasing financial and resource constraints, a dominant trend toward the performance of surgery in the ambulatory setting has emerged. Indeed the percentage of all surgical procedures performed on an outpatient basis in the United States rose from 20% in 1982 to 60% in 1995, a phenomenon particularly relevant to the arthroscopic techniques of orthopedic surgery. Among the benefits of these developments has been the opportunity to move the preoperative medical evaluation to the outpatient arena. This change in practice allows time for discourse with the other physicians involved in the patient's care, for supplementary consultation and investigation, and, when necessary, for the institution of therapy directed at optimizing the patient's medical status before the contemplated surgery. Approached in this manner, the preoperative evaluation becomes a focal point of communication among all members of the medical team, enhancing the collaborative nature of the consultative process and, ultimately, the patient's care.

Although the efficacy of preoperative assessment has not been definitively established, the aging and increasing complexity of modern-day surgical patients justifies this clinical practice. Although no consensus exists regarding what constitutes the optimal preoperative medical evaluation, a growing literature pertaining to perioperative medicine supports various core principles that underlie effective medical consultation in this clinical setting (Chapter 431).

ANESTHESIA IN THE ORTHOPEDIC PATIENT

Given the protean clinical features that accompany chronic arthritis and the connective tissue diseases, a variety of issues, including airway considerations, the surgical site (joint region), the anticipated duration of surgery, and comorbidities are important determinants of the type of anesthesia to be employed, whether invasive monitoring will be necessary, and the length of time the patient will require intensive monitoring after surgery.

General anesthesia and regional anesthesia are commonly used in the orthopedic patient (Chapter 432). General anesthesia with endotracheal intubation may present a particular danger in patients with rheumatoid arthritis or ankylosing spondylitis. Patients with cervical spine instability or those with a rigid spine may require fiberoptic intubation. Regional anesthesia may involve local anesthesia or peripheral nerve block for minor procedures or epidural-spinal anesthesia for total joint arthroplasty.

Although the debate concerning the relative merits of regional versus general anesthesia remains unresolved, many procedures, particularly orthopedic surgery, are well suited for regional anesthetic techniques. Advantages of regional approaches include a reduction in blood loss, deep vein thrombosis and pulmonary embolism, adverse postoperative respiratory events, and death. Further postoperative pain, a significant problem for patients with a painful rheumatic disease, may be best managed with regional anesthesia. For example, peripheral nerve blocks using longer acting anesthetics and infusion methodologies are often employed because they provide excellent intraoperative anesthesia and postoperative pain relief.

A number of options exist for the control of postoperative pain, including the traditional intravenous and intramuscular routes of narcotic medications (systemic), the use of epidural analgesia, and the local infiltration of anesthetics into the surgical site. The direct administration of local mixtures of medications, including long-acting anesthetics and anti-inflammatory drugs, has become more popular because of the ease of use and excellent efficacy, particularly around the hip and knee joints. Patient-controlled analgesia (PCA) using an epidural route of administration is also an effective method of pain control after lower extremity surgery. Further, epidural PCA and local soft tissue injections facilitate postoperative physical therapy, which is important to the restoration of range of motion in patients undergoing orthopedic procedures. Both methods also reduce the systemic absorption of analgesics, thereby minimizing the problem of narcotic-induced respiratory depression. Parenterally administered nonsteroidal anti-inflammatory drugs (NSAIDs) are also useful and can be used to reduce narcotic requirements after major surgery. However, the common contraindications to NSAID therapy, such as peptic ulcer, renal, and ischemic heart disease, should be observed in the postoperative setting.

SURGICAL MANAGEMENT

Surgical treatment of joint disease is focused primarily on the relief of pain; secondary objectives are improvement in joint motion, reduction in swelling, return to function, and prevention of continued cartilage destruction. Realizing that surgical treatment has limitations and complications, the decision to move forward is one that must be individualized for each patient. Factors such as disease severity, the patient's desired activity level, and the anticipated longevity of the patient are all relevant to decision making. Typically, patients who are candidates for the surgical treatment of joint diseases have failed conservative measures (NSAIDs, physical therapy, intra-articular injections) and have daily pain that hinders their function and diminishes their quality of life.

ORTHOPEDIC PROCEDURES

Osteotomy

In circumstances in which a structural abnormality around a joint has led to mechanical overload, an osteotomy (cutting bone) may be an option to correct alignment problems. The most common sites for osteotomy are the hip, to treat acetabular dysplasia, and the tibia, to realign the knee. In acetabular dysplasia, the hip socket is excessively shallow, leading to abnormal stresses on the articular cartilage and premature osteoarthritis. An acetabular osteotomy can be performed in patients in whom significant cartilage still remains. By rotating the pelvic bones, a deeper socket can be formed, reducing stresses on the cartilage and thereby slowing down the arthritic process. With tibial osteotomy, the knee joint can be realigned to direct forces away from the region of cartilage damage. Usually a varus (bow-legged) deformity indicates that the medial compartment of the knee is excessively worn and, as such, a tibial osteotomy realigns the joint in such a way to direct forces to the uninvolved, lateral compartment. Typically, osteotomy is considered an option for younger patients (<40 years); beyond this age, the loss of cartilage is generally such that more reproducible results would be attained with total joint arthroplasty.

Arthroscopy

Arthroscopic surgery is performed by inserting a camera and specialized instruments into a joint through small, puncture-type incisions. Arthroscopic surgery is effective in the treatment of intra-articular pathology such as meniscal tears of the knee, labral tears of the hip, cartilage flaps, small chondral defects, and loose bodies. However, after the articular cartilage is significantly damaged, arthroscopic débridement is usually ineffective in the absence of mechanical symptoms such as locking and clicking. In some instances, underlying joint arthritis may lead to tears in the meniscus or labrum; if such a tear results in new mechanical symptoms, then arthroscopic surgery may be helpful in selected cases.

In the assessment of the hip, there has been an increased focus on the femoral head and neck architecture as a cause of osteoarthritis. In certain patients, the anatomy of the femoral head and neck may lead to impingement of the femoral neck upon the acetabular rim, typically in flexion and internal rotation. This condition, known as *femoroacetabular impingement*, results in the repetitive contact between the femoral neck and acetabular rim and is believed to result in labral tears, cartilage damage, and eventually arthritis.[2] Thus, there is currently much interest in reshaping the bones of the femur and acetabulum by so-called osteochondroplasty. This procedure is being performed as an open or arthroscopic procedure and provides good symptomatic relief in the short term. The long-term effects, specifically the impact on the future development of arthritis, have yet to be demonstrated for this procedure.

Synovectomy

Synovectomy refers to removal of the synovial lining of the joint, either through an open or an arthroscopic approach. In conditions such as rheumatoid arthritis, in which the disease process involves an actively inflamed synovium, it follows that debulking the pathologic tissue may reduce symptoms and slow the destruction of cartilage. In practice, synovectomy can be effective at relieving pain as long as there is remaining cartilage. However, the procedure is not predictable in terms of regaining joint motion. Further, after the cartilage is completely worn through, the joint deterioration is too advanced for synovectomy to be helpful. Therefore, synovectomy is generally performed in patients with rheumatoid arthritis (or other forms of inflammatory arthritis) who have active synovitis in the presence of relatively preserved articular cartilage. The most common joints that benefit from synovectomy are the knee and elbow. However, synovectomy should be considered as "buying time" because the synovium will reappear.

Arthrodesis

Arthrodesis, or fusion of a joint, achieves the goal of pain relief by creating a nonmobile joint. Rather than have the arthritic joint surfaces elicit pain with

movement, a surgical fusion (arthrodesis) of the articulating bones creates a construct that can bear weight and is stable. This is achieved by removing the articular surfaces from the joint and immobilizing the bones such that they heal in a solid union. This procedure was formerly the treatment of choice for hip and knee arthritis in young, active laborers because of its durability and avoidance of implants with their propensity to wear. However, creating stiffness at one joint will increase stresses on the joints above and below the fused joint.

Hip fusion may be performed in young patients to treat the sequelae of slipped capital femoral epiphysis, Legg-Calvé-Perthes disease, post-septic arthritis, or osteonecrosis of the femoral head. Fusion surgery can achieve a painless, supportive joint that is capable of bearing heavy loads while avoiding artificial implants. However, the gait mechanics are altered, requiring more energy for ambulation. Further, the lack of motion at the hip increases stresses on the joints above and below the hip. Thus, the natural history of a hip fusion is the development of ipsilateral knee arthritis and low back pain after 20 to 25 years, necessitating much later the conversion of a fused hip to a hip replacement (fusion takedown). Although hip arthrodesis is still a viable option in the young arthritic patient, patients' desire for maintaining hip mobility in order to sit and drive has made this largely a treatment of the past.

Fusion of the knee joint is performed less commonly than hip fusion. In addition to the lack of motion that may make it difficult to sit or climb stairs, knee fusion cannot be successfully converted to total knee replacement. Thus, knee fusion is generally considered a salvage procedure, mainly employed in situations in which replacement is not possible (e.g., lack of muscle function or persistent infection).

Ankle fusion is still commonly performed as the treatment of choice of tibiotalar arthritis. Because the historical results of ankle replacement have not been durable, fusing the ankle is the best method of creating a pain-free joint. Furthermore, the ability of the knee and subtalar joints to compensate for a stiff ankle has made this procedure more tolerable.

Total Joint Arthroplasty

Joint arthroplasty refers to the re-creation of congruent joint surfaces, typically with artificial parts. In certain patients and in non-load-bearing joints such as the elbow, interpositional arthroplasty can be performed by placing a tissue graft between the arthritic surfaces. In the case of weight-bearing joints such as the hip and knee, however, metal and plastic materials produce the most durable results. In such circumstances, the articular surfaces are replaced by shaped materials designed to recreate the joint kinematics; thus, the procedures are commonly called total hip, knee, and shoulder replacements.

In general, after the articular cartilage is completely worn or destroyed on both sides of the joint, arthroplasty is the most predictable option to relieve pain. After total joint arthroplasty, it is advisable to reduce stresses on the joint to promote implant longevity. This includes weight loss and avoidance of impact activities; walking, cycling, and gliding type activities are permitted, but in general, running and jumping should not be performed. Because a total joint arthroplasty involves artificial, moving components, the replaced joints are subject to the same wear and tear as native joints. Thus, they have a finite lifespan that is dependent on a patient's weight and activity level and the implant materials. Subsequent revisions of joint replacements can be difficult and less durable; thus, it is wise to defer joint arthroplasty until there are no other options.

Total hip replacement was first developed in the 1950s in the United Kingdom using metal and plastic components attached to the bone with cement. The early results were so predictable and reproducible that the technique rapidly spread worldwide. The National Institutes of Health, in 1994, published a consensus statement that total hip replacement "is one of the most successful surgical procedures and provides immediate and substantial improvement in a patient's pain, mobility, and quality of life. Compared with treatments for other chronic debilitating diseases, total hip replacement is highly cost effective."

Total hip replacement is the treatment of choice for end-stage arthritis caused by any of the aforementioned pathobiologic processes. It involves the exposure of the joint, removal of the arthritic femoral head at the level of the femoral neck, and removal of enough acetabular bone to place a prosthetic socket. The femoral implant is inserted into the intramedullary canal and anchored with bone-ingrowth techniques or bone cement. The typical bearing materials for the hip joint are metal-on-polyethylene, ceramic-on-polyethylene, and ceramic-on-ceramic implants. These combinations of materials may be chosen based on the patient's age, activity level, and surgeon preference (Fig. 276-3). Metal-on-metal total hip replacement, popular for a time period in early to mid-2000s, has now fallen out of favor because of findings of adverse local tissue reactions to the metal debris.

FIGURE 276-3. Radiograph of a total hip replacement consisting of uncemented acetabular and femoral components. The articulating materials are a metal ball and polyethylene liner.

Using modern implant materials and surgical technique, the implant survival rates are 90 to 95% successful at 15 years; however, longevity will vary depending on patient factors such as weight and activity. There have been cases in which total hip replacement implants have lasted more than 30 years.

A major cause of failure of total hip replacement has been wearing of the implant materials coupled with the body's reaction to the particulate debris shed into the joint space over time. In the process of immunologic uptake of the debris, inflammatory cytokines are released, causing osteoclasts to resorb periprosthetic bone. The end result of this osteolytic process is that the implant attachments to bone may be compromised, causing loosening of the prosthesis and pain. The hope is that the current generation of implant materials will reduce the amount of particulate wear debris, thereby extending longevity further.

Total knee replacement was developed in the United States shortly after total hip replacement. The surgery involves the removal of the arthritic surfaces of the tibia and femur followed by their replacement with a metal femoral implant and a metal and/or polyethylene tibial component (Fig. 276-4). It is termed "total" knee replacement to distinguish it from a unicompartmental or "partial" knee replacement.

The recovery from total knee replacement is more difficult than after total hip replacement because of greater postoperative pain and the emphasis on regaining motion. Nonetheless, pain relief and function are usually excellent when recovery is complete. Current studies demonstrate modern implant survival to be 90 to 95% at 15 years, again depending on patient factors.

The long-term outcome after total hip or knee arthroplasty has improved steadily over recent decades. Despite more pre-surgical morbidity, rates are declining especially for cardiac disease, stroke, and pulmonary embolism.[3]

Although less commonly performed than hip and knee replacement, total shoulder replacement is an excellent pain-relieving procedure for glenohumeral arthritis. Developed from experience gained for total hip replacement and total knee replacement, total shoulder replacement uses a stemmed humeral implant with a metal ball and metal and/or polyethylene glenoid socket. Total shoulder replacement requires an extensive rehabilitation protocol to regain range of motion and strength; however, 1 year after surgery, 95% of patients have pain-free use of the shoulder.

Surgical Innovations in Joint Arthroplasty

Minimally Invasive Surgery

As in all surgical subspecialties, there has been a movement toward minimally invasive surgery. This may be a misnomer because the actual work done inside the joint has not changed. Some surgeons have suggested the terminology be changed to "smaller incision surgery" or "less invasive surgery." In any case,

the idea is that the smallest incision possible be used to perform the operation, resulting in less tissue trauma. The interest in this type of surgery has resulted in improvements in instrument design and surgical training. Typically, a hip replacement, performed until recently using a 10-inch incision, can now be done through a 4- to 5-inch incision. Similarly, knee replacement incisions are about one half of their former length. Despite these surgical advances, even larger benefits have resulted from the increased attention to various nonsurgical modalities, all directed at more rapid surgical recovery. Examples include the increased use of peripheral nerve blocks and local tissue anesthetic infiltration, preemptive analgesia, and a more expeditious approach to rehabilitation. Such approaches have reduced the average hospital length of stay to 2 to 3 days after a total hip replacement and 3 to 4 days after a total knee replacement.

Improvements in Implant Technology

As the average age of patients undergoing hip and knee replacement decreases, while their activity levels increase, the number of revision surgeries is projected to grow. Therefore, much research is being performed to improve the longevity of implant materials.[4] The gold standard of arthroplasty is to use a cobalt-chrome (metal) implant against a polyethylene (plastic) surface. Unfortunately, the harder metal surface will eventually wear away the softer plastic surface. Therefore, biomechanical engineers have developed a more resistant, "highly cross-linked" polyethylene that demonstrates greater wear resistance in laboratory simulators. Such highly cross-linked polyethylene has been in clinical use for about 10 years, and the early experience suggests significantly less wear compared with standard polyethylene.[5] Other materials such as ceramics and metals are also being used in an attempt to improve longevity. Nonetheless, to date, there is no consensus concerning the optimal weight-bearing surfaces.

Bone-preserving implants have also been developed in order to maintain more options when revision surgery becomes a necessity. Such procedures may require the removal of the implant and placement of a new prosthetic device; thus, with more bone available, surgical options are enhanced. One such bone-preserving implant is the hip-resurfacing device introduced in the United States in 2006. This is discussed more fully later.

Unicompartmental knee replacement is a bone-preserving implant for the knee. As suggested by its name, it involves replacing only one of the three knee compartments with a prosthetic device (Fig. 276-5). Therefore, candidates for unicompartmental knee replacement must have arthritis limited to a single compartment. Because the surgical trauma and dissection are significantly reduced compared with total knee replacement, patient recovery tends to be less painful and quicker. However, there remains a higher failure rate for unicompartmental knee replacement compared with total knee replacement because of the possibility for developing arthritic changes elsewhere in the joint.

FIGURE 276-4. Radiograph of a total knee replacement. The components are metal, with a polyethylene insert between the tibial and femoral components.

Resurfacing Arthroplasty

Hip resurfacing is an alternative treatment to total hip replacement in the younger, active patient. The primary benefit is the preservation of proximal femoral bone in the event that future (revision) surgery is necessary. Rather than removing the femoral head and portion of the femoral neck as in total hip replacement, the bone is sculpted to accept a metal resurfacing cap (like a tooth), preserving an additional 4 to 5 centimeters of bone (Fig. 276-6). The acetabulum is prepared to accept a metal socket, creating a metal-on-metal joint. There are currently no alternatives to the metal-on-metal articulation of a hip-resurfacing implant; however, in contradistinction to metal-on-metal total hip replacements, there appear to be fewer issues arising from the materials in hip resurfacing. The likely explanation for this finding is that there are fewer pieces and junctions in a hip resurfacing compared with total hip replacement. The preservation of the proximal femoral bone raises an additional risk for failure (i.e., femoral neck fracture below the resurfacing implant), which is estimated to occur in 1% of cases. Although there are no defined age limits for hip resurfacing, the best candidates have been males younger than 55 years, likely because the bone quality in this demographic group is the strongest and most robust. In this age group, the 10-year results of hip resurfacing in Australia have demonstrated a 94% rate of survival (free of revision), which is superior to total hip replacement. However, concerns regarding longevity, a greater short-term failure rate than total hip

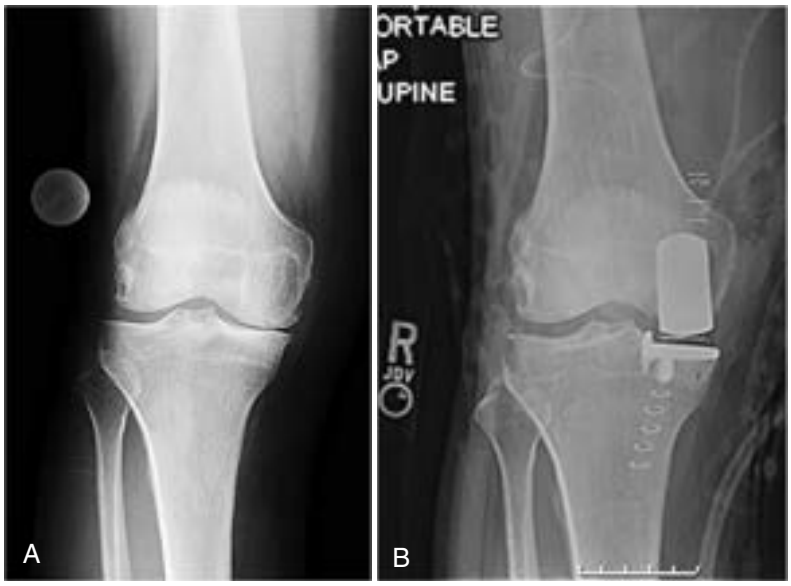

FIGURE 276-5. A, Radiograph of a knee with arthritis limited to the medial compartment. **B,** A medial unicompartmental knee replacement.

FIGURE 276-6. Radiograph of a patient with a right total hip replacement and a left hip resurfacing. The total hip replacement consists of a longer stem placed into the medullary canal of the femur. The hip resurfacing implant preserves the proximal femoral bone.

replacement, poorer results in women, and metal ion release have led to questions concerning the superiority of the procedure.

Computer Navigation

An orthopedic surgeon relies on visualization, instrument jigs, and experience in order to recreate the proper joint mechanics. Although the surgeon may know exactly how the artificial components are to be placed, it may be difficult to achieve perfect alignment in every operation. Computer navigation is a tool that can be used to aid in the reproducible positioning of implants. Although some errors are inherent in the precision of computer navigation, such techniques have reliably diminished outlier results. It has yet to be determined whether the longevity of hip and knee replacements inserted with the aid of computer navigation differ from those inserted by conventional approaches. For this reason, as well as the expense and time associated with its use, computer navigation is not universally practiced.

ORTHOPEDIC PROCEDURES ON OTHER JOINTS

Elbow, Ankle, and Wrist

The elbow, ankle, and wrist are less frequently replaced joints. With the exception of the rheumatoid wrist, these joints are less commonly afflicted by chronic arthritis. Further, the smaller bones making up these joints also translate to a diminished surface area for implant fixation, thus lowering the durability of the surgical procedures. Although total joint arthroplasty can be successful at relieving pain in the short term, 10-year results do not approach that of total hip or knee replacement. Synovectomy remains an effective surgical option in selected patients with inflammatory arthritis of the elbow, ankle, or wrist.

Spine

The spine consists of multiple levels of articulating bone, discs, and facets. Although not a "joint" in the typical sense of the word, various spinal segments may be differentially involved in chronic arthritis. Generally, the lumbar spine is the most affected, although a similar process can occur in the cervical spine; more than 95% of patients older than 50 years will demonstrate degenerative changes in the lumbar spine. With aging, the nucleus pulposus of the intervertebral disc loses water content and elasticity, resulting in disc space collapse and increased forces across the vertebral facets. As a consequence of the resultant increased pressure, bone spurs develop, leading to stenosis (narrowing) of the neural foramen. As a result of the degenerative process or *spondylosis*, patients may experience mechanical back pain with bending, extending, and twisting. Pain, numbness, or weakness radiating down the extremities in a radicular distribution can result from the neural foraminal stenosis.

Mechanical back pain is the most common affliction of the spine. Unfortunately, this constellation of back symptoms is not reproducibly relieved by surgical intervention. Physical therapy and use of proper back mechanics are the mainstay of treating mechanical back pain.

The advanced sequela of spinal arthritis is spinal stenosis, which can result in lower extremity pain and weakness. This disorder can reliably benefit from decompressive surgery with or without instrumented fusion. The spinal unit must be evaluated for stability in order to determine whether or not spinal fusion is necessary.

Newer surgical treatments such as lumbar disc replacement may be used in certain cases to treat spinal disorders. Whereas the gold standard, vertebral fusion, eliminates painful motion at degenerative disc levels, disc replacement attempts to preserve motion of the spinal unit. As in hip and knee arthrodesis, fusion of the spinal unit will increase forces at the levels above and below the fused segment; thus, further degeneration will often occur. Disc replacement surgery aims to eliminate the progression of arthritis at adjacent levels by retaining motion. Long-term studies comparing disc replacement and spinal fusion are not yet available.

MANAGEMENT ISSUES IN PATIENTS WITH ARTHRITIS UNDERGOING SURGERY

Prevention of Postoperative Infection

Efforts to prevent and detect any infectious processes before and after surgery are of utmost importance. The skin and urinary tract are sites of specific concern, and infection can be ruled out by a careful physical examination and routine preoperative urine culture. In addition, dental consultation may be appropriate in patients with poor oral hygiene and dentition.

Prophylactic antibiotic therapy for total joint arthroplasty patients should begin less than 2 hours before surgery and continue for 24 hours. A common protocol involves cefazolin (Ancef) 1 g every 8 hours (total of three doses) or, in penicillin allergic patients, vancomycin 1 g every 12 hours (total of two doses).

Peripheral Nerve Injuries

Peripheral nerve injuries arise more often after upper and lower extremity surgery because they generally result from excessive traction on the nerve or, alternatively, as a consequence of nerve compression resulting from prolonged positioning of the extremity during surgery or while in a cast. Early detection and intervention are critical to the outcome in these circumstances. Patients with chronic neurologic disorders, such as neuropathies in the setting of diabetes or spinal stenosis, are at increased risk for nerve injury.

Venous Thromboembolism

Prevention of venous thromboembolic phenomena after orthopedic surgery is the most thoroughly studied of potential postoperative complications, and pulmonary embolism remains an important cause of mortality. The orthopedic literature has concentrated on lower extremity arthroplasty, although a recent study suggests that similar approaches should also be considered after total shoulder arthroplasty, in which the risk for thromboembolism may be higher than generally appreciated.

After orthopedic surgery, a complicated balance exists between a possible life-threatening pulmonary embolus and the potential for postoperative bleeding. Numerous protocols have documented the effectiveness of prophylaxis, which should begin at the time of the procedure. Short intraoperative time reduces the risk for deep vein thrombosis, as does the type of anesthesia. Epidural anesthesia reduces the risk for proximal deep vein thrombosis following total hip replacement by two- to three-fold and also reduces the overall risk for deep vein thrombosis by at least 20%. Other intraoperative interventions, such as hypotensive anesthesia and intraoperative heparin administration, further reduce thrombogenesis. Mechanical methods also have proven efficacy at reducing risk for thromboembolism. These include compression methodologies such as stockings and various pneumatic devices, foot flexion-extension exercises, and early ambulation. These are safe, effective approaches that do not increase the risk for bleeding.

The mainstay of prevention is prophylactic anticoagulation, which should begin immediately after surgery. Regimes include aspirin, warfarin, low-molecular-weight heparin, and several new oral anticoagulants, often used in combination with various mechanical compression devices (Chapter 38). Continuing prophylaxis for 21 days rather than 7 days reduces risks of thromboembolism while increasing risks of minor bleeding.[6]

Fat Embolism Syndrome

Fat embolization, a well-described complication of skeletal trauma, may also occur after procedures involving instrumentation of the femoral medullary canal. Although the embolization of fat is believed to occur almost entirely in the setting of hip or femoral fractures, 1 to 3% of patients undergoing joint replacement surgery (particularly simultaneous bilateral procedures) develop fat embolism syndrome (FES).

The signs and symptoms of FES involve the respiratory, neurologic, and hematologic systems, as well as the skin.[7] Time of onset is variable, with hemodynamic instability developing almost immediately in some or insidiously over the first 2 to 3 postoperative days in others. In the latter, patients gradually become hypoxemic, may be hypotensive, and are often confused. Respiratory signs are the most common manifestation. Most patients develop mild to moderate hypoxemia or radiographic changes (mainly bilateral alveolar infiltrates), but only a minority will develop life-threatening adult respiratory distress syndrome. Neurologic manifestations range from mild drowsiness to acute confusional states or to severe obtundation and coma, all consequences of the hypoxemia and the direct effect of the embolization of fat on the brain. The skin eruption, which is rare in total joint arthroplasty patients, takes the form of a petechial rash involving the folds of the neck and axillae, as well as petechiae in the subconjunctiva and oral mucosa. Retinal edema and hemorrhage are also seen. Transient thrombocytopenia is common.

Although patients suspected to have developed FES need to be closely monitored, in most instances after total joint arthroplasty, the condition is relatively benign. Treatment is supportive and includes the administration of oxygen and the prevention of pulmonary hypertension (by fluid restriction and the use of diuretics and venodilators). Corticosteroids are not effective. In most patients, the condition resolves within 3 to 7 days, although in severe cases, the mortality rate has remained in the 5 to 15% range even with modern aggressive therapy.

Cervical Spine

In those rheumatoid arthritis patients who exhibit advanced destructive disease, cervical spine instability should be ruled out before surgery with flexion-extension films in patients with neck pain or crepitus on range-of-motion testing, radicular symptoms, or arm and/or leg weakness. Affected patients should wear a soft cervical collar to the operating room. When possible, epidural or spinal anesthesia should be employed.

Conversely, in patients with ankylosing spondylitis, the patient's rigid cervical spine may also present technical challenges for the anesthesiologist during intubation. Fiberoptic methods are often employed in this clinical setting.

Immunosuppressive and Anti-inflammatory Therapy

The potential contribution of corticosteroids, the disease-modifying antirheumatic drugs (DMARDs), and the newer biologic agents to the risk for postoperative infection and wound dehiscence are well recognized by clinicians, although the debate concerning how to manage these medications in the perioperative setting is not settled. The primary challenge in this context is to achieve an optimal balance between the maintenance of control of the underlying disease while minimizing the risk for postoperative wound infection and/or wound breakdown.

Methotrexate (MTX) is the most commonly used DMARD for the treatment of rheumatoid and other forms of inflammatory arthritis, so it is frequently seen in the perioperative setting. Given its importance in the maintenance of disease control, coupled with observations concerning the low rates of postoperative wound infection and dehiscence associated with its use, it appears safe, indeed desirable, to continue MTX throughout the perioperative period.

With respect to the biologic (anti–tumor necrosis factor) agents, recommendations have been formulated by international groups in which such agents are discontinued for short periods of time before surgery, generally 2 to 4 weeks. Some favor the longer 4-week interval for agents with longer half-lives. There is virtually no information concerning postoperative infection and wound healing with the newer agents such as anakinra, rituximab, and abatacept. Recommendations similar to the other biologics must suffice until more data can be gathered.

The other important medication commonly encountered in the perioperative setting is corticosteroids. In addition to problems related to wound healing, there is the additional concern of postoperative adrenal insufficiency. Traditionally, steroids have been shown to increase the rate of wound infection and dehiscence in surgical patients, although data derived from the orthopedic setting per se remain scant. Similarly insecure is the published experience concerning postoperative adrenal insufficiency. In contrast to MTX and the biologic therapies, however, the question is not whether to stop corticosteroids before surgery because this is generally not feasible. Rather, management considerations pertain to how much and for how long steroid augmentation (stress doses) will be required. In this regard, a nuanced approach, premised on patient-specific considerations, is required. For the patient chronically managed with low doses of corticosteroid (i.e., prednisone ≤7.5 mg/day) or on any dosage for less than 3 weeks, stress dose steroid therapy is unnecessary, and maintenance of the patients' usual daily dosage should be sufficient. In contrast, for patients taking larger dosages (≥20 mg/day) for longer periods (>3 weeks) of time, it is prudent to assume secondary adrenal suppression exists, justifying the use of stress dose steroid therapy. For those taking intermediate dosages (i.e., 7.5 to 20 mg/day), decision making needs to be individualized. In addition to the dosage and duration of steroid therapy, other considerations, such as the presence of diabetes, the use of other immunosuppressive therapy, hypoalbuminemia, and poor nutritional status, as well as the magnitude of the surgical procedure, need to be taken into account.

REVIEW QUESTIONS

1. A 47-year-old man presents with groin pain of 2 years' duration. The pain is worse with weight-bearing activity, such as standing or walking. On physical examination, the hip demonstrates evidence of limited flexion and internal rotation. He has tried nonsurgical measures, such as oral nonsteroidal anti-inflammatory drugs (NSAIDs), physical therapy, and rest; none has provided any lasting relief. Radiographs demonstrate complete loss of the cartilage space in the hip joint. His bone structure and quality appear to be good. The patient feels extremely debilitated at this point because of his inability to perform activities of daily living (ADLs). In addition to ADLs, the patient would like to have the ability to run, in the future. Which of the following is the most appropriate recommendation?

A. Hip arthroscopy
B. Hip resurfacing
C. Total hip replacement
D. Fusion of the hip
E. Bracing of the hip

Answer: B Hip resurfacing is appropriate in this category of patient: a male patient, younger than 65 years. Hip arthroscopy is not likely to alleviate the symptoms in this patient because of full-thickness cartilage loss. Total hip replacement is an option, but the preservation of bone is desirable in younger patients, and impact sports are not advisable with a total hip replacement. Fusion of the hip has essentially become a historical operation: few surgeons perform this anymore because of the superior function of a hip replacement. Bracing of the hip would not be expected to help in situations of complete cartilage loss.

2. A 67-year-old woman presents with knee pain and an increasing deformity over the past 2 years. She notices that her knees are becoming "more bowlegged." With any prolonged weight-bearing activity, she experiences diffuse pain within the knee joint. In addition, the knee swells up on occasion, causing difficulty bending. She has only tried oral supplements such as glucosamine and chondroitin sulfate sporadically for pain relief. Physical examination reveals medial joint line tenderness and a small joint effusion. Her radiographs demonstrate moderate to severe joint space narrowing. The patient desires to return to walking activities and improve motion in her knee. What is the most appropriate recommendation for this patient?

A. Immediate total knee replacement surgery
B. Knee arthroscopy
C. Knee fusion
D. Partial knee replacement
E. A trial of nonsurgical measures, such as weight loss, physical therapy, and bracing

Answer: E Given the patient's moderate joint space narrowing and lack of prior nonsurgical interventions, a trial of weight loss, physical therapy, and bracing is worthwhile. Knee arthritis can respond well to this treatment regimen, reducing the stresses on the knee joint and helping the patient delay total knee replacement surgery.

3. Inflammatory arthritis can be distinguished from osteoarthritis by which of the following?

A. Mechanical overload
B. Sclerosis
C. Symmetrical joint space narrowing
D. Cystic changes
E. Osteophyte formation

Answer: C The hallmark of inflammatory arthritis is the presence of symmetrical joint space narrowing, a feature best appreciated radiographically. All the other characteristics are those of degenerative disease processes.

4. The advantages of the use of regional (epidural) anesthesia in lower extremity orthopedic surgery include which of the following?

A. Reduction in blood loss
B. Reduction in postoperative thromboembolic complications
C. Reduction in postoperative pulmonary complications
D. Facilitation of postoperative pain control
E. All of the above

Answer: E Regional anesthesia is a popular and commonly employed anesthesiology technique for patients undergoing lower extremity orthopedic procedures for a variety of reasons. Each of the potential advantages listed has been demonstrated with this form of anesthesia in this setting.

5. A 52-year-old obese man undergoes bilateral total hip replacement for severely symptomatic osteoarthritis of the hip. During the surgical procedure, after cementing of the first hip, the anesthesiologist notes a rise in the patient's pulmonary artery pressures that persists through the completion of the surgery. In the recovery room, the patient develops progressive hypoxemia and may require mechanical ventilation. Fat embolism is suspected. What additional sign of this condition is *least* likely to be helpful securing this diagnosis?

A. Bilateral pulmonary infiltrates
B. Mental confusion
C. Retinal hemorrhage
D. Petechial skin eruption
E. Signs of right heart strain

Answer: D All of the above phenomena have been described as important features of classic fat embolism syndrome. Nonetheless, in the postoperative arthroplasty setting, the classic petechial skin eruption is virtually never seen.

INTRODUCTION TO MICROBIAL DISEASE: HOST-PATHOGEN INTERACTIONS

W. MICHAEL SCHELD

Infectious diseases have profoundly influenced the course of human history. The "black death" (caused by *Yersinia pestis*) changed the social structure of medieval Europe, in the process eliminating approximately a third of the population. The outcomes of military campaigns have been altered by outbreaks of diseases such as dysentery and typhus. Examples include Napoleon's retreat from Russia, after typhus did more damage to his army than the opposition forces did; the decision by the French to sell the Louisiana Territory after French soldiers died from yellow fever in Cuba and the Gulf Coast; and the introduction of smallpox to the nonimmune population of the New World by Europeans, thus facilitating the "conquest" and the dawn of the colonial age. Malaria influenced the geographic and racial pattern and distribution of hemoglobins and erythrocyte antigens in Africa. The development of *Plasmodium falciparum* is inhibited by the presence of hemoglobin S, and Duffy blood group–negative erythrocytes are resistant to infection with *Plasmodium vivax.* Thus, populations with these erythrocyte factors are found in areas where malaria is common.

Infections are a major cause of morbidity and mortality in the world. Of the approximately 53 million deaths worldwide in 2009, at least a third were due to infectious diseases. In the United States, pneumonia is the fifth leading cause of death overall and the most common cause of death related to infection. Acquired immunodeficiency syndrome (AIDS) threatens to disrupt the social fabric in many countries of Africa and is severely distressing the health care system in the United States and other parts of the world. The year 2011 marked the 30th "anniversary" of the AIDS epidemic. Approximately 35.3 million people worldwide are currently infected with human immunodeficiency virus (HIV), and since 1981, approximately 36 million have died (≈600,000 in the United States alone). AIDS is now the leading cause of death in sub-Saharan Africa.

Infection can be defined as the multiplication of microbes (from viruses to multicellular parasites) in the tissues of the host. The host may or may not be symptomatic. For example, HIV infection may cause no overt signs or symptoms of illness for years. The definition of infection should also include the multiplication of microbes on the surface or in the lumen of the host that causes signs and symptoms of illness or disease. For example, toxin-producing strains of *Escherichia coli* may multiply in the gut and cause a diarrheal illness without invading tissues. Microbes can cause diseases without actually coming in contact with the host by virtue of toxin production. *Clostridium botulinum* may grow in certain improperly processed foods and produce a toxin that can be lethal on ingestion. A relatively trivial infection, such as that caused by *Clostridium tetani* in a small puncture wound, can cause devastating illness because of a toxin released from the organism growing in tissues. It has now become apparent that multiple virulence factors of microorganisms can be carried in tandem on so-called pathogenicity islands of the genome (the "virulome").

We live in a virtual sea of microorganisms, and all our body surfaces have indigenous bacterial flora. In fact, we are a "super organism" as our native flora outnumbers our own human cells by a ratio of 10 : 1. This normal flora actually protects us from infection. Reduction of gut colonization increases susceptibility to infection by pathogens such as *Salmonella enteritidis* serovar *typhimurium.* Bacteria that constitute the normal flora are thought to exert their protective effect by several mechanisms: (1) using nutrients and occupying an ecologic niche, thus competing with pathogens; (2) producing antibacterial substances that inhibit the growth of pathogens; and (3) inducing host immunity that is cross-reactive and effective against pathogens. These conclusions appear to be oversimplistic, however. For example, colonization of the gastrointestinal tract with *Bacteroides fragilis* expressing an immunodominant bacterial polysaccharide causes dendritic cell activation and induction of a T_H1-mediated response, leading to a splenic response characterized by normal numbers of $CD4^+$ T cells, lymphoid architecture, and systemic lymphocytic expansion. Thus, a single bacterial molecule in our gut is necessary to make us "immunologically fit." Indeed, it has become apparent that a healthy, diverse microbiome is vital to proper immune system function. The timing of changes in the microbiome can also be of crucial importance. For example, pregnant mice fed antibacterials pass along their altered gut microbiome to their offspring. The neonates, in turn, display decreased total number and composition of gut microbes that is associated with decreased numbers of circulating and bone marrow neutrophils. This disordered neutrophil homeostasis leads to impaired host defense and increased susceptibility to *E. coli* K1 and *Klebsiella pneumoniae* sepsis, classic neonatal pathogens in humans.[1] Furthermore, because children are often prescribed multiple courses of antibacterials, one must wonder if these (often unnecessary) exposures later predispose them to epidemic disorders, such as asthma, autoimmunity, inflammatory bowel disease, and obesity.

Only a small proportion of microbial species can be considered primary or professional pathogens, and even among these species, a relatively small number of clones have been shown to cause disease. For example, epidemic meningococcal meningitis and meningococcemia are due to a small number of clones of *Neisseria meningitidis,* and the worldwide explosion of penicillin-resistant *Streptococcus pneumoniae* can be traced to a few clones originating in South Africa and Spain. This observation supports the concept that pathogenic organisms are highly adapted to the pathogenic state and have developed characteristics that enable them to be transmitted, to attach to surfaces, to invade tissue, to avoid host defenses, and thus to cause disease. In contrast, opportunistic pathogens cause disease principally in impaired hosts, and these organisms, which may be harmless members of normal flora in healthy persons, can act as virulent invaders in patients with severe defects in host defense mechanisms. Although opportunistic infection has traditionally been viewed as the exploitation of a weakened host through physiologic stress or immunocompromise (or both) by relatively "avirulent" pathogens, this is an oversimplification. For example, *Pseudomonas aeruginosa* recognizes host immune activation, specifically by binding interferon-γ to a cell surface protein OprF, which in turn, through a quorum-sensing signaling system, leads to the overexpression of virulence determinants such as PA-I (lecA) and pyocyanin. Thus, bacteria have developed a "contingency system" that recognizes immunologic perturbations in the host and counters this response by the expression of virulence factors.

Pathogenic organisms may be acquired by several routes. For example, direct contact has been implicated in the acquisition of staphylococcal disease. Airborne spread, usually by droplet nuclei, occurs in respiratory diseases such as influenza, in severe acute respiratory syndrome (SARS), and in the recently recognized Middle East respiratory syndrome (MERS). Contaminated water is the usual vehicle in *Giardia* infection and typhoid fever. Food-borne toxic illnesses may be caused by extracellular toxins produced by *Clostridium perfringens* and *Staphylococcus aureus.* Blood and blood products may be vectors for transmitting hepatitis B and C viruses as well as HIV. Sexual transmission is also important for these agents and for a variety of other pathogens, including *Treponema pallidum* (syphilis), *Neisseria gonorrhoeae* (gonorrhea), and *Chlamydia trachomatis* (nonspecific urethritis). The fetus may be infected in utero, and the infection may be devastating if the agent is rubella virus, cytomegalovirus, or parvovirus B19. Arthropod vectors may be important, as illustrated by mosquitoes for malaria and dengue, ticks for Lyme disease and ehrlichiosis, and lice for typhus.

Pathogens are able to cause disease because of a finely tuned array of adaptations, including the ability to attach to appropriate cells, often mediated by specialized structures such as the pili on gram-negative rods. Microbes such as *Shigella* species have the ability to invade cells and cause damage. Toxins may act at a distance or may intoxicate only infected cells. Pathogens have the ability to thwart host defenses by a variety of ingenious maneuvers. The antiphagocytic coat of the pneumococcus is an example. Organisms may change their surface antigen display at an astonishingly rapid rate to outmaneuver the host immune system. Examples include influenza virus and trypanosomes. Certain pathogens (e.g., *Toxoplasma gondii*) have the ability to inhibit the respiratory burst of phagocytes, and others (e.g., *Streptococcus pyogenes*) can destroy phagocytic cells that have engulfed them. The environment plays an important role in infection, both in transmission and in the host's ability to combat the invader. The humidity and temperature of air may affect the infectivity of airborne pathogens. The sanitary state of food and water, woefully lacking in many areas of the developing world, is an important factor in the acquisition of enteric pathogens, one of the major causes of mortality, morbidity, and disability, such as physical and mental developmental delay leading to poor performance in school. The malaria associated with the "bad air" of swamps is, in fact, due to the mosquitoes there, but the

environmental association was appropriate. The nutritional status of the host is clearly a significant factor in certain infectious diseases. It is likely that micronutrient deficiency contributes to the invasion and multiplication of certain pathogens. A new concept is the possibility that infectious diseases cause malnutrition through a vicious circle of diarrhea leading to dehydration and poor oral intake, resulting in secondary diarrhea with a propensity for "stunting" and delaying intellectual development. Establishment of infection is a complicated interplay of factors involving the microbe, the host, and the environment.

Host reaction to infection may result in illness. For example, previous infection with *Campylobacter jejuni* is responsible for about 40% of cases of Guillain-Barré syndrome. The mechanism is thought to be the production of antibodies against *C. jejuni* lipopolysaccharides that cross-react with gangliosides in peripheral nerves. Similarly, much of the damage resulting from meningitis is due to the host's response to invading bacterial pathogens.

With some exceptions, infectious diseases are often treatable and curable. Thus, it is important to make an accurate etiologic diagnosis and to institute appropriate therapy promptly. In acute infections such as pneumonia, meningitis, or sepsis, rapid institution of therapy may be life-saving; thus, a presumptive etiologic diagnosis should be established before a definitive diagnosis. This presumptive diagnosis is based on the history, physical examination, epidemiology of illness in the community, and rapid techniques such as microscopic examination of appropriate gram-stained specimens or molecular techniques such as antigen detection or polymerase chain reaction. Antimicrobial therapy can then be instituted for the presumptive etiologic agents, but it must be reevaluated as more definitive diagnostic information becomes available.

The study as well as the understanding of infectious diseases is a dynamic process. A number of factors or themes of current interest contribute to this conclusion, including the following.

EMERGING INFECTIONS

The most obvious is AIDS, but recent examples with a major impact on the public health in the United States include community-associated methicillin-resistant *S. aureus*, a hypervirulent strain of *Clostridium difficile*, the 2009 H1N1 influenza, and multidrug-resistant gram-negative bacteria, such as carbapenamase-producing Enterobacteriaceae. More than 400 new, emerging infectious diseases have been described in the last 70 years; approximately 60% are zoonoses associated with geographic "hotspots." Their emergence is driven largely by ecologic, socioeconomic, and environmental factors.[2]

GENOMICS AND OTHER "OMICS"

The exact sequence of the genome of more than 2000 microbes relevant to humans has been determined. This new information, in concert with genomic information from multicellular organisms such as the *Anopheles* mosquito, offers significant promise for the development of new therapies and vaccines.[3] Careful analysis of the genomes of pathogens will continue to yield important information about the pathogenesis of infection. For example, genome sequencing of group A streptococci, collected over time with relevant robust clinical information, has detected the acquisition of new determinants (often by prophage) responsible for increased virulence and resulting in toxic shock syndrome, necrotizing fasciitis, or both, even within a single patient with sequential samples. Proteomics, transcriptomics, metabolomics, and virulomics have transformed research on infectious diseases and promise significant improvements in diagnostics and therapeutics in the future.

GENETIC FACTORS ALTERING SUSCEPTIBILITY TO INFECTION AND THE RESPONSE TO INFECTIOUS DISEASES

This field promises new and significant information relevant to the wide variety of responses to infectious diseases in humans. For example, an overvigorous response, with generation of tumor necrosis factor-α, may accentuate the development of cerebral complications in falciparum malaria. Analysis of single-nucleotide polymorphisms of the human genome will lead to an enhanced understanding of two fundamental issues in infectious diseases: why invasive, overt disease develops in only a small fraction of individuals colonized with a given microbe, and why infections are more severe in some people than in others. Variants in genes that encode molecules that mediate attachment, pathogen recognition, inflammatory cytokine response, and innate and adaptive immunity are being identified at an astonishing rate.

INNATE IMMUNITY

This is the most active field in the immunology of infectious diseases. The identification of pattern recognition receptors (e.g., Toll-like receptors and nucleotide oligomerization domain–like receptors) that recognize pathogen-associated molecular patterns, as well as endogenous substances reflecting tissue injury (e.g., alarmins), has revolutionized our understanding of the early host response to infection. Agonists or antagonists of Toll-like receptors have already entered clinical trials as adjuvant therapies or to improve the immunogenicity of vaccines. The other area that has exploded recently is the study of antimicrobial peptides (e.g., defensins, cathecidins, histatins, galectins) and their role in the early response to infectious disorders.

ANTIMICROBIAL RESISTANCE

The development of new antibacterial agents has slowed despite the burgeoning problem of antimicrobial resistance. This disconnect has been the focus of meetings among the pharmaceutical industry, the Infectious Diseases Society of America, the U.S. Food and Drug Administration, and internationally. Multiresistant pneumococci, vancomycin resistance in *S. aureus* and enterococci, and, perhaps most important, multidrug-resistant gram-negative bacilli are just a few examples. Some multidrug-resistant gram-negative bacilli are susceptible to only a few agents of "last resort," such as colistin or tigecycline; others are truly untreatable. Unfortunately, new agents active against these latter strains are years if not decades away from introduction.

THE ROLE OF INFECTIOUS AGENTS IN CHRONIC DISEASES

Many so-called idiopathic diseases may in fact have an infectious basis. Conditions for which there is some evidence (but not conclusive proof) of an infectious basis include diabetes, atherosclerosis, acute leukemia, collagen vascular diseases, and inflammatory bowel disease. Detection of "uncultivatable" microorganisms by newer techniques, such as 16S RNA analysis, may uncover agents responsible for "noninfectious" diseases or suggest a role in conditions that are considered infectious but in which the pathogen or pathogens are controversial (e.g., bacterial vaginosis). In addition, we know that hepatitis C virus, human papillomavirus, and *Helicobacter pylori* cause human cancers. Furthermore, changes in our own microbiome may lead to disease. Alterations in the gut microbiome are associated with obesity. Another recent example comes from experiments with mice lacking TLR5. These mice develop hyperphagia and hallmark features of the metabolic syndrome, including hyperlipidemia, hypertension, insulin resistance, and increased adiposity, associated with an altered gut microbiome. Further, transfer of this changed microbiota into germ-free wild-type mice induces most features of the metabolic syndrome in the recipients.[4] The explosion of new knowledge on the role of the human microbiome in health and disease has been so rapid and profound in the last decade that we thought a separate chapter on this subject was warranted (see Chapter 279).

THE HUMAN MICROBIOME

ILSEUNG CHO AND MARTIN J. BLASER

Until recently, our understanding of the microbiota of humans (formerly called the normal flora) was handicapped by the limitations of traditional microbial cultivation. However, DNA-based analyses have expanded our horizons by generating enormous new data sets that can be mined for information about the composition and functional properties of our indigenous microbial communities (the human microbiome) and its collective genes (the metagenome). There has been great progress in characterizing the compositional range of the "normal" microbiome of healthy individuals.[1] Major clustering patterns at body sites such as the gastrointestinal tract provide new

ways to classify individuals and, possibly, their disease risks. Substantial progress has been made in defining the overarching concepts that advance the field. However, the subject is vast, and the implications for human health and disease are wide-ranging. Although most focus has been on bacteria, inquiries aimed at eukaryotes, archaea, viruses, and retroviruses also are needed.

CHARACTERIZING THE MICROBIOME

Animals have had residential microbes for hundreds of millions of years, and comparisons of the phylogenies of animal hosts and their microbiota suggest the existence of specific selection based on co-adaptation. Cooperative interactions between microbes and their hosts typically involve microbial participation in host functions such as defense, metabolism, and reproduction. The composition of the microbiome varies by anatomic site (Fig. 278-1). The primary determinant of community composition is anatomic location, and individuals can be grouped according to the major types present at specific sites, such as the gastrointestinal tract. However, dietary changes can rapidly cause substantial changes in intestinal composition and function. Similarly, nasopharyngeal microbiota in young children varies seasonally, and vaginal microbiota may vary with menses. The aggregate microbiota of an individual appears to have a host-specific pattern, but large perturbations, such as antibiotic exposure or enteric infections, can lead to transient disequilibria or to the development of new stable states.

Among all mammals, the microbiota is extensively conserved at high taxonomic levels, but variation increases at progressively lower taxonomic levels. Consequently, most of the sequences obtained from the mouse gut represent genera that are not detected in humans. Furthermore, intraspecies variability of the microbiota within the human population is also substantial. Indicator organisms such as *Helicobacter pylori* and *Streptococcus mutans* highlight some differences across the microbiota and metagenome among human ethnic groups; however, the extent of ethnic variation in overall metagenomic composition is unknown. The microbiomes of monozygotic twins are more closely related to one another than to those of unrelated individuals but not strikingly so, indicating important postnatal influences on composition.

The extensive lower-level taxonomic variation and large compositional differences observed even among highly related host organisms (e.g., mice and humans) are counterbalanced by the substantial conservation of metagenomic core functions (Fig. 278-2), reflecting the conservation of core bacterial properties involved in nucleic acid and protein synthesis and in metabolic and structural requirements. Of the more than 50 known phyla, most of the human microbiota is composed of fewer than 10 (and mostly six) phyla. Bacteria from other phyla, often of plant origin, that may be present in skin, nasopharyngeal, or gut samples are generally infrequent (<0.01% of the sequences) and probably represent transient carriage from food-borne and airborne exposures. The parallel needs of individual bacteria lead to competition for key substrates and to functional redundancy in the microbiota. Nevertheless, the enormous bacterial biomass also provides many unique or minimally redundant bacterial genes.

Resilience and Community Disturbance

Resilience, the ability to withstand disturbance, is a central concept in ecology. Whereas the microbiome of human adults appears highly resilient, the same may not be true for children. Because microbial population

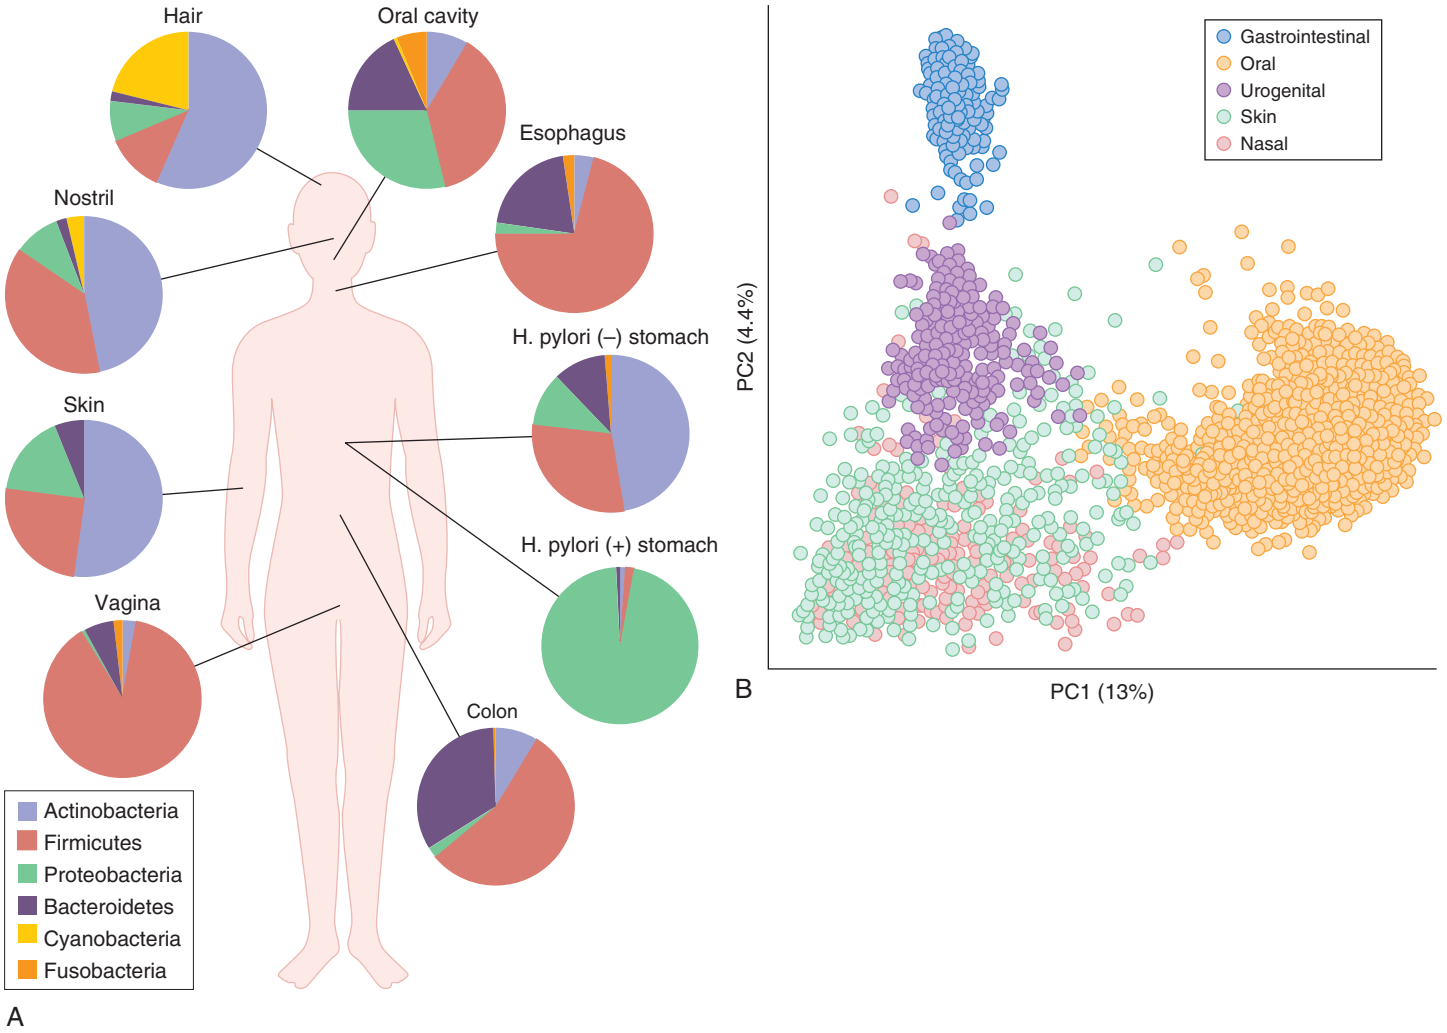

FIGURE 278-1. Compositional differences in the microbiome and metagenome by anatomic site. A, Substantial intersite microbiome variation. Higher level (e.g., phylum) taxonomic features display temporal (longitudinal) stability in individuals at specific anatomic sites. The figure indicates percentages of sequences at the taxonomic phylum level from selected references. Certain features, such as the presence or absence of *Helicobacter pylori*, are associated with alternative community composition states. (Modified from Cho I, Blaser MJ. The human microbiome: at the interface of health and disease. *Nat Rev Genet*. 2012;13:260-270.) **B,** Taxonomic variation and spatial relationships. Primary clustering, shown by principal coordinate analysis, is by anatomic site. Gastrointestinal, oral, urogenital, and skin populations separate, but samples from the nasal cavity bridge both the oral and skin populations. Site-specific differences as well as observed interpersonal conservation provide a framework to understand biologic and pathologic significance of particular microbiome compositions. (From Human Microbiome Project Consortium. Structure, function and diversity of the healthy human microbiome. *Nature.* 2012;486:207-214.)

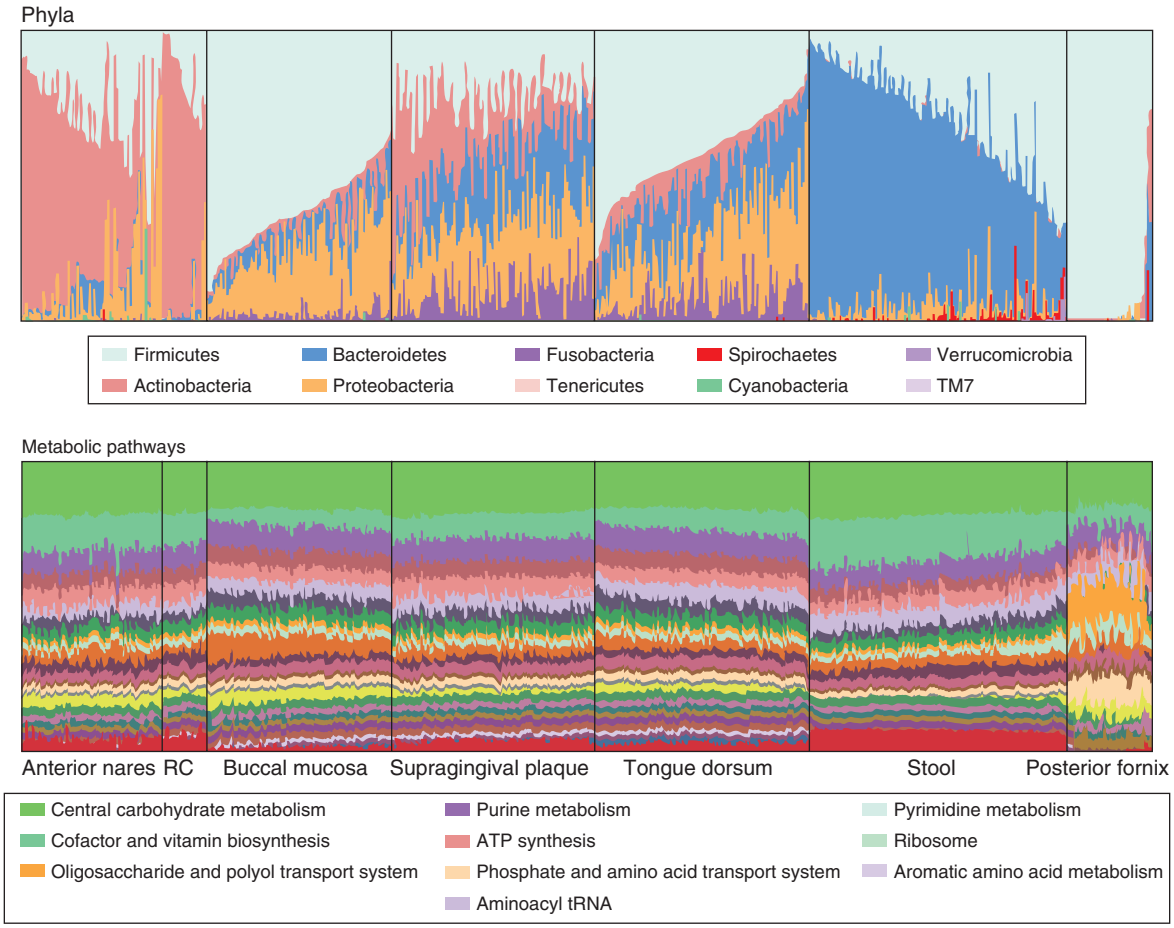

FIGURE 278-2. Variation and conservation in the microbiome and metagenomic functions of human anatomic sites. The phylogenetic composition of the microbiome at several anatomic sites shows substantial variation among individuals (*top panel*). Most but not all communities' membership consists of one or two dominant species (e.g., Firmicutes and Bacteroidetes in stool). However, the core metabolic functions of the microbial communities (*bottom panel*) are evenly distributed and highly conserved within a healthy population and across anatomic sites. Vertical bars represent microbiome samples of 242 individuals; colors represent relative abundance of microbial phyla or metabolic pathways in those samples. RC = retroauricular crease. (From Human Microbiome Project Consortium. Structure, function and diversity of the healthy human microbiome. *Nature*. 2012;486:207-214.)

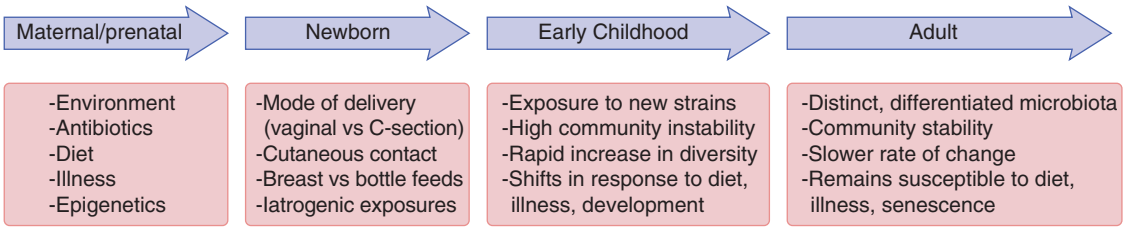

FIGURE 278-3. Factors and characteristics affecting acquisition and development of the microbiota from birth to adulthood. Numerous factors can affect the microbiome, beginning with prenatal exposures, such as to antibiotics, that can alter the composition of the maternal microbiome. Evidence exists that the mode of delivery can affect the initial composition of an infant's microbiome. The microbiome of young children is dynamic, but later in childhood (after 3 years of age), communities stabilize. At every stage of life, the microbiota are susceptible to external pressures, such as antibiotic exposure, diet, or disease.

structures appear more dynamic and developmental, resilience may be lower. An important natural experiment has been occurring during the past 70 years in which most of the world's population has been exposed to pharmacologic doses of antimicrobial agents. Such usage has been based on the implicit belief that the human microbiome is completely resilient and returns to the *status quo ante* after antibiotic-induced perturbation. These exposures also may cause medium- and long-term selection of resistant organisms and destabilization of the microbiome with new species compositions in the absence of further antibiotic exposure. Thus, despite the extensive resilience inherent in a complex ecosystem, there may be loss of recovery from continued perturbations, with important future implications for human health.

Extinctions

The human microbiome represents one or more complete ecosystems. Such communities may resist random perturbations, but if keystone species are lost, effects may cascade with secondary extinctions. High biodiversity diminishes this risk. In the short term, functional redundancy may mask extinction effects, but in the longer run, extinctions lead to loss of contingency responses that can cause ecologic crashes. Considering the importance of guilds of bacteria exploiting parallel and sequential metabolic pathways and the extent of medical interventions that are perturbing them, these concepts are germane to the human metagenome.

INFLUENCES ON THE MICROBIOTA DURING THE LIFE CYCLE

Differences in microbiota composition exist across body sites and between individuals.[2] However, changes are also evident across the human lifespan. Studies have answered important questions, such as whether temporal changes are life-stage specific and if they are predetermined by host genetic characteristics or environmental factors (Fig. 278-3).

Inheritance of Microbiota

The congruent phylogenies of mammals and their microbiota provide strong evidence for the inheritance of the microbiota. Increasing evidence supports maternal inheritance. Until the amniotic sac ruptures, a fetus has been considered to be essentially sterile. Immediately after vaginal delivery, microbial

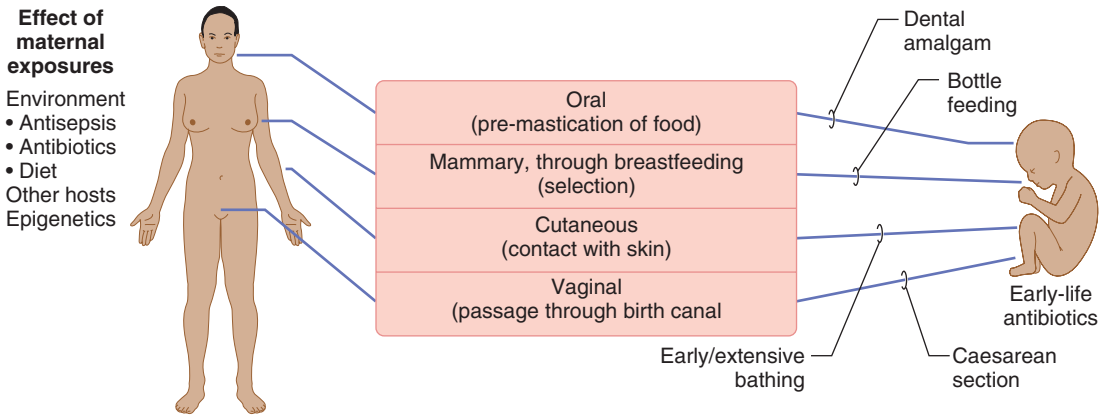

FIGURE 278-4. Factors affecting maternal exposures and vertical transmission of the microbiome between mother and child. Natural birth provides important opportunities for mother-to-child microbial transmission through a series of direct physical contacts. However, modern health practices can reduce flow of organisms and genes, thereby affecting the composition of the early infant microbiome. Many factors can affect early microbiomic development, including offspring genetics and epigenetics as well as dietary variation and environmental exposures. Organisms that have particular tissue or niche specificity explain conserved microbiome compositions at specific anatomic sites. (Modified from Cho I, Blaser MJ. The human microbiome: at the interface of health and disease. *Nat Rev Genet*. 2012;13:260-270.)

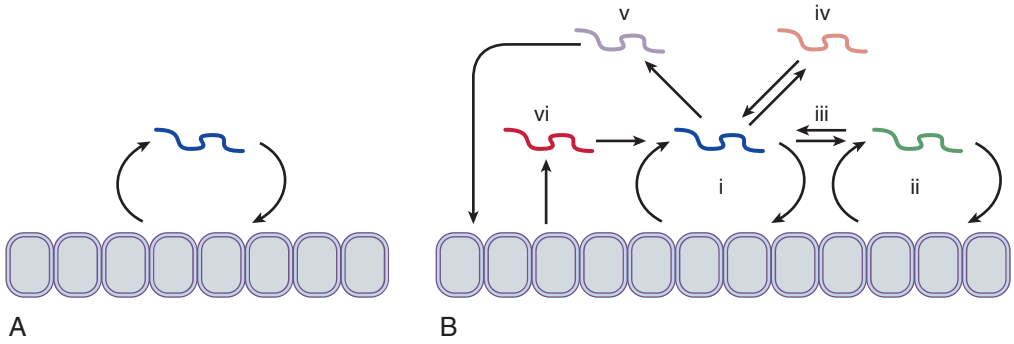

FIGURE 278-5. Equilibrium between co-evolved microbes and host cells. A, Single-organism equilibrium. In this model, there is a counter-regulatory interaction involving metabolic and physical signals between the microbe and host. **B,** Multiple organisms in equilibrium. This more complex model better approximates the interactions that occur in the human microbiome. Organisms may have individual equilibrium relationships (e.g., *i* and *ii*) with host cells. However, the interactions between these two microbes (*iii*) will affect their individual interactions. Similarly, another microbe (*iv*) may interact exclusively with an organism (*i*) but not with the host. Some interactions may be primarily unidirectional, as with a microbe (*v*) that is influenced by others and directly signals the host but does not receive direct host signals back. This may also proceed in the opposite direction as well (*vi*). (Modified from Plottel CS, Blaser MJ. Microbiome and malignancy. *Cell Host Microbe.* 2011;10:324-335.)

populations in the infant closely resemble those of the mother's vagina, with lactobacilli predominating. Because lactic acid–producing bacteria dominate both the vaginal canal and mother's milk, the initial bloom of lactobacilli cannot be considered accidental.

The multiple opportunities for the microbiota to be transferred from a mother to her baby may be disrupted by modern lifestyles.[3] Cesarean section instead of vaginal delivery is an obvious example of the potential impact of medical practice on microbiota composition, with substantial differences in founding populations that may persist for months. Such difference may alter infant immune responses, potentially leading to long-term consequences (Fig. 278-4).

Postnatal Influences on the Microbiota

Over a lifetime, each person develops a densely populated microbiome. The eruption of teeth is responsible for major successions in the oral microbiota, suggesting that succession may be a general property of human microbiome dynamics. Exposure (or not) to environmental microbes is another important but highly variable reservoir for the resident microbiota. Antibiotic use early in life produces major shifts in both microbiota characteristics and host developmental phenotypes, both on the farm and in experimental animals. Whether such precedents are applicable to human children is unknown but seems likely. If so, then both the timing of microbiome succession and the specific organisms present may affect metabolic, immunologic, and even cognitive development.

Microbiome Dynamics in Adults

Our knowledge of microbiome dynamics, especially age-related changes, during human adulthood is limited. We know that the postmenopause vaginal microbiota differs substantially from that during the reproductive period. Similarly, in the stomach, the age-related progressive development of gastric atrophy (enhanced by *H. pylori* presence) selects for gastric microbiota that are substantially different from the norm. Analogous changes may be occurring in other body sites as senescence advances. In the gut, the ratio of Bacteroidetes to Firmicutes changes with age. The specific interactions that the microbiome has with human hosts are enormously complex (Fig. 278-5), and further studies will be needed to define the specific pathways that inform the maintenance of health or the pathogenesis of disease. These concepts are particularly relevant to oncogenesis, which is generally age related. In the multistep Nordling hypothesis of oncogenesis, four to six somatic cell mutations are needed for cancer development. Microbiota shifts may contribute to this multistep process. Residential microbes can contribute to host cell mutagenesis by inflammation, increased cell proliferation, and production of promutagenic metabolites (e.g., butyrate).

DISEASE LINKS AND HEALTH IMPLICATIONS

How, then, does the microbiome affect human health? For many conditions, the challenge is to discover whether there is a causal link between microbiome variation and significant disease. Limitations in the definitions and stratification of clinical syndromes, including irritable bowel syndrome and nonulcer dyspepsia, reduce the potential of microbiome studies. Several examples of preliminary but promising observations follow.

Cutaneous Microbiome

The cutaneous microbiome could be involved in specific diseases, such as psoriasis, a chronic, idiopathic inflammatory condition. In some studies, Actinobacteria were significantly underrepresented in psoriatic lesions compared with unaffected skin both in psoriasis patients and in normal controls. Atopic dermatitis, another chronic inflammatory condition, has substantially increased in incidence in developed countries, suggesting a potential role for microbiome alterations. Classic atopic dermatitis occurs in areas, such as the antecubital and popliteal fossae, with similar microbial populations, suggesting a microbiome role. Similarly, *Propionibacterium acnes* has been implicated in the common dermatologic condition acne. Although *P. acnes* thrives in the cutaneous pilosebaceous units and secretes enzymes that cause local injury

and inflammation, continuing investigations are identifying *P. acnes* strain differences as well as other microbes in acne development. In chronic skin ulcers, often secondary to venous stasis or diabetes, cutaneous microbiome shifts occur. For example, Pseudomonadaceae are increased in patients with chronic ulcers treated with antibiotics, and Streptococcaceae are increased in diabetic ulcers.

Gastric Microbiome

The discovery of *H. pylori* overturned the dogma that the stomach is sterile. In *H. pylori*–negative persons, gastric microbiota diversity is high. Most of the prominent gastric species also are abundant in the oropharynx, indicating that many constituents are swallowed from more proximal sites or that close relatives of the oral microbiota colonize more distally. In contrast, among *H. pylori*–positive persons, *H. pylori* often accounts for more than 90% of sequence reads from the gastric microbiota, reducing the overall diversity in this discrete niche. *H. pylori* is a classical amphibont; the presence (or absence) of an *H. pylori*–dominated gastric microbiota is strongly associated with particular diseases with important age-related differences. Its presence increases risk for development of peptic ulcer disease, gastric mucosa-associated lymphoid tissue (MALT) tumors, and gastric adenocarcinoma, but its absence is associated with increased reflux esophagitis and childhood-onset asthma. These disease relationships illustrate our complex biologic interactions with our microbiota.

The Colonic Microbiota and Colorectal Cancer

Involvement of the colonic microbiota in the development of colorectal cancers has long been suspected.[4] Synthesis of short-chain fatty acids, in particular butyrate, may induce apoptosis, cell cycle arrest, and differentiation through Wnt signaling. Microbes may also be genotoxic to colonic epithelial cells, inducting polyploidy. The colonic microbiota also might promote colorectal cancer by eliciting host responses, for example, by stimulating exaggerated immune responses, potentially through T_H17 cells. Another link with colorectal cancer is suggested by antibiotic administration, altering the composition of the colonic microbiota, affecting expression of host genes involved in cell cycle regulation, and reducing epithelial proliferation. Early studies limited to identifying culture-dependent species, such as *Streptococcus bovis*, could not adequately assess anaerobic constituents. However, the anaerobic genus *Fusobacterium* has recently been associated with colorectal cancer, especially *Fusobacterium nucleatum*, a mucosally adherent, proinflammatory microbe first identified in the mouth. In colorectal cancer samples, *F. nucleatum* sequences were significantly enriched compared with control subjects, whereas both Bacteroidetes and Firmicutes were relatively depleted in those with *Fusobacterium*-rich malignant neoplasms. However, the causal direction of the association has not yet been ascertained. Finally, epigenetic phenomena, such as DNA hypermethylation, have been demonstrated to play an important role in the development of colorectal cancers through microsatellite instability and the sessile serrated adenoma pathway. It is possible that interactions with the microbiome may affect epigenetic pathways for colonic carcinogenesis.

The Colon Microbiota and Inflammatory Bowel Disease

The microbiome is essential for the activation of host immune responses.[5] For example, in mice, T_H17 cell differentiation in the lamina propria requires the presence of segmented filamentous bacteria, and polysaccharide A produced by *Bacteroides fragilis* mediates conversion of $CD4^+$ T cells into regulatory T cells. Accordingly, microbes are suspected to be involved in inflammatory bowel diseases (Chapter 141). Susceptibility to inflammatory bowel disease is associated with host polymorphisms in bacterial sensor genes such as nucleotide-binding oligomerization domain–containing protein 2 (*NOD2*; also known as *CARD15*) and toll-like receptor 4 (*TLR4*), and patients with inflammatory bowel disease sometimes improve after antibiotic treatment. Exposure to antibiotics in early childhood has been associated with significantly increased risk for Crohn's disease, suggesting that gut microbiome perturbations may enhance disease risk. Microbial diversity is significantly diminished in Crohn's disease, suggesting decreased gut microbiome resilience. Gut microbiome population structures of patients with ulcerative colitis or Crohn's disease are not normal and are clustered by disease. More recent investigations have implicated adherent-invasive *Escherichia coli* as a candidate pathogen in ileal Crohn's disease, given its ability to adhere to and invade epithelial cells and to replicate within macrophages. Specific bacteria among the Enterobacteriaceae may synergize with a disordered microbiome to increase the risk of ulcerative colitis. Among twins discordant for ulcerative colitis, those affected had significantly reduced bacterial diversity but increased Actinobacteria and Proteobacteria. Patients with Crohn's disease have overrepresentation of *Enterococcus faecium* and several Proteobacteria compared with controls. The microbial patterns observed for the conditions described are preliminary, and their specificity and causal direction have not been established.[6]

The Gut Microbiota and Diseases of the Liver

The gut microbiota may be involved in hepatic conditions, including nonalcoholic fatty liver disease, alcoholic steatosis, and hepatocellular carcinoma. The liver is the first solid organ exposed to the metabolic products generated by the gut microbiome, including acetaldehyde, ammonia, and phenols. Compared with germ-free mice, the presence of a microbiome in conventional mice led to suppression of intestinal epithelium angiopoietin-related protein 4, which inhibits lipoprotein lipase, increasing downstream triglyceride accumulation in the hepatic parenchyma and adipocytes. Chronic ethanol exposure disturbs the gut microbiome, but roles for the microbiome in steatosis are unresolved. Particular murine colonic commensals (e.g., *Helicobacter hepaticus*) promote the development of hepatocellular carcinoma. Patients with cirrhosis have a substantially altered microbiome, including community-wide changes at multiple taxonomic levels, with enrichment of Proteobacteria and Fusobacteria (phyla) and of Enterobacteriaceae, Veillonellaceae, and Streptococcaceae (family). Although many observations suggest links between microbiome composition and liver disease, definitive associations in humans are lacking.

The Gut Microbiota and Obesity

Genetically obese (*ob*/*ob*) mice have decreased ratios of Bacteroidetes to Firmicutes compared with lean (*ob*/+ and +/+ wild-type) siblings. Transplantation of gut microbiota from the obese (*ob*/*ob*) to germ-free mice conferred an obese phenotype, which shows the transmissibility of metabolic phenotypes; the transferred microbiomes had increased capacity for energy harvest. Studies have shown that transplantation of human microbiota can achieve parallel effects. In humans, relative Bacteroidetes proportions increase with weight loss. In monozygotic and dizygotic twins, obesity has been associated with decreased Bacteroidetes and diminished bacterial diversity, with enrichment of genes related to lipid and carbohydrate metabolism. In early life, the administration of antibiotics or alterations in diet may select for altered microbiota compositions, contributing to development of obesity.[7] Antibiotic use in human infancy, before the age of 6 months, has been significantly associated with obesity development. In contrast, in another study, perinatal administration of a *Lactobacillus rhamnosus* GG–based probiotic decreased excessive weight gain during childhood. These preliminary studies provide support for the concept that the early-life microbiota is modifiable, with alterations affecting risk of childhood-onset obesity. Studies are ongoing in adults to determine specific characteristics of the microbiome that may predict the risk of adiposity-related comorbidities.[8] Interventions used to treat obesity, such as the Roux-en-Y gastric bypass, substantially alter the gut microbiome, which may contribute to the metabolic effects.

The Gut Microbiota and Rheumatoid Arthritis

Altered regulation of host responses secondary to dysbiosis within the gut lumen could affect distant anatomic sites. This may be a mechanism in rheumatoid arthritis, another chronic idiopathic inflammatory condition. In mice, the presence of segmented filamentous bacteria in the gut microbiome causes local expansion of T_H17 cells that then migrate to peripheral immune compartments and activate B cells into antibody-producing plasma cells. Antibody production leads to immune-mediated destruction of the joints that mirrors rheumatoid arthritis. Substantial alterations in the gut microbiota have been identified in patients in the early stages of rheumatoid arthritis, consistent with a pathogenic role.

The Effect of the Microbiota on the Brain and Behavior

Early work suggests potential links between the gut microbiome and specific neurologic processes and disorders. Germ-free mice showed an exaggerated hypothalamic-pituitary response to stress that diminished after conventionalization with fecal matter. Subsequent investigations showed that the microbiome could alter neurotransmitter levels, such as brain-derived neurotropic factor and serotonin.[9] The rising incidence of autism in developed societies has led investigators to question whether shifts in gut microbes may play a causative role in these neurodevelopmental disorders. However, causal associations are difficult to determine from existing studies because many affected

children have concomitant gastrointestinal symptoms and were repeatedly treated with antibiotics. Microbiome effects on multiple sclerosis and other neurologic diseases have been hypothesized.

CAUSE OR EFFECT?

Microbiome analysis in humans has been largely observational, associating disease phenotypes with particular microbiota constituents. But which is causal? Does factor A cause factor B, does factor B cause factor A, or does factor C cause both A and B? Bradford Hill developed criteria to address the questions, "In what circumstances can we pass from this observed association to a verdict of causation? Upon what basis should we proceed to do so?" The criteria include the strength of association; its consistency, specificity, temporality, and biologic plausibility; and whether biologic gradients are present, experimental support exists, and support can be extrapolated from known causal relationships. These criteria are applicable to understanding either environmental or genetic (including metagenomic) causal roles.

For understanding causation and pathogenesis, model organisms provide an important approach. Animal models approximate some human diseases (e.g., asthma, atherosclerosis), but others (e.g., psoriasis) are not well reproduced. For those diseases that can be studied in model organisms, microbiota roles can be explored. Standard models of inbred mice are limited by their uncontrolled microbiome diversity. Certain disease states are well studied in these models, such as the effects of segmented filamentous bacteria on T_H17 development or the susceptibility to type 1 diabetes in nonobese diabetic mice. The use of germ-free mice eliminates microbiome variability until the introduction of "test" microbiota but requires specialized facilities, limiting their widespread use. The recent availability of germ-free animals from commercial sources permits their conventionalization without requiring such facilities, permitting direct observation of microbiota effects.

PERSPECTIVES

To better understand the implications of microbiota and metagenome variation in human health and disease, improved informatics tools are needed. The multidimensionality of the human and microbial phenotypes and the dynamic, nonlinear interactions challenge simple linear solutions.

The inherent compositional complexity of the microbiome limits investigations of microbe-associated diseases by classical approaches, such as Koch's postulates. Instead of single organisms associated with disease, community characteristics (composition and metagenomic functionality) may be more relevant. The principles of host interaction with pathogens and commensals contain many parallel features, which can help tutor the new field, but the nature of the selection for commensalism is more complex and highly dynamic. The scale of the interface suggests that microbiome-host interactions have important bearings on disease susceptibility; microbial effects on host metabolism and immunity provide "proof-of-principle" for the broader phenomenon of disease susceptibility. Modifying disease risk by altering metabolic, immunologic, or developmental pathways is an obvious strategy. Study of the microbiome, leading to new understandings of complex traits, will ultimately lead to new preventives, diagnostics, and therapies.

REVIEW QUESTIONS

1. Which of the following statements is correct regarding the human microbiome?

A. The human microbiome is a DNA-based analysis of the composition of the indigenous microbial communities throughout an individual's gastrointestinal tract (formerly called normal flora).
B. In a healthy individual, the phylogenetic composition of the microbiome remains mostly constant from one anatomic site to another, but the core metabolic functions of these microbial communities vary greatly across anatomic sites.
C. Changes in microbiota composition occur during the entire life cycle of an individual, with the most dramatic changes developing after early childhood (after 3 years of age).
D. There is strong evidence for an inherited basis of the microbiota, particularly supporting maternal inheritance.
E. Metabolic and physical signaling occurs among the microbes but not between the microbes and their host, creating dynamic equilibrium relationships within the microbiome independent of its host.

Answer: D The congruent phylogenies of mammals and their microbiota provide strong evidence for the heritability of the microbiota. In humans, increasing evidence supports a maternal inheritance. Choice A is incorrect because the human microbiome involves much more than the gastrointestinal tract. Indeed, the presence of major clustering patterns at various body sites provides new ways to classify individuals and their potential for disease risks (see Fig. 278-1). Choice B is incorrect because the reverse is true: it is the phylogenetic composition of the microbiome that varies greatly from one anatomic site to another, whereas the core metabolic functions remain remarkably constant and conserved across anatomic sites (see Fig. 278-2). The most dramatic changes in the microbiome occur in the prenatal and neonatal periods, but the microbiome after the age of 3 years tends to stabilize. At every stage of life, the microbiota is susceptible to external pressures, diet or disease in the host, with constant metabolic and physical signaling occurring between microbes and host cells, not just among the microbes themselves.

2. An example of a determinant that is *not* known to be associated with variation in the composition of microbial communities at different sites is

A. Colonic microbiota varying with colon cancer
B. Vaginal microbiota varying with menses
C. Periodontal microbiota varying with tooth brushing
D. Gastrointestinal tract microbiota varying with diet
E. Nasopharyngeal microbiota in young children varying with seasonal change

Answer: C Cooperative interactions between microbes and their hosts typically involve microbial participation in host functions such as defense, metabolism, and reproduction. All of the above except C are known to cause perturbations. Large perturbations, such as antibiotic exposure or enteric infections, can lead to transient disequilibria or even the development of new stable states.

3. For which of the following conditions does the presence of *Helicobacter pylori* alter the risk?

A. Gastric cancer
B. Peptic ulcer disease
C. Reflux esophagitis
D. Childhood-onset asthma
E. All of the above

Answer: E In the absence of *H. pylori*, gastric microbiota diversity is high (although it was once believed that the stomach is sterile). In contrast, among *H. pylori*–positive individuals, this organism accounts for more than 90% of the sequence reads from gastric microbiota. The presence of *H. pylori* increases the risk for peptic ulcer disease, gastric cancer, and mucosa-associated lymphoid tissue (MALT) lymphomas. On the other hand, the absence of *H. pylori* increases the risk of reflux esophagitis and childhood-onset asthma. (See section on gastric microbiome under Disease Links and Health Implications.)

4. Which of the following disease links with gut microbiota is correct?

A. Antibiotic use in infancy is associated with obesity development.
B. Shifts in gut microbes in infancy play a role in causation of autism.
C. Changes in gut microbiota are pathogenic in the early stages of systemic lupus erythematosus.
D. Disturbances in the gut microbiome by chronic alcohol exposure contribute to development of alcoholic steatosis of the liver.
E. None of the above

Answer: A Most microbiome associations with human disease have been observational in nature and therefore do not prove cause-and-effect relationships (see Cause or Effect?). Although a causal relationship cannot be considered definitive at this time, antibiotic use in human infancy, before the age of 6 months, has been significantly associated with later obesity development. Furthermore, perinatal administration of *Lactobacillus*-based probiotics has been shown to decrease excessive weight gain during childhood. These and other observations have suggested that early-life microbiota are modifiable, with alterations affecting the risk of childhood-onset obesity (see The Gut Microbiota and Obesity). At this point, associations between shifts in gut microbes and autism or alcoholic steatosis (although chronic alcohol exposure does alter the gut microbiome) are entirely observational and preliminary. Substantial alterations in the gut microbiota have been identified in patients with early rheumatoid arthritis, consistent with a pathogenic role, but not with systemic lupus erythematosus. (See corresponding sections under Disease Links and Health Implications.)

PRINCIPLES OF ANTI-INFECTIVE THERAPY

GEORGE M. ELIOPOULOS

Among the pharmaceutical agents used in the treatment of human disease, antimicrobial agents are distinctive because they target invading microorganisms rather than abnormal human cellular functions. As a result, to select an appropriate antimicrobial regimen, it is necessary to consider both the activity of the agent against the known or suspected pathogen and the effects that agent might have on the individual under treatment. Although the term *anti-infective agent* can be used more broadly to include substances that ameliorate infection by altering the virulence of the pathogen or modulating the host's response to infection, for purposes of this chapter, *anti-infective agent* and *antimicrobial agent* are used interchangeably to refer to drugs that inhibit the growth of microbial pathogens. This chapter focuses primarily on agents directed against bacterial pathogens, although many parallels can be drawn to the use of antimicrobial agents for the treatment of fungal, viral, or parasitic infections.

On the time scale of human history, the modern antibiotic era is short. Since the introduction of penicillin for general clinical use in the mid-1940s, the numerous antimicrobial agents developed for human use have saved countless lives and have led to amazing advances in cancer chemotherapy, organ transplantation, and implant surgery that have improved and extended the lives of many others. Unfortunately, over time, resistance to available antibiotics has become widespread among many common bacterial pathogens,[1] making the selection of appropriate antimicrobial regimens ever more challenging and threatening to thrust an unfortunate few into a situation resembling the pre-antibiotic era.

SELECTING ANTIMICROBIAL THERAPY TARGETING THE PATHOGEN

Empirical Antimicrobial Therapy

In most instances, selection of the initial antimicrobial therapy proceeds empirically, before a causative organism is identified or tested for susceptibility to antimicrobial agents. The clinician's first decision is whether a patient's symptoms are likely to represent infection. Fever may result from neoplastic, rheumatologic, or other noninfectious processes and does not necessarily imply the presence of infection. Noninfectious causes of fever, such as deep vein thrombophlebitis, drug reaction, and vasculitis, may pose just as great a risk to the patient as infection and must not be overlooked.

Additional symptoms, signs, and laboratory or radiographic data usually help define whether infection is likely and, if so, localize the organ systems involved. This information allows an initial prediction about the organisms likely to be involved. For example, if the initial data cause one to suspect a diagnosis of community-acquired pneumonia in a previously healthy person who does not have any unusual exposures, *Streptococcus pneumoniae* and atypical bacteria such as *Mycoplasma pneumoniae* or *Chlamydophila pneumoniae* would be prominent on the list of potential pathogens to be targeted in selecting antimicrobial therapy. Examination of a gram-stained slide of expectorated sputum may provide valuable information. The prominent appearance of gram-positive cocci in clusters, for example, would alert the clinician to the possible presence of *Staphylococcus aureus*, many isolates of which are now methicillin resistant, and thus lead the clinician to select treatment options to include targeting of these organisms.

Guidance regarding the probable pathogens for site-specific infections and the susceptibility of these organisms to antimicrobial agents is available from a number of sources.[2] In some cases, the susceptibility of suspected pathogens can be predicted with a high degree of certainty. For example, *Streptococcus pyogenes* remains uniformly susceptible to penicillin G. In other instances, resistance has emerged to antimicrobials previously considered to be highly active against a species. Resistance rates for a given organism may vary widely by region, by health care institution, or even by patient care area within a hospital. For this reason, access to periodically updated, cumulative antibiotic susceptibility profile data specific to an institution can be important. Typically presented in tabular form, these "antibiograms" show the percentage of recently isolated bacterial pathogens that proved "susceptible" to the antibiotics tested and can help guide the selection of appropriate empirical regimens at that practice site.

There is mounting evidence that selection of an appropriate regimen (i.e., one that contains an antimicrobial that can be expected to inhibit the causative pathogen at the site of infection) and the prompt initiation of that empirical treatment result in improved clinical outcomes in those with serious infections. Published guidelines for the treatment of community-acquired pneumonia (Chapter 97) advise administration of the first dose of appropriate antimicrobial therapy while the patient is still in the emergency department.

Whenever possible, samples of purulent exudates, blood, or other body fluids suspected to be infected should be obtained for culture before antimicrobial therapy is started. Identification and susceptibility testing of the microorganisms detected can be used to direct subsequent definitive treatment. At times, however, this principle must be overridden. For example, when bacterial meningitis is suspected, antibiotic therapy (often with

adjunctive corticosteroids) must not be delayed when a lumbar puncture cannot be performed promptly to obtain material for culture. In such instances, blood samples taken for culture before the administration of antibiotics often reveal the causative organism, or the pathogen may grow from spinal fluid even if lumbar puncture is delayed.

Definitive Antimicrobial Therapy

Identification of the causative microorganism and determination of its susceptibility to available drugs are the basis for optimizing definitive antimicrobial regimens. Often, the antibiotics used for empirical therapy are appropriate for definitive therapy and can be continued. At other times, the results allow one to switch to a narrower spectrum, better tolerated, or less expensive antimicrobial.[3] In some instances, test results indicate the need to broaden the spectrum of an anti-infective regimen by adding or substituting agents active against pathogens inadequately targeted by the initial empirical regimen.

In almost all cases, it is desirable to test an infecting organism's susceptibility to antimicrobials that may be useful. To extend the example cited earlier, although it is not necessary to test the susceptibility of *S. pyogenes* to penicillin G, some isolates are resistant to macrolide antibiotics (e.g., erythromycin, azithromycin) and other drugs, so the testing of alternative agents might be useful for patients who are intolerant of β-lactam antibiotics. Even when the activity of certain antimicrobials can be predicted with great confidence, susceptibility testing is still useful. For example, surveillance studies examining hundreds of isolates have predicted that vancomycin or linezolid would inhibit virtually all *S. aureus* strains recovered from initial clinical specimens. Therefore, on statistical grounds, testing of these agents would not seem warranted; however, rare isolates resistant to these agents have now been encountered, and it is advantageous to detect such isolates for both therapeutic and epidemiologic purposes. For most bacterial pathogens, resistance to commonly used agents is sufficiently frequent that testing of antimicrobials being considered for definitive therapy is essential. Organisms of the family Enterobacteriaceae that are resistant to multiple antibiotics are isolated often enough, even among outpatients, that susceptibility to agents previously considered broadly active, including third-generation cephalosporins, fluoroquinolones, and aminoglycosides, is no longer ensured. Even more challenging problems of drug resistance are encountered among isolates of species such as *Pseudomonas aeruginosa*, *Acinetobacter baumannii*, and *Stenotrophomonas maltophilia*.

Susceptibility Testing

Several methods are available for determining the susceptibility of a bacterial isolate to antimicrobial agents being considered for therapy. Tests most frequently used in clinical microbiology laboratories today are variations of three methods: serial dilution, disc diffusion, and gradient diffusion. The minimal inhibitory concentration (MIC) represents the lowest concentration of an antimicrobial tested that inhibits growth of the microorganism in test media.

In the dilution method, the antimicrobial is diluted in broth or agar to span a range of (usually) two-fold decreasing concentrations, and the medium is then inoculated with a standardized number of organisms. After incubation for a specified period (usually 16 to 24 hours) at 35° to 37° C, the series of dilution tubes or microtiter wells (for broth dilution) or agar plates (for agar dilution) is examined for growth. The MIC is determined by direct inspection as the lowest concentration that prevents turbidity of the broth or colony formation on agar. Modifications of this method allow the automation of many steps in the process, permitting more efficient test performance in clinical laboratories.

In the disc diffusion method, paper discs impregnated with a standardized amount of the antimicrobial are placed on an agar plate, the surface of which has been seeded with the bacterium to be tested. During incubation, the antimicrobial diffuses from the disc into the surrounding agar and inhibits growth of the seeded organism. After a specified period of incubation, the zone of growth inhibition around the disc is measured. By this method, the MIC is not determined directly. Instead, relying on accumulated data correlating inhibition zones with MICs, the measured zone is used to predict the susceptibility of the organism to the drug tested.

The gradient diffusion method is similar to the disc diffusion method, except that instead of using a round paper disc impregnated with a single concentration of the antimicrobial, this test uses a strip impregnated with the antimicrobial applied in a concentration gradient along its length. The strip is laid on the surface of an agar plate that has been inoculated with a suspension of the organism to be tested, and the plate is then incubated. By visually inspecting where the zone of growth inhibition on the agar surface intersects the strip (which is marked at intervals corresponding to MIC equivalents), it is possible to determine the MIC value directly.

To perform susceptibility studies and to interpret the results, it is necessary to identify the organism to be tested. This knowledge allows the selection of appropriate methods and interpretive criteria to determine whether an organism is "susceptible," "intermediate," or "resistant" to an antimicrobial on the basis of measurement of the MIC or the inhibition zone diameter. To illustrate this point, consider that an enterococcus is determined to be susceptible to penicillin if the MIC is less than or equal to 8 μg/mL, whereas for viridans streptococci, the corresponding breakpoint for susceptibility to penicillin is the MIC of 0.12 μg/mL. Thus, knowledge that the MIC of penicillin against a gram-positive coccus growing in short chains is 2 μg/mL does not allow the determination of whether it is susceptible to penicillin unless the organism has been identified.

Additional tests are sometimes required to fully assess susceptibility to an antimicrobial. For oxacillin-susceptible *S. aureus*, a test for penicillinase production is performed to assess susceptibility to penicillin G. For erythromycin-resistant, clindamycin-susceptible *S. aureus*, the laboratory may perform a supplementary D-zone test or equivalent before reporting the clindamycin result. A positive D-zone test result (i.e., blunting of the inhibition zone around a clindamycin disc in proximity to an erythromycin disc) predicts the presence of *erm* genes. Their product, a ribosomal methylase, can confer resistance to clindamycin if it is expressed; however, clindamycin is a poor inducer of this resistance trait (in contrast to erythromycin, which is a good inducer). A positive test result thus implies the presence of inducible resistance traits. Mutants with constitutive production of methylase can be selected during treatment, resulting in the emergence of clindamycin resistance and an increased risk of clinical failure when this drug is used to treat serious staphylococcal infections caused by strains with the *erm* gene.

In principle, tests for the presence of resistance genes, their products, or both can be used in place of phenotypic resistance testing. Such methods have the potential to provide answers more rapidly than can be obtained with the usual susceptibility tests of growth inhibition, which generally require several hours of incubation. At present, these tests are not yet widely employed, with the exception of testing for methicillin resistance by detection of the *mecA* gene or its product, penicillin-binding protein 2a, or testing for rifampin resistance by detection of resistance mutations in *Mycobacterium tuberculosis*. Newer technologies, such as matrix-assisted laser desorption ionization–time of flight mass spectrometry, are being explored as a means of providing not only more rapid identification of organisms but also their predicted susceptibility to antimicrobial agents.[4]

Bactericidal Activity

In some circumstances, an antimicrobial regimen that kills pathogenic microorganisms would be preferable to an alternative regimen that only inhibits growth of the pathogen. Bactericidal activity is desirable in the treatment of endocarditis or meningitis; in these infections, bacteriostatic agents have generally performed poorly, possibly because of inadequate host responses to infection at these sites. Tests to measure the bactericidal activity of an antibiotic in vitro have been developed. Bactericidal activity is usually defined as a 99.9% reduction in the number of viable colony-forming units relative to the inoculum density at a specified incubation time, which is usually 20 to 24 hours.

Despite the theoretical benefit of determining the bactericidal activity of an antibiotic or drug regimen, these tests are rarely used clinically because of several factors, including (1) the labor-intensive nature of the tests, (2) the potential for discordant results due to the various methods and criteria for determining bactericidal activity, and (3) the imperfect correlation between bactericidal activity measured in vitro and clinical outcomes observed.

SELECTING ANTIMICROBIAL THERAPY APPROPRIATE TO THE INFECTION AND PATIENT

Nature of the Infection

Determination that a pathogenic microorganism is susceptible to an antibiotic in vitro does not ensure that treatment with that drug will result in a successful clinical outcome. The antimicrobial must reach the site of infection in adequate concentration, which is generally assumed to be some multiple of the MIC, and it must demonstrate activity in the infection milieu. For some infections and antimicrobials, these requirements cannot easily be met.

A number of antimicrobials fail to penetrate into cerebrospinal fluid sufficiently well to permit their use for the treatment of bacterial meningitis in

adults. First-generation cephalosporins or aminoglycosides given intravenously do not enter the subarachnoid space well enough to allow their use as primary agents for treatment of this disease. Aminoglycosides have been administered by intrathecal or intraventricular instillation when needed for the treatment of gram-negative meningitis, but the availability of newer β-lactams with broad activity, high potency, and reasonable cerebrospinal fluid penetration when administered intravenously has largely eliminated the need for direct instillation of antimicrobials.

In other situations, antimicrobials may penetrate to the site of infection, only to be inactivated by local factors. For example, daptomycin is inactivated by interaction with pulmonary surfactant, so this antibiotic is not indicated for the treatment of bronchopneumonia, even though it is highly active against *S. pneumoniae* isolates in vitro. Antibiotics can also be inactivated by cellular debris or macromolecules present within abscesses, and some exhibit reduced potency at the low pH and reduced oxygen tensions prevailing at these sites. Finally, high densities of microorganisms within abscesses may elaborate sufficiently high concentrations of β-lactamases to inactivate some relatively labile β-lactam antibiotics. All these factors provide a rationale for the drainage of large abscesses as an adjunct to antimicrobial therapy.

Bacterial infections associated with foreign bodies such as artificial joints, cardiac pacemakers, or prosthetic heart valves can be particularly difficult to eradicate without removal of the foreign material. The reasons are not completely understood, but they relate, at least in part, to the presence of biofilm, which is composed of bacteria embedded within extracellular material that is adherent to the foreign body. Bacteria recovered from biofilms are metabolically different from and less susceptible to antimicrobial agents than planktonic cells (i.e., those freely suspended in liquid medium) of the same organism. Rifampin is often added to antimicrobial regimens for the treatment of infections involving prosthetic material. This inhibitor of RNA polymerase rapidly penetrates into biofilms and demonstrates relatively similar activity against both biofilm-associated and planktonic cells of a susceptible organism. However, because resistance to rifampin emerges rapidly, it is not used as a single agent in these circumstances; rifampin must be combined with a second active drug to minimize the risk that resistance will emerge. Despite such approaches, many infections involving implanted devices prove refractory to antimicrobial therapy alone and require removal of the foreign material for eradication.

Host Factors

After consideration of the nature of the infection and the antimicrobials determined in vitro to be active against a bacterial isolate (or likely to be active against probable pathogens when an isolate is not yet available), the ultimate choice of an antimicrobial regimen must take into account a number of additional patient-specific factors, some examples of which are examined in the following paragraphs.

Allergies

It is imperative to obtain a history of previous allergic reactions to antimicrobial agents. Some reactions are by nature so severe and potentially life-threatening that one must avoid using the same agent or drugs within the same class for which cross-reactivity is likely to occur. Examples of such reactions include an immediate hypersensitivity reaction to penicillin (e.g., hives, lip swelling, laryngeal edema, circulatory collapse) and a mucocutaneous bullous eruption from a sulfonamide (e.g., Stevens-Johnson syndrome).

In cases in which the allergic reaction was mild, such as a faint, self-limited rash in a patient receiving penicillin, the clinician may elect to use a related antimicrobial, such as a cephalosporin, when the probability of cross-sensitivity and the risk for a severe adverse outcome if a reaction were to occur are both assessed to be low. In these instances, careful monitoring of the patient for adverse reactions is essential. Rarely, for patients with significant allergies to potentially life-saving antimicrobial agents for which no alternative exists, desensitization of the patient to the antimicrobial is attempted so that the agent can be used. For example, desensitization protocols are available for penicillin and for trimethoprim-sulfamethoxazole. Because of the risks involved, these procedures may need to be performed in intensive care unit settings.

Pregnancy

A number of antimicrobial agents have the potential to cause fetal harm if they are administered to a pregnant woman. For example, tetracyclines can cause tooth discoloration and hypoplasia of dental enamel and are thus avoided in pregnant women and young children. Streptomycin given during pregnancy can cross the placenta, and evidence of eighth nerve toxicity in the child has been reported. A few other antimicrobials are labeled by the Food and Drug Administration as pregnancy category D (evidence of human risk) or are contraindicated because of fetal harm (category X). Many more antimicrobials, however, are assigned to category C; for these drugs, the potential risk to the fetus is based on animal studies. In designing antimicrobial regimens, the possibility of pregnancy should be considered in any woman of childbearing age so that the risks of candidate agents can be individually reviewed and the safest possible therapy selected.

Many antibiotics used to treat lactating women can be found in breast milk. Thus, it may be necessary to suspend breast-feeding during treatment if exposure of the infant to the drug must be avoided.

Pregnant women may be particularly susceptible to certain antimicrobial-associated toxicities. Death resulting from hepatic failure has been described in pregnant women receiving large doses of tetracycline. Potentially life-threatening hepatic steatosis has been observed in patients treated with a combination of the antiretroviral agents didanosine plus stavudine; pregnant women may be especially vulnerable to this toxic effect.

Age

For reasons discussed earlier, tetracycline antibiotics are avoided in children during tooth development to prevent discoloration and enamel hypoplasia of the permanent teeth. Because fluoroquinolone antimicrobials produce erosion of cartilage and arthropathy in juvenile animals, they are avoided in children when alternative agents are available. Recently, limited pediatric indications were added for ciprofloxacin (for complicated urinary tract infection and pyelonephritis and after inhalational exposure to anthrax) and for levofloxacin (inhalational exposure to anthrax and for plague). Musculoskeletal complaints appear to be more frequent in children treated with ciprofloxacin than with nonfluoroquinolone antimicrobials.

Pediatric dosing regimens differ from those appropriate for adults. Some agents, such as linezolid, are eliminated much more rapidly in young children (excluding preterm neonates) than in older children and adults, so higher doses may be required. In premature infants and neonates, renal function has not yet reached full capacity, and elimination of some antimicrobials may be delayed. Similarly, hepatic clearance activity is not fully developed in the very young, which has led to cardiovascular collapse and fatalities from chloramphenicol treatment. Absorption of oral antimicrobials may also differ with age if their absorption is dependent on gastric pH. The gastric pH of young children is higher than that of adults, and achlorhydria resulting in higher gastric pH is more common in adults older than 60 years than in younger adults. Thus, in young children and older adults, the absorption of oral drugs that are unstable in acid, such as penicillin G, may be higher than that in younger adults. In contrast, antimicrobials such as ketoconazole require gastric acid for absorption and may be less bioavailable in persons with reduced gastric acid production.

A curious association between the appearance of a rash and the patient's age and sex was noted during development of the fluoroquinolone antimicrobial gemifloxacin. In clinical studies, rash was more common in young women than in men and older women, suggesting that there may be hormonal influences on the risk for development of a rash.

Renal and Hepatic Function

Renal excretion and hepatobiliary excretion are the major routes of elimination for antimicrobial agents. Relatively few antibacterial agents can be administered without dosage adjustments in patients with renal dysfunction. Included among these drugs are nafcillin, ceftriaxone, doxycycline, azithromycin, and linezolid. Although linezolid exposure is not significantly altered, microbiologically inactive metabolites of the compound do accumulate in end-stage renal disease; what, if any, effect this has is unknown.

A number of antimicrobial agents require major dosage adjustments in the presence of renal dysfunction. The dosing interval for ceftazidime, usually administered every 8 hours in patients with normal renal function, is extended to once every 24 to 48 hours in persons with creatinine clearance below 10 mL/minute. Vancomycin is also administered at substantially increased dosing intervals or at smaller doses as renal function declines. Because of the increased efficiency of newer hemodialysis membranes in removing vancomycin, dosages are usually based on measured serum drug concentrations, and dosing may be required after each dialysis session.

In some instances, clearance of the antimicrobial agent is not affected by renal dysfunction, but excipients may accumulate, with the potential for toxic effects. For example, clearance of the antifungal agent voriconazole is not

dependent on renal function. However, its intravenous preparation contains the solubilizing agent sulfobutyl ether β-cyclodextrin, which does accumulate in the presence of renal insufficiency. The intravenous preparation should not be used in those with moderate to severe renal dysfunction, but the oral formulation, which does not contain β-cyclodextrin, can be administered. A number of other antimicrobials may accumulate in the presence of severe liver disease, with the possibility of an increased risk for adverse events. Antimicrobials requiring dose adjustments for various levels of hepatic insufficiency include metronidazole, chloramphenicol, tigecycline, caspofungin, and voriconazole. For ceftriaxone, dosage adjustments or careful monitoring may be required in patients with both hepatic and renal dysfunction.

Drug-Drug Interactions

One of the most important considerations in the selection of an appropriate antimicrobial regimen is to determine whether the drug or drugs will interact with other medications the patient is taking. Some drug-drug interactions can have severe or even fatal consequences. There are too many potential interactions to list comprehensively, but some examples are provided in this section. Fortunately, resources are now available that allow the clinician to check for potential drug-drug interactions when an antimicrobial agent is ordered.

A large number of antimicrobials are eliminated through cytochrome P-450 pathways. As a result, they may interfere with the elimination of other drugs cleared by these pathways, leading to their accumulation to potentially dangerous levels. Several macrolide antibacterials, some fluoroquinolones, and human immunodeficiency virus protease inhibitors are among the most likely antimicrobials to inhibit the clearance of other drugs. For example, use of the protease inhibitor darunavir/ritonavir is contraindicated with several drugs, including ergot derivatives, the neuroleptic drug pimozide, certain sedative-hypnotic agents, and others. Macrolides may result in increased levels of some 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors, which can lead to rhabdomyolysis.

In contrast, administration of rifampin induces the cytochrome P-450 system and may enhance the clearance of other drugs, some of which have narrow therapeutic windows. This may result in a number of important effects, including reduced effectiveness of oral contraceptives and increased warfarin requirements to maintain desired levels of anticoagulation. It is important to consider these potential interactions not only when starting rifampin therapy but also when *stopping* treatment. When rifampin is stopped, unless the previously increased dose of warfarin is adjusted downward accordingly, excessive anticoagulation and possibly serious bleeding can occur.

A number of other drug interactions have been described. Linezolid has weak monoamine oxidase inhibitor activity. As such, it has the potential to enhance the hypertensive effect of adrenergic agonists and has been associated with the development of serotonin syndrome in patients taking serotonergic antidepressants. Patients with this syndrome can exhibit a number of signs and symptoms, including fever, tachycardia, tremulousness, agitation, confusion, and clonus, occasionally with fatal results. Serotonin syndrome (Chapter 434) has been described in patients taking linezolid together with drugs other than selective serotonin re-uptake inhibitors; in principle, it could occur when linezolid is combined with any of a large number of agents that increase serotonin concentrations in the central nervous system.

Other Host Factors

Several additional host factors may influence the choice of a suitable antimicrobial regimen. Some antimicrobials have the potential to induce hemolysis in persons with glucose-6-phosphate dehydrogenase deficiency (Chapter 161). Among the drugs that should be avoided in these individuals are primaquine, nitrofurantoin, and various sulfonamides.

Coexisting diseases should also be taken into account. Use of fluoroquinolones or linezolid has been associated with abnormalities in glucose homeostasis. Hyperkalemia has been observed in patients with renal insufficiency during treatment with trimethoprim-sulfamethoxazole because trimethoprim blocks the renal excretion of potassium in the distal tubule.

In some cases, the patient's occupation might play a role in the selection of a treatment regimen. Antibiotics that can cause transient (minocycline) or permanent (streptomycin) dizziness or unsteadiness may create hazardous situations in those whose occupations require excellent balance. Antimicrobial agents with the potential to cause photosensitivity, such as tetracyclines, fluoroquinolones, trimethoprim, and sulfonamides, may be problematic in persons with significant sun exposure during outdoor employment or other activities.

ANTIMICROBIAL COMBINATIONS

It is common for hospitalized patients to receive more than one antimicrobial agent simultaneously. The rationale for using antimicrobials in combination is not always clearly defined, and there are a number of potential disadvantages to combination therapy. The basis for using combination therapy is considered in this section.

Reasons to Use Combination Antimicrobial Therapy

The clinical indications for using combination antimicrobial therapy can be divided into five categories. Two of these categories (empirical therapy and polymicrobial infections) relate to maximizing the likelihood that at least one agent in the combination will be active against known or suspected pathogens. The other three reasons (minimizing toxicity, preventing the emergence of resistance, and obtaining synergistic inhibition or killing) attempt to exploit the unique advantages of some combinations as compared with a component drug alone.

To Provide Broad Coverage during Empirical Therapy

A common reason for using more than one antimicrobial in hospitalized patients is to provide broad coverage against potential pathogens and to maximize the likelihood of delivering an active antimicrobial agent as quickly as possible to seriously ill patients. When the pathogen is unknown, the antimicrobial regimen often includes an agent broadly active against gram-positive bacteria, including methicillin-resistant *S. aureus* (MRSA), such as vancomycin, as well as an agent active against aerobic or facultative gram-negative bacteria. Selection of the latter is strongly influenced by local patterns of antimicrobial resistance specific to the institution and might include an extended-spectrum cephalosporin, an aminoglycoside, a fluoroquinolone, a β-lactam–β-lactamase inhibitor drug, or a carbapenem.[5] The last two choices also provide activity against gram-negative anaerobes. Alternatively, one could add an agent such as metronidazole to provide anaerobic activity. Because of the high frequency of antibiotic resistance in *P. aeruginosa* isolates, in settings in which that pathogen is encountered frequently, empirical use of two agents with antipseudomonal activity may be justified to maximize the likelihood that at least one of the agents will inhibit the organism.

Combination therapy is widely used in the initial treatment of hospitalized patients with community-acquired pneumonia. Commonly used regimens include a third-generation cephalosporin such as ceftriaxone with a macrolide or fluoroquinolone. This cephalosporin provides antimicrobial activity against *S. pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis*, and several other "typical" bacterial pathogens associated with community-acquired pneumonia, with the notable exception of MRSA. The macrolide azithromycin is commonly added to provide activity against "atypical" bacteria that cause pneumonia, including *M. pneumoniae*, *C. pneumoniae*, and *Legionella* species. One of the respiratory fluoroquinolones may also be added to attain coverage of the atypical organisms. Although fluoroquinolones approved for respiratory tract infections are likely to cover most or all of the organisms targeted by the cephalosporin, isolates of *S. pneumoniae* resistant to fluoroquinolones do exist, so guidelines recommend combination therapy in patients with severe pneumonia requiring hospitalization.

To Treat Documented Polymicrobial Infections

For many infections from which two or more pathogens are recovered, it is possible to provide adequate coverage with a single, broadly active antimicrobial agent. Switching to a single agent reduces the patient's exposure to potential antibiotic toxicities, is usually more convenient for nursing staff, and may be less expensive. For some patients, susceptibility profiles or allergies to broad-spectrum agents justify the use of antibiotic combinations for the treatment of polymicrobial infections.

To Attempt to Reduce Toxicity

It is theoretically possible to use two or more drugs of different classes with additive antimicrobial activities and independent toxicities, each at relatively low doses, to achieve sufficient potency while avoiding toxicity. However, there are no situations in which the approach of using submaximal doses of multiple agents is predictably effective in accomplishing this goal. This does not exclude the possibility that, in isolated instances, a successful response might be attained from additive effects when drugs with marginal activities are combined for treatment of infection due to multiply resistant organisms.

To Prevent the Emergence of Drug Resistance

The treatment of tuberculosis provides the paradigm for using combinations of drugs in an attempt to prevent the emergence of resistance to any one agent. The basis for this approach is that if resistance to two different agents occurs by independent mechanisms, the probability of resistance developing to both drugs is the product of the probability of resistance developing to each drug, which is likely to be very low, so resistance should not emerge. Similar reasoning has justified the use of combination regimens when rifampin is required for the treatment of nonmycobacterial infections. Rifampin is not used alone (with rare exceptions, such as brief courses for the eradication of meningococcal carriage) because resistance to this agent can emerge quickly. As mentioned earlier, rifampin is particularly useful in the treatment of infections related to foreign devices because of its activity against biofilm-associated bacteria. In such cases, it is combined with another active antimicrobial, such as vancomycin for coagulase-negative staphylococcal prosthetic valve endocarditis (usually with a brief course of gentamicin as well to reduce the bacterial inoculum further at the beginning of therapy) or a fluoroquinolone for orthopedic device–related infections.

It has been difficult to show unequivocally that combination therapy protects against the emergence of resistance to antimicrobial drugs in other situations, including infections caused by *P. aeruginosa* or *Enterobacter* species. There are two plausible explanations of why combinations do not prevent resistance predictably. First, there may be differential penetration of the two antimicrobials at an infected site or differences in activity at the site of infection. Thus, a more readily penetrating agent may be left relatively unprotected in a privileged site of infection. Second, for many commonly encountered bacteria, resistance mechanisms against unrelated antimicrobial classes may not be truly independent. Some bacterial efflux pumps recognize chemically unrelated substrates, so upregulation of pump activity may confer resistance to several classes of antimicrobials. In other instances, there may be coordinated upregulation of efflux mechanisms and downregulation of outer membrane protein channels (porins), again potentially conferring resistance simultaneously to two or more antimicrobial classes.

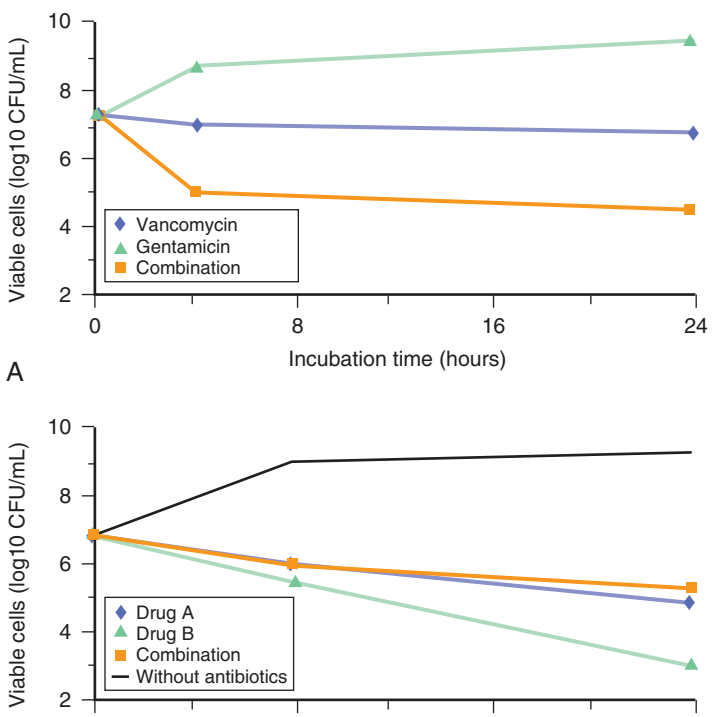

FIGURE 279-1. Bactericidal synergism and antagonism. A, Bactericidal synergism between vancomycin and gentamicin against an isolate of *Enterococcus* species. Killing by the combination of drugs is substantially greater than that by each agent alone. **B,** Antagonism of the bactericidal activity of drug B by the more slowly bactericidal drug A. Killing by the combination of drugs is less than that by drug B alone. Growth in the absence of antibiotics is also shown. CFU = colony-forming unit.

To Attain Synergism

Decades ago, the surprising benefits of using penicillin and streptomycin together for the treatment of enterococcal endocarditis were discovered empirically. Penicillin alone usually inhibits but does not kill enterococci, and failure rates were high when penicillin G was used alone to treat enterococcal endocarditis. Streptomycin has no significant activity against enterococci at clinically relevant concentrations. However, the combination results in bactericidal synergism in vitro and high cure rates in patients with enterococcal endocarditis. Detailed studies of this phenomenon demonstrated that in the presence of a cell wall–active antibiotic, uptake of the aminoglycoside into the bacterial cell increases substantially. Unfortunately, increasing rates of high-level resistance to streptomycin (MIC > 2000 μg/mL), gentamicin (MIC > 500 μg/mL), or both have nullified the benefit of such combinations against a substantial number of enterococcal isolates today. An example of bactericidal synergism between vancomycin and gentamicin against an *Enterococcus* isolate is illustrated in Figure 279-1A.

Combinations of cell wall–active agents plus aminoglycosides have been shown to achieve synergistic killing against a broad range of gram-positive and gram-negative bacteria when tested in vitro. Modest clinical benefits were shown when short courses of gentamicin were added to nafcillin for the treatment of *S. aureus* endocarditis, but at the cost of added nephrotoxicity. Against strains of viridans streptococci that are relatively insensitive to penicillin, the addition of an aminoglycoside for the first 2 weeks of a 4-week course of penicillin G is believed to result in a higher likelihood of cure.

Although it was once considered important in the treatment of gram-negative bacterial infections, especially in immunocompromised (e.g., neutropenic) patients, the clinical value of a synergistic combination of a cell wall–active agent and an aminoglycoside has been difficult to prove in recent experience. To a large extent, the introduction of agents with potent activity against gram-negative bacteria has diminished the perceived value of synergistic combinations. Nevertheless, there is some evidence that administration of two or more active drugs for empirical therapy may achieve a better outcome than is possible with a single active agent for *P. aeruginosa* infections, especially in neutropenic patients. The major value of combination therapy in this setting is to ensure that at least one active agent is administered promptly. The combination of sulfamethoxazole and trimethoprim, agents that block sequential steps in folic acid synthesis, can also achieve bactericidal (or bacteriostatic) synergism against a number of important gram-positive and gram-negative pathogens. Quinupristin and dalfopristin are streptogramin antibiotics that display inhibitory activity against gram-positive organisms. Combining these two agents, as is done in the commercial formulation, results in bactericidal synergism against organisms susceptible to both.

β-Lactam–β-lactamase inhibitor antimicrobials represent another example of synergistic combinations. Five drugs in this category are currently marketed in the United States: amoxicillin-clavulanate, ampicillin-sulbactam, ticarcillin-clavulanate, piperacillin-tazobactam, and ceftolozane-tazobactam. The β-lactamase inhibitors themselves, clavulanic acid, sulbactam, and tazobactam, are devoid of significant antimicrobial activity, with rare exceptions. However, by inhibiting common β-lactamases that are sensitive to these agents, the inhibitors restore the activity of the hydrolyzable companion penicillins against many target pathogens elaborating these enzymes.

Antagonism

Antibiotic combinations can sometimes result in microbiologic antagonism, such that the combination may have *reduced* activity compared with the most active single agent of the treatment regimen. Time-kill curves illustrating in vitro antagonism are shown in Figure 279-1B. In this example, the more slowly bactericidal drug A antagonizes the killing effect of the intrinsically more bactericidal drug B. Antagonistic interactions against *S. aureus* between less bactericidal (linezolid) and more bactericidal (vancomycin) antimicrobials have also been demonstrated in vivo in experimental endocarditis. In vitro antagonism can be demonstrated when certain β-lactams are tested in combination against gram-negative bacteria with inducible β-lactamases. Here, exposure to one β-lactam can de-repress the synthesis of inducible β-lactamases, which then degrade the second antibiotic.

It is uncommon to encounter clinically apparent antagonism between antibiotics in the patient care setting, in part because offending combinations are not likely to be used in routine clinical care today. However, if unusual antimicrobial combinations are used, in desperation, against isolates exhibiting

multiple drug resistance, it is possible that clinically relevant antagonism will be encountered more often in the future. Antagonism of bactericidal activities may also be difficult to detect in clinical practice because most common infections (with the exception of endocarditis and meningitis) do not unequivocally benefit from bactericidal therapy. As long as one agent maintains inhibitory activity, it is unlikely that failure resulting from antagonism will be observed.

CONSIDERATIONS IN ANTIMICROBIAL ADMINISTRATION

Route of Administration

In almost all instances, antimicrobial therapy for infections of mild to moderate severity that are treated in the outpatient setting can be undertaken with oral agents. There are notable exceptions, such as the use of intramuscular injections of benzathine penicillin for the treatment of syphilis or ceftriaxone for the treatment of otitis media or gonorrhea caused by strains resistant to oral agents.

Drugs such as levofloxacin and linezolid demonstrate virtually complete bioavailability when administered by the oral route in persons with normally functioning gastrointestinal tracts, and they can be used as an alternative to intravenous therapy in many patients with more serious infections. Even for these well-absorbed antimicrobials, however, treatment of seriously ill patients in the hospital is often initiated with intravenous formulations because of the uncertainty of gastrointestinal tract function under conditions of hemodynamic instability.

Antimicrobial therapy can be administered by other routes, including topical administration for the treatment of infected skin lesions (e.g., mupirocin or retapamulin ointments) and intravaginal administration for candidiasis (e.g., azole creams) or for bacterial vaginosis (e.g., metronidazole gel). Topical administration *onto* the eye is used to treat conjunctivitis or as adjunctive therapy for deeper infections; administration *into* the globe itself is a component of regimens for the treatment of endophthalmitis. Infections associated with peritoneal dialysis are frequently treated by intraperitoneal instillation of antimicrobials admixed with the dialysis solution. Rarely, direct administration into the thecal space or into the cerebral ventricles is necessary for the treatment of meningitis when the required antimicrobials do not achieve adequate concentrations in cerebrospinal fluid after systemic administration. For the treatment of *Clostridium difficile*–associated diarrhea, vancomycin reaches high concentrations in the intestine when it is given orally, but it is occasionally administered directly into the colon for the intraluminal treatment of severe infections.

The availability of protocols for the outpatient use of long venous catheters, whether inserted centrally or peripherally, has made it possible to administer antimicrobial agents that are not well absorbed orally. Thus, many patients who require long-term antibiotic treatment for infections such as endocarditis, osteomyelitis, neuroborreliosis, and other conditions can be treated as outpatients, often after an initial period of hospitalization for a full assessment of the infection, initiation of therapy, and stabilization of the medical condition. In addition to monitoring for adverse effects from the antibiotic itself, patients treated through indwelling intravenous devices require close observation for complications related to the catheter, such as thrombophlebitis, entry site infections, or line-related blood stream infections.

Pharmacodynamic Considerations

In recent years, the scientific basis for selection of a dosing regimen has extended well beyond empirical dosing strategies based primarily on the pharmacokinetic characteristics of antimicrobial agents. Pharmacodynamics relates the time course of antibiotic concentrations after dosing, the observed antimicrobial effects against likely pathogens, and the potential adverse effects of the agent.

Studies of the pharmacokinetic and pharmacodynamic properties of antimicrobial agents allow the prediction of their activities with various dosing regimens. For β-lactam antibiotics, the time during which the concentration of free drug (i.e., the non–protein-bound fraction) exceeds the MIC of the pathogen best relates to antimicrobial effectiveness in animal models. This provides the rationale for the frequent dosing schedules of β-lactams with short half-lives, such as penicillin G and the antistaphylococcal penicillins, and for the use of extended intravenous infusions when β-lactams are used to treat marginally susceptible organisms.

In contrast, the aminoglycosides and fluoroquinolones demonstrate concentration-dependent killing of bacteria. For these drugs, animal models show that the ratio of either peak concentration to MIC or the area under the 24-hour drug concentration curve to MIC better predicts effectiveness. With these agents, less frequent, higher dosing would be optimal (except perhaps when used with cell wall–active agents to achieve synergy). For the aminoglycosides, less frequent dosing may also allow more time for washout of the drug from the kidney, thus potentially minimizing the risk for nephrotoxicity.

For daptomycin, the adoption of once-daily dosing largely mitigated the muscle toxicity that had been seen with more frequent dosing and allowed the use of this agent for serious gram-positive infections.

MONITORING ANTIMICROBIAL CONCENTRATIONS

From a practical point of view, there are few situations in which assays to determine concentrations of antimicrobials in blood or body fluids are readily available. Commercial assays for the measurement of serum aminoglycoside concentrations are available and, because of these agents' great potential for toxicity, are used frequently. Commercial assays to measure vancomycin concentrations are also widely available. It may be prudent to monitor serum concentrations of vancomycin in patients with unstable renal function, those undergoing hemodialysis, patients at the extremes of body composition, or those with particularly serious infections in which high concentrations may be desirable. In some young adults, clearance of vancomycin may be so great that unexpectedly low concentrations result with the usual dosing regimens.

ADMINISTRATIVE ASPECTS OF ANTIMICROBIAL THERAPY

Formularies

In most practice settings today, the choice of antimicrobials is constrained in some way. For example, in hospitals and other facilities, institutional formularies may limit the choice of antimicrobial agents available, require special approval for the use of selected agents, or both. Such policies can, in principle, enhance efficiency by avoiding the need to stock and to dispense multiple agents with similar antimicrobial activities, minimize costs by allowing purchase of the most cost-effective alternatives, and potentially increase patient safety by encouraging clinical personnel to become familiar with a manageable number of agents. In the outpatient setting, it is common practice for health insurers to assign oral drugs to various tiers of coverage and copayment; as a result, there may be dramatic financial benefits or disincentives for the patient to receive specific agents. In both health care settings, the practitioner must be familiar with the options available to patients under these constraints.

Interchangeability

Although two drugs may have antimicrobial spectra that are so similar that only one need be included on a formulary, it is not always safe to assume that the activity of either agent can be predicted perfectly by susceptibility to the other. For example, for most bacterial species, the percentage of isolates susceptible to meropenem and imipenem will be roughly comparable. However, there are differences in mechanisms of resistance to these two carbapenems, so it is possible that a specific strain will be susceptible to one but resistant to the other. For serious infections, even when two drugs are considered interchangeable, one should determine susceptibility to the specific antimicrobial that is to be used.

Impact on the Institutional Environment

In contrast to other medications, which almost always affect only the patient receiving them, antimicrobial use can have a significant impact on the institutional environment as well.[6] As a result, it is sometimes necessary or desirable to manage the use of antimicrobial agents on an administrative level to avoid selective pressure leading to the spread of antibiotic resistance. Within institutions, antimicrobial-resistant organisms not only threaten the patient treated with the antimicrobial but also can be transmitted to other vulnerable persons, including those who have not been exposed to the drug. These considerations have given rise to the movement to promote antimicrobial stewardship in health care environments.[7]

REVIEW QUESTIONS

1. Which of the following host factors should be considered in selecting an antibiotic regimen for treatment of a patient?

A. Prior history of allergies
B. Whether the patient is currently pregnant or breast-feeding
C. Age and sex of the patient
D. Options A and B
E. Options A, B, and C

Answer: E The need to consider host factors A and B is obvious. The age and sex of the patient are also relevant. Some antibiotics (e.g., fluoroquinolones, tetracyclines) are generally avoided in children with only a few exceptions. In clinical studies, young women were more likely to develop rash to gemifloxacin than were men or older women.

2. Important justifications for use of antimicrobial combinations in clinical practice include all of the following *except*

A. To reduce drug toxicity by allowing use of half of the usual full doses of each of two agents
B. To attain bactericidal synergism for treating enterococcal endocarditis
C. To treat documented polymicrobial infections
D. To minimize emergence of resistance to rifampin in treating prosthetic device infections
E. To target a broader range of potential pathogens during empirical therapy

Answer: A Although using combinations to reduce doses of individual component drugs is a theoretically plausible consideration, it is not currently feasible to accomplish this in practice. Combinations are used to achieve bactericidal synergism to treat endocarditis (e.g., cell wall–active agent plus an aminoglycoside to treat endocarditis due to an enterococcus or a penicillin-nonsusceptible viridans streptococcus), to treat polymicrobial infections (e.g., vancomycin plus a carbapenem to treat infection due to both MRSA and extended-spectrum β-lactamase–producing Enterobacteriaceae), and to minimize resistance to rifampin for infections due to prosthetic devices such as heart valves and joint prostheses.

3. Which of the following statements about antimicrobial agents is true?

A. Regardless of the antimicrobial used, administration by the intravenous route is always more effective when doses are given at least every 4 hours.
B. Daptomycin is effective for treatment of community-acquired pneumonia if it is administered once daily.
C. In this day and age, there is no role for intramuscular administration of antimicrobial agents.
D. It is usually wise to measure serum bactericidal titers in treating endocarditis.
E. None of the above

Answer: E Answer A might be relevant to agents such as β-lactams, the effectiveness of which depends on "time above the MIC," but does not apply to agents such as fluoroquinolones or aminoglycosides. Answer B is incorrect because daptomycin is not indicated for treatment of bronchopneumonia, as it is inactivated by pulmonary surfactant. Answer C is also not correct. Benzathine penicillin and ceftriaxone are used intramuscularly for treatment of syphilis and gonorrhea, respectively, in the outpatient setting. Answer D cannot be justified either. Although studies have suggested that higher serum bactericidal titers correlate with cure in endocarditis, the correlation is imperfect, the results are not always reproducible, and the procedures are labor-intensive. For these reasons, this test is rarely used in clinical practice.

280 APPROACH TO FEVER OR SUSPECTED INFECTION IN THE NORMAL HOST

JAMES E. LEGGETT

We are constantly exposed to microorganisms through our skin or mucous membranes. Most microorganisms are adapted to niches in the environment that make them avirulent to humans (Chapter 279). Pathogens in a normal host are relatively few, and most of the time, exposure results in only transient or stable colonization. Infection can be defined as invasion of a pathogen that triggers an immune response, whether the infection is asymptomatic or symptomatic. Manifestations of infection are protean and are due as much to our immune response as to the attributes of the particular pathogen.

The inflammatory response that accompanies infection is usually marked by fever. Fever is a tightly controlled elevation in body temperature above the normal range in response to a central nervous system change in the set point. Defining normal body temperature is somewhat problematic because it is dependent on both physiology and the method of measurement. Normal oral temperature in 99% of the population ranges from 36.0° to 37.7° C, with a circadian variation of 1° C or more between the morning nadir and the evening peak. Mean oral temperature in healthy adults is 36.8° ± 0.4° C, with women exhibiting slightly higher values than men (36.9° vs. 36.7° C). In menstruating women, the morning temperature may rise by 0.6° C with ovulation and remain higher until menses occur. Measured rectal temperatures are 0.4° C higher than oral and 0.8° C higher than aural (tympanic membrane) temperatures. However, considerable individual variability exists. Clinicians generally define significant fever as a temperature higher than 38.3° C (101.0° F). Despite historical claims, fever patterns are not especially helpful in establishing a specific diagnosis.

The majority of acute febrile illnesses lasting less than 2 weeks have an infectious cause. These infections occur predominantly where body surfaces interact with the environment, such as the upper and lower respiratory tracts, gastrointestinal and genitourinary systems, and skin. The majority of acute respiratory and gastrointestinal infections are viral in nature. As the duration of the febrile illness lengthens beyond 3 weeks, other inflammatory illnesses become more prominent in the differential diagnosis. Most chronic febrile illnesses are not caused by infection.

PATHOBIOLOGY OF INFECTION AND FEVER

Infection ensues only when a pathogen overcomes both nonspecific innate and specific adaptive humoral and cellular immune responses. The normal indigenous microflora, host physical barriers (e.g., skin, mucous membranes, cilia), and soluble factors (e.g., cytokines, complement) provide important barricades to pathogen invasion. Disruption of these barriers, which provide a first line of defense, permits the invasion of pathogens. The acute phase response triggered by such disruption provides direct antimicrobial activity and prompts the development of adaptive immunity mediated by lymphocytes and macrophages. This inflammatory response plays an important role in containing infection. Unfortunately, an exaggerated response may worsen the clinical condition. It is the neutrophil response that causes the damage seen in septic arthritis, and it is the unchecked immune response that precipitates the systemic inflammatory response syndrome.

Body temperature is regulated both physiologically and behaviorally. Basal metabolic processes, governed especially by thyroid hormones but also by catecholamines and growth hormone, are responsible for the normal resting body temperature. Thermogenesis may be increased up to 80% by hyperthyroidism and decreased as much as 50% by hypothyroidism. Moderate activity increases thermogenesis and results in a transiently increased temperature until heat-dissipating processes are engaged. Each 1° F increase in temperature results in a 7% increase in the basal metabolic rate. Vaporization from the lungs and skin accounts for a third of basal body heat loss and for as much as all heat loss at ambient dry temperatures above 36° C. The elderly have a decrease in basal metabolism as well as blunted responses to thermogenetic stimuli, but they have the same average core temperature as young people.

The hypothalamus contains temperature-sensitive neurons that have receptors for pro-inflammatory and anti-inflammatory cytokines, which are continuously balanced to maintain a homeothermic set point. When body temperature becomes elevated, cutaneous vasodilation and sweating occur, and people may reduce activity and seek a cooler environment. In contrast, low body temperature is increased by shivering, piloerection, cutaneous vasoconstriction, adding clothes, and seeking a warmer environment. In a febrile illness, symptoms may be due to the underlying disease or to the fever itself. Malaise is the rule, and many febrile patients experience myalgia secondary to the muscle contractions used to generate temperature elevation. Although it was once thought that the back and thigh pain related to rigors suggests bacteremia, any febrile stimulus can produce such symptoms. The chill associated with rigors may be related to the surface vasoconstriction that accompanies the increase in core temperature.

Fever is a complex physiologic process involving metabolic and immunologic responses (Fig. 280-1). Exogenous pyrogens cause fever largely mediated by endogenous pro-inflammatory pyrogenic cytokines produced by phagocytic leukocytes, including interleukin-1, interleukin-6, tumor necrosis factor-α, and interferon-γ. These cytokines stimulate the immune responses of T and B cells, macrophages, and polymorphonuclear leukocytes. They appear to act through a common mechanism involving the activation of Toll-like receptors and induction of prostaglandin synthesis. Feedback inhibitory responses are mediated by adrenocorticotropic hormone, arginine vasopressin, serotonin, dopamine, and other homeostatic mechanisms, thus emphasizing the orchestrated nature of fever production and response to infection. These thermoregulatory mechanisms rarely allow fevers to exceed 41° C (106° F). Temperatures exceeding 41° C are often due to a drug-induced imbalance in these mechanisms and may cause direct cellular damage.

Failure of fever to develop during severe bacterial infection has, in some studies, been associated with higher morbidity and mortality. Whether this is due to the absence of fever or to associated conditions, such as chronic renal failure or corticosteroid use, has not been determined. Favorable effects of fever on host-microbe interactions are suggested by inhibited multiplication of some pathogens (such as *Streptococcus pneumoniae* and *Treponema pallidum*), reduced proliferation of pathogens in the presence of

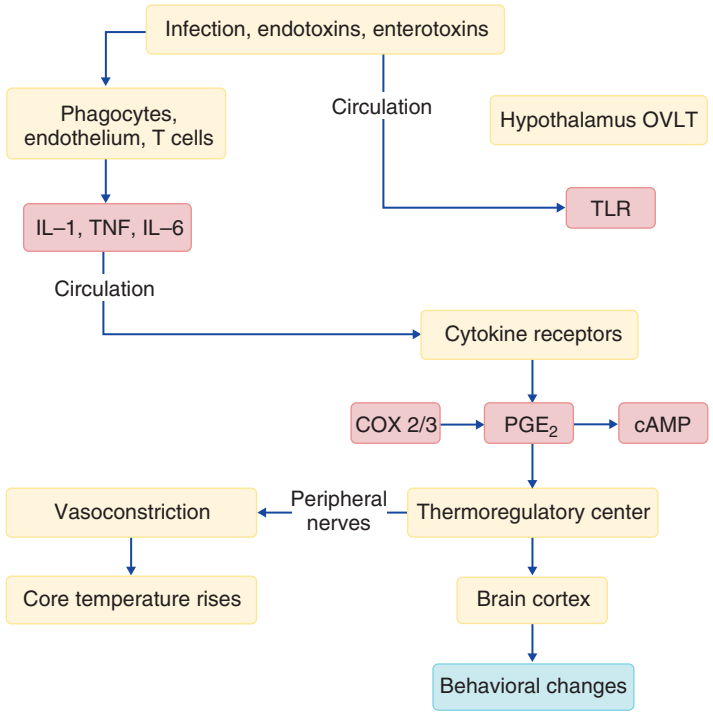

FIGURE 280-1. Pathways leading to the production of fever in bacterial infection, whether local or systemic. Bacteria release cell wall products such as peptidoglycans and endotoxin as well as enterotoxins, which bind to Toll-like receptors (TLRs) on phagocytes (neutrophils, macrophages) and endothelial cells. As a result, pyrogenic cytokines such as interleukin (IL)–1, IL-6, and tumor necrosis factor (TNF)–α are released into the circulation and bind to cytokine receptors in the hypothalamic organum vasculosum of lamina terminalis (OVLT). Bacterial products may also directly bind to TLRs on the OVLT. Activation of TLRs and cytokine receptors induces cyclooxygenase 2 (COX2), which leads to the production of prostaglandin E_2 (PGE_2) and elevates cyclic adenosine monophosphate (cAMP) in the brain. This, in turn, triggers neurons in the thermoregulatory center to raise the hypothalamic thermostatic set point. In addition, neuronal signals to the cortex prompt behavioral changes to conserve heat (e.g., posturing, adding clothing). The hypothalamus also triggers sympathetic peripheral efferent nerves that constrict peripheral blood vessels and conserve central heat until hypothalamic PGE_2 levels fall.

hypoferremia, augmented complement-mediated lysis, and increased neutrophil entry into inflammatory sites. Indeed, vertebrate endothermy restricts most fungi as potential pathogens in hosts with intact immune systems.

Temperature-pulse dissociation, in which there is relative bradycardia compared with the usual increase of 2.44 beats/minute per 1°F, has been described in typhoid fever, leptospirosis, rickettsiosis, dengue, legionellosis, and babesiosis, for unclear reasons.

No laboratory abnormalities accompany typical benign acute viral infections. Leukocytosis (Chapter 167) of various lineages is usually seen in other infections in immunocompetent adults. Neutrophilia is the norm in most acute infections, whatever the cause. The elderly, although not mounting a neutrophilic response, generally display bandemia during an acute bacterial infection. Neutropenia (Chapter 167) may be seen in rickettsial, severe viral, and overwhelming bacterial infections. Eosinophilia (Chapter 170) is typical of invasive helminthic and some protozoal infections. Lymphocytosis may accompany many viral and rickettsial infections and is common during convalescence from acute bacterial infection. Monocytosis may be seen in tuberculosis. Virtually all infections have an impact on the erythroid system, but given the long half-life of erythrocytes, usually only chronic infections or other inflammatory diseases result in anemia (Chapter 158). Few acute infections rapidly produce anemia. For instance, *Helicobacter pylori* may induce a bleeding ulcer, *Plasmodium falciparum* may directly lyse erythrocytes, overwhelming clostridial and other bacterial infections associated with disseminated intravascular coagulopathy may cause hemolytic anemia, and *Mycoplasma pneumoniae* may induce immunologically mediated hemolysis.

APPROACH TO FEBRILE ILLNESS IN OUTPATIENTS AND INPATIENTS

Infectious disease epidemiology depends on the interaction among pathogens, susceptible hosts, and environmental conditions allowing exposure. Most infections are transmitted horizontally between people by contact (e.g., hands, fomites), a common vehicle (e.g., food, water), air (e.g., tuberculosis), or vectors (e.g., mosquitoes). Evaluation of a patient with a known or possible infection should determine whether the condition might be due to a transmissible agent and its source, whether the patient has done any recent traveling, whether there are secondary causes, and what measures need to be taken to contact health department officials and to prevent additional infections.

The age of a patient influences which illnesses should be considered. Natural exposure or immunization generally limits certain illnesses, such as rubeola, rubella, and varicella. Waning of immunity may likewise lead to pertussis in young adults or reactivation of tuberculosis in the elderly. Other physiologic effects of aging, such as impaired bladder emptying, lead to increased rates of urinary tract infection in the elderly.

A patient's occupation and travel history should be noted. An abattoir worker is more likely to have been exposed to *Brucella* (Chapter 310) than is someone with another occupation. Indiana residents are more likely be infected with histoplasmosis (Chapter 332), whereas those from the Southwest desert may have coccidioidomycosis (Chapter 333), despite having a similar febrile illness. Many other illnesses are likewise directly related to specific geographic exposure, with varying incubation times before their onset (Chapter 286). Typhoid fever should be manifested within a few weeks, whereas amebic liver abscess might not cause symptoms until months after a traveler's return from an endemic area (Table 280-1). The Centers for Disease Control and Prevention website (http://www.cdc.gov) and many others provide more specific information about prevalent infections in all parts of the world (Chapter 286).

Many travelers return home with fever after a variable incubation time, generally with other symptoms and signs as well. The first consideration in evaluating such a patient is that an infection unrelated to travel is more likely to be the cause of the illness.[1] Once such routine infections have been ruled out, the differential diagnosis should include infections related to travel,[2] whether within a region of the United States (e.g., ehrlichiosis, Colorado tick fever, hantavirus) or abroad (e.g., visceral leishmaniasis, tick-borne encephalitis in Europe) (Chapter 286). For example, prompt evaluation of a patient who has traveled to a malaria-endemic area should be undertaken and blood tests performed to determine the presence of parasites.

The setting in which a febrile illness occurs influences both the diagnostic approach and the differential diagnosis. In the ambulatory arena, with a generally healthy febrile patient, the clinician should not necessarily pursue a diagnosis as aggressively as with a hospitalized or chronically ill patient. Empirical treatment of a presumed urinary tract infection is warranted in the outpatient setting, where the cost of a culture is often more than that of the antibiotic. However, the cost of a urine culture in a hospital setting is minimal in comparison to the daily cost of care, and accurate identification of the pathogen may speed hospital discharge. Likewise, the pathogens commonly causing febrile illness in health care facilities, including nursing homes, may differ from those seen in ambulatory settings. Most patients in the ambulatory setting have noncritical, self-limited infections.

TABLE 280-1 SELECTED EXAMPLES OF FEVER ASSOCIATED WITH RECENT TRAVEL

	INCUBATION PERIOD	
DISEASE	**<2-3 WEEKS**	**>3-4 WEEKS**
COMMON		
Dengue	+	
Dysentery	+	
Entamebic liver abscess		+
Enteric fever	+	
Malaria	+	+
Pulmonary tuberculosis		+
Viral hepatitis		+
LESS COMMON		
Ehrlichiosis	+	
Leptospirosis	+	
Schistosomiasis		+
Viral (hemorrhagic, encephalitic)	+	
Visceral leishmaniasis		+

Higher temperatures are usually due to invasive visceral disease, such as community-acquired pneumonia or pyelonephritis. Common viral respiratory infections and gastroenteritis as well as some cases of subacute bacterial endocarditis are accompanied by temperatures below 102°F. Moreover, many infections may not be associated with fever, such as Lyme disease, osteomyelitis, and most sexually transmitted diseases. The clinician must always keep in mind that certain infections, such as sexually transmitted diseases (Chapter 285) or herpes zoster, occur normally in immunocompetent hosts and may signal a higher risk for infection with human immunodeficiency virus (HIV) or an already established immunodeficiency.

Fever in Outpatients

In the ambulatory setting, an acutely febrile patient represents a common problem and only infrequently presents an enigmatic diagnostic challenge. In most instances, a febrile illness is accompanied by localizing symptoms and signs suggesting a specific diagnosis. For instance, leg erythema, pain, and fever in a patient with tinea pedis or a saphenous vein graft incision immediately suggests streptococcal cellulitis. Several diseases may masquerade as infectious cellulitis.[3] If the patient has had a gradual onset and does not appear toxic, only clinical observation and follow-up are required. If the patient appears toxic, with tachypnea and apprehension or confusion accompanying localized findings, clinically focused diagnostic studies should be performed immediately, and hospitalization should be considered. When a patient has fever and only nonspecific constitutional symptoms, it may be more difficult to address the problem in a single ambulatory clinic visit, requiring a balance between observation and investigation.

Fever in Inpatients

Fever and leukocytosis are probably the main clinical parameters for evaluating potential infections in hospitalized patients. However, about 10% of nosocomial bacteremias occur without fever, and health care–associated infections occur without fever in a substantial proportion of patients who are elderly or have significant comorbid conditions. Most cases of hospital-associated fever represent nosocomial infection, which typically involves the lower respiratory tract, urinary tract, or surgical wounds (Table 280-2). Some important causes of nosocomial fever may not exhibit easily discernible localizing symptoms or signs. Antibiotic-induced colitis secondary to *Clostridium difficile* (Chapter 296) is increasing in prevalence and may be characterized by little or no diarrhea. It is probably the most common cause of a leukemoid reaction in hospitalized patients. Other intra-abdominal processes involving the hepatobiliary system, bowel infarction, viscus perforation, or abscesses may have little in the way of localizing symptoms or signs.

Given the greater severity of illness and comorbid conditions in intensive care unit (ICU) patients, it is logical that fever and infection are more frequent in the ICU than elsewhere. Infection was recently found to be present in more than 80% of febrile ICU patients, although both infectious and noninfectious

TABLE 280-2 SELECTED CAUSES OF HOSPITAL-ASSOCIATED FEVER

COMMON	LESS COMMON
INFECTIOUS	**INFECTIOUS**
Clostridium difficile enterocolitis	Biliary tract disease
Pneumonia	Endometritis
Surgical wound	Intra-abdominal abscess
Urinary tract	Mediastinitis
Vascular catheter	Sinusitis
NONINFECTIOUS	**NONINFECTIOUS**
Drug-induced fever	Adrenal insufficiency
Hematoma	Gout
Immediate postoperative state	Myocardial infarction
Transfusion reaction	Organ infarction
Venous thromboembolism	Pancreatitis

causes of fever may coexist. Indeed, ischemia or devitalization of tissue provokes an inflammatory response similar to that prompted by infection. About half of patients with acute myocardial infarction have a temperature between 38.0° and 38.5° C within 2 to 3 days of their infarction. Similarly, about half of patients with deep venous thrombosis and pulmonary embolism have a temperature in the same range, most commonly in the first 3 days after diagnosis. A third or more of patients with stroke demonstrate fever, which is also a common consequence of subarachnoid or intracerebral hemorrhage and subdural hematoma, especially within 72 hours of onset.[4] The fever in such cases may result from damage to the hypothalamus or pulmonary aspiration secondary to obtundation. Iatrogenic causes of fever should be considered. Fever and chills may be seen in up to a quarter of patients receiving platelet transfusions, although the frequency is much less with other blood products.

SYNDROMIC APPROACH

Fever and Rash

A syndromic approach is valuable to narrow the many possible causes of a suspected infection. Two approaches must be juxtaposed in this evaluation, and both are key in recognizing patterns. The clinician must be aware of (1) the differential diagnosis of the particular type of lesion observed and (2) the constellation of findings produced by individual pathogens. Because of the variety of possible manifestations and the often overlapping symptoms and signs, both elements are key in arriving at a probable diagnosis. Moreover, fever and associated findings, such as exanthem, lymphadenopathy, or jaundice, may be due to noninfectious systemic diseases as well as infectious ones. For instance, leukocytoclastic vasculitis and fever may be found in meningococcemia, Rocky Mountain spotted fever, and hepatitis C, but they are also seen in noninfectious inflammatory diseases. Likewise, fever and adenopathy may be due to lymphoma or to cat-scratch disease.

A recognizable exanthem may lead to the immediate recognition of a particular pathogen (Chapter 441), but often a larger differential diagnosis must be entertained. The clinician must recognize the type or types of skin lesions present, the distribution of the exanthem, and the chronologic progression with respect to the onset of fever and other symptoms (Table 280-3). Morphologic variations in skin lesions help in the differential diagnosis. Maculopapular exanthems are frequently seen in viral illness, hypersensitivity drug reactions, and immune complex–mediated diseases. Some of the most common viral causes include the many enteroviruses, but similar lesions may also be seen with hepatitis B and West Nile viruses. Erythema multiforme, a subset of maculopapular exanthem, can result from various viral infections or drug eruptions (Chapter 440). It may have a spectrum of disease that ranges from benign to the life-threatening Stevens-Johnson syndrome/toxic epidermal necrolysis complex. Herpes simplex virus is perhaps the most common cause of erythema multiforme. Although drugs, especially antibiotics, are the major precipitating factor in the Stevens-Johnson syndrome/toxic epidermal necrolysis complex, *M. pneumoniae* has been associated with it as well. Evolution of the cutaneous findings over time may give clues to the cause; for example, the initial blanching, erythematous, maculopapular lesions may later evolve into petechiae, as seen in meningococcemia, Rocky Mountain spotted fever, and dengue. Secondary syphilis may be manifested with a multitude of morphologic skin lesions. Sometimes, many different manifestations occur simultaneously in the same patient. Most vesiculobullous skin exanthems are immunologically mediated. The few infections associated with these eruptions include herpes simplex and varicella-zoster viruses and enteroviruses such as echovirus and coxsackievirus. The poxviruses, which

can also cause such exanthems, are much rarer or are associated with bioterrorism. Pustules, or vesicles containing leukocytes, are usually associated with psoriasis or infections with *Pseudomonas*, *Staphylococcus*, or *Neisseria*. Bullous exanthems in the presence of sepsis suggest severe streptococcal cellulitis or necrotizing fasciitis, staphylococcal impetigo, or *Vibrio* infections.

Petechial and purpuric eruptions are due to the extravasation of red blood cells and should always lead to consideration of a potentially serious illness. Pathogens creating such lesions most commonly include *Neisseria meningitidis*, *Rickettsia*, and *Capnocytophaga canimorsus*, but these eruptions may be seen with a variety of other pathogens, including *Staphylococcus aureus*, group B streptococci, and other gram-negative bacilli. A petechial exanthem may also be seen with enteroviruses and viral hemorrhagic fevers. The most common causes of petechiae not attributable to infections include thrombocytopenia and vasculitis.

The presence of fever and rash involving the palms and soles allows considerable narrowing of the differential diagnosis (Table 280-4). In addition to the diffuse erythema associated with toxic shock syndrome, illnesses such as Rocky Mountain spotted fever, secondary syphilis, hand-foot-and-mouth disease, *Neisseria* infections, and rat-bite fever should be considered in patients with maculopapular exanthems involving these areas.

Nodular skin lesions may be either noninfectious, as seen in malignant disease or with certain drugs (e.g., sulfonamides), or infectious, as seen in a variety of inflammatory diseases. Atypical mycobacteria and disseminated fungi often produce skin nodules. The tender nodules of erythema nodosum usually occur in crops located pretibially, but they may be solitary or occur on other parts of the body. They do not typically suppurate, and they heal without scarring. Infectious agents are the most likely cause of erythema nodosum. Diffuse erythema may be seen with scarlet fever, toxic shock syndrome, Kawasaki disease, Stevens-Johnson syndrome, and toxic epidermal necrolysis, with desquamation occurring late in all these syndromes. Sweet's syndrome, a febrile neutrophilic dermatosis, represents a hypersensitivity reaction often preceded by an upper respiratory tract infection.

Fever and Musculoskeletal Complaints

Fever and localized tenderness, swelling, or erythema generally accompany septic arthritis and often accompany osteomyelitis (Chapter 272). Septic

bacterial arthritis in adults usually is manifested acutely and involves a single large joint such as the knee, hip, or shoulder, unless the infection is directly inoculated by trauma or surgery. Septic oligoarthritis may be seen with endocarditis and rat-bite fever. Disseminated gonococcal disease is the usual cause of arthritis involving small joints of the wrist, ankle, and digits, often with tenosynovitis. Acute or subacute polyarthritis may be seen in several viral diseases, including parvovirus B19 and hepatitis B, and in Lyme disease, but it is more typical of immunologic disorders. Rheumatologic diseases generally have more subacute manifestations, with more symmetrical polyarthritis. Hematogenous osteomyelitis in adults frequently involves the vertebrae and is almost always initiated by discitis with symmetrical involvement of adjacent vertebrae (as opposed to malignant metastasis, which is asymmetrical and does not involve the disc).

Myositis secondary to clostridia, streptococci, *Aeromonas*, or mixed aerobic-anaerobic infections usually causes an acutely septic picture with painful, edematous involvement of the limb or torso. Pyomyositis frequently involves deep muscles such as the psoas or gluteus and is usually due to *S. aureus*. Diffuse myositis may be seen with leptospirosis or toxoplasmosis, and rhabdomyolysis occurs with a variety of viral infections and legionellosis.

Fever and Lymphadenopathy or Hepatosplenomegaly

Fever and lymphadenopathy may suggest a variety of illnesses, both infectious and noninfectious (Table 280-5). Lymphadenopathy (Chapter 168) may be regional or generalized. Local enlargement can occur with either a local infection or some systemic illnesses (e.g., posterior cervical lymphadenopathy with Epstein-Barr virus and other viral illnesses). Generalized lymphadenopathy usually suggests a systemic disorder, which may itself be either infectious or noninfectious. Although the combination of fever and lymphadenopathy secondary to infection is especially common during childhood, it is also frequently seen in adults. As in other syndromes, acute versus chronic adenopathy tilts the diagnosis toward different broad categories of illness. In chronic adenopathy, histopathologic evaluation of enlarged lymph nodes may point to a particular diagnosis. For instance, toxoplasmosis or cat-scratch disease can be easily differentiated from mycobacterial disease or sarcoidosis.

Fever and hepatosplenomegaly (Chapter 168) may provide an important clue to the cause of a febrile illness, which is typically either an infection or a malignant neoplasm arising from bone marrow or the reticuloendothelial system. Jaundice may also limit the differential diagnosis (Table 280-6).

TABLE 280-5 COMMON CAUSES OF FEVER AND LYMPHADENOPATHY

Syphilis (primary)	

Aside from the viral hepatitides and other diseases affecting primarily the liver, many pathogens producing sepsis can cause hyperbilirubinemia.

APPROACH TO FEVER OF UNKNOWN ORIGIN

The majority of febrile illnesses are short-lived, but fever may be prolonged for weeks or months as part of an infectious disease, inflammatory disorder, or occult neoplasm. When fever is caused by infection, the site is an area not easily controlled by host defenses, leading to the continued release of inflammatory cytokines. Likewise, macrophage and lymphocyte involvement in inflammatory disorders causes persistent cytokine production, as do certain neoplasms. Given this final common pathway, it is easy to understand why the majority of cases of classic fever of unknown origin (FUO), loosely defined as lasting longer than 3 weeks despite routine investigation, are found in these three broad categories.[5,6] Two other categories round out the bulk of FUO cases: miscellaneous illnesses and cases in which the fever remains undiagnosed (Table 280-7). The proportion of patients in each category varies by geographic locale, age, duration of fever, and immune status. As more effective methods of diagnosing viral and bacterial infections have become available, and with improved serologic studies to detect connective tissue disorders and better imaging techniques to detect occult malignant neoplasms, the proportion of patients with FUO in the miscellaneous and undiagnosed categories has increased to about a third of the total in developed countries. The longer a febrile illness persists without a diagnosis or appropriate therapy, the less likely it is to be due to an infection. In one study, only 6% of patients who had persistent FUO beyond 6 months were found to have infection. Most such cases resolve spontaneously, with a mortality rate of less than 3% at 5 years.

Bacterial species, particularly *Mycobacterium tuberculosis*, make up the largest category of infections that cause prolonged FUO. *M. tuberculosis* and other bacterial pathogens causing FUO have adapted to survive intracellularly or frequently change their surface antigens so that they are not readily eradicated by host defenses. Other infections causing FUO are localized in cryptic abscesses, especially intra-abdominally, or reside on heart valves, where the inflammatory response is blunted. Persistent viral infections constitute a small and shrinking subset of patients with FUO because modern techniques can more readily detect infection with Epstein-Barr virus, cytomegalovirus, and others. Among the pathogens likely to be characterized initially by fever alone, cytomegalovirus is the most common cause of mononucleosis in adults, and malaria is a common cause of fever in returning travelers.

Malignant disease may result in persistent fever due to the production of inflammatory cytokines, necrosis, or the presence of a complicating infection. The most common malignant neoplasms manifesting as FUO are lymphomas, leukemias, and solid tumors with metastases to the liver. Connective tissue disorders may lead to tissue inflammation, which produces fever as a prominent feature of the illness. In a recent series, adult Still's disease (Chapter 261) was the leading rheumatologic disorder manifesting as FUO. Temporal arteritis and polymyalgia rheumatica (Chapter 271) are seen almost exclusively in patients older than 50 years. Systemic lupus erythema-

Occult abscess		Temporal arteritis	Pulmonary embolism	
Tuberculosis				

tosus (Chapter 266) is an occasional cause of FUO, especially if it is manifested in an atypical fashion.

The miscellaneous category of FUO includes several disparate groups of diseases. Granulomatous diseases such as granulomatous hepatitis, Crohn's disease, or sarcoidosis may incite cellular immune responses that result in fever. Granulomatous hepatitis was present in up to 6% of National Institutes of Health cases with fever lasting longer than 6 months. Chronic pancreatitis may occasionally cause FUO, as may recurrent pulmonary embolism.

Drug-induced fever (Table 280-8) may be the only manifestation of an adverse drug event in up to 5% of cases of drug hypersensitivity. Recognition of drug-induced fever is important to avoid extra tests, additional therapy, and prolonged hospitalization.[7] The mechanisms by which drugs incite fever are not well understood in many cases. These events may result from hypersensitivity reactions, altered thermoregulatory homeostasis directly related to either drug administration or the drug's pharmacologic action, or idiosyncratic reactions. Hypersensitivity reactions are usually accompanied by an exanthem or enanthem and hepatic, renal, or pulmonary dysfunction in addition to fever. Antimicrobial agents appear to be the most common cause of drug-induced fever and are responsible for approximately a third of episodes in some studies. β-Lactams and sulfonamides account for most cases because they are among the most frequently administered antimicrobials. Anticonvulsants are also common causes of drug-induced fever secondary to hypersensitivity reactions. Altered thermoregulation is possible with a variety of drugs, including those with anticholinergic activity, such as phenothiazines and tricyclic antidepressants. Sympathomimetic agents, such as amphetamines and cocaine, may also cause fever. Drug administration itself may cause fever if the vehicle of the drug is contaminated with exogenous pyrogens or chemical phlebitis occurs. Some drugs appear to have intrinsic pyrogenic properties, such as amphotericin B and bleomycin. Others cause fever as a result of their pharmacologic activity, such as interferon alfa or interleukin-2. With antibiotics, drug-induced fever occurs with the rapid lysis of spirochetes or other bacteria, known as the Jarisch-Herxheimer reaction. Idiosyncratic drug-induced febrile reactions include malignant hyperthermia, neuroleptic malignant syndrome, and serotonin syndrome (Chapter 434). Drugs implicated in these reactions are inhaled anesthetic agents, central nervous system dopamine-depleting agents, and serotonin re-uptake inhibitors, among others. Drug-induced fever is usually a diagnosis of exclusion. The duration of drug exposure before the onset of fever, the clinical appearance of the patient, and the pattern of the fever are not particularly useful. Elimination of a single drug at a time, beginning with the one most likely to be implicated, is the usual means of identifying the causative agent. The fever abates once the drug has been eliminated from the body, usually within 3 to 4 days of discontinuing use of the drug.

Laboratory evaluation and diagnostic imaging studies should be chosen according to information derived from a detailed history and physical examination. These may initially include complete blood count and blood chemistry determinations, erythrocyte sedimentation rate or C-reactive protein, blood cultures, and antibody tests (antinuclear antibody, cytomegalovirus, Epstein-Barr virus, HIV) as well as a chest radiograph and computed tomography of the abdomen.[8] 18-Fluoro-2-deoxy-D-glucose positron emission tomography (FDG-PET) may also be useful in difficult cases.[9] Despite the recent focus on "emerging" infectious diseases, the cause of FUO is still more likely to be a common pathogen presenting atypically.

Interferon alfa	Cimetidine
Interleukin-2	Tacrolimus

INITIAL MANAGEMENT OF SUSPECTED INFECTION IN THE AMBULATORY SETTING

An acutely febrile patient in the ambulatory setting presents a common but often demanding diagnostic problem. In most cases, the history and physical examination reveal diagnostic clues and may guide decisions about additional studies or therapy. More difficult to diagnose is a fever that occurs without localizing symptoms or is accompanied only by nonspecific symptoms, such as malaise or anorexia. Fortunately, most such acute, undifferentiated febrile illnesses are benign and resolve spontaneously within 1 or 2 weeks without a specific diagnosis being made. In such cases, no further evaluation beyond the initial visit is warranted. If symptoms persist, the history and physical examination should be repeated, looking for previously unsought clues and new physical findings. Laboratory studies might be required.

In patients with an illness involving cough of less than 3 weeks' duration, the evaluation should focus on ruling out a serious disorder. Normal vital signs and normal findings on a chest examination effectively rule out most cases of pneumonia. Such cough illnesses are caused by viral pathogens in more than 90% of cases. Antibiotics are ineffective in such patients, and antimicrobial therapy does not prevent bacterial complications such as pneumonia. The presence of sputum and its characteristics are not helpful in distinguishing bacterial from viral infections. Adults with prolonged coughing lasting longer than 3 weeks or with recurrent episodes should be evaluated for reactive airway disease, gastroesophageal reflux, and other illnesses. Infections rarely causing prolonged cough include *Bordetella pertussis*, *M. pneumoniae*, and *Chlamydophila pneumoniae*. Clinicians in this case should obtain a chest radiograph; treat for exacerbation of chronic obstructive pulmonary disease (fever, leukocytosis, purulent sputum), if present; treat a confirmed bacterial infection; and direct therapy to a specific underlying cause or other causes.

Symptoms and signs of pharyngitis include fever, tonsillar exudates, tender anterior cervical lymph nodes, and absence of cough. If fewer than two of these criteria are present, the patient should be managed as though viral pharyngitis were the cause. With two or more of these criteria, one should consider obtaining a rapid streptococcal antigen test.[10] Because of the low incidence of streptococcal infection and acute rheumatic fever in adults, a negative rapid test result alone is sufficient to rule out infection with *Streptococcus pyogenes*. If the antigen test result is positive, the patient can be managed with a β-lactam antibiotic if not allergic. Ninety percent of cases of pharyngitis in adults are viral in origin. In a patient with symptoms of upper respiratory tract infection and a mucopurulent nasal discharge of less than 10 days' duration, purulent nasal secretions do not predict bacterial infection. Most cases of acute rhinosinusitis seen in the outpatient setting are caused by uncomplicated upper respiratory viral infection. If symptoms have been present for more than 10 days without improvement, or if there are specific symptoms of sinusitis of any duration (purulent nasal discharge lasting 3 to 4 days, unilateral facial pain and pressure, maxillary toothache, or worsening of symptoms after initial improvement), amoxicillin or another β-lactam should be considered, with other antimicrobial classes used in penicillin-allergic patients. Most clinical outcomes are not adversely affected by delayed antibiotics for upper respiratory infections.

Community-acquired pneumonia (Chapter 97) should be suspected in a patient with cough, sputum production, or dyspnea, especially if it is accompanied by fever and altered breath sounds. A chest radiograph should be performed to confirm the diagnosis. Determining where to care for the patient is the most important immediate decision. Outpatient care generally suffices for patients younger than 50 years with no cardiopulmonary disease; for patients with no comorbid conditions (including malignant disease, heart failure, diabetes, or hospitalization within the last year); and for patients with no physical examination findings, such as altered mental status, pulse of 125 beats/minute or greater, or respiratory rate of 30/minute or greater. Recent guidelines developed by the American Thoracic Society and the Infectious Diseases Society of America suggest a β-lactam, macrolide, or doxycycline. Fluoroquinolones should be used for outpatients only when the patient has failed to respond to first-line therapy, has a significant comorbidity, or has a known allergy to a first-line agent.

Skin and soft tissue infections are caused, for the most part, by streptococci; a minority are due to *S. aureus* and, rarely, other bacteria whose presence may be suggested by epidemiologic considerations (e.g., swimming in fresh water, where *Aeromonas* may be the pathogen). Pain may be present for

12 hours or more before skin discoloration is noted. A furuncle or abscess formation should prompt consideration of *S. aureus* and, rarely, *Streptococcus anginosus* group. Incision and drainage may be sufficient for a skin abscess, although the rapidly expanding, virulent, community-acquired methicillin-resistant *S. aureus* phenotype may require antimicrobial therapy. Septic bursitis is nearly always due to *S. aureus*, and the infected bursa should be aspirated and drained, in addition to using antibiotics (Chapter 272).

Gastrointestinal infections may be due to ingested toxins, viruses, or, less commonly, bacteria, with or without associated toxin production. The appropriate approach depends on the epidemiologic setting, such as improper food storage, travel abroad, or contact with another ill person (Chapter 283). Symptoms of cystitis in a young, sexually active woman can be treated with empirical antibiotics, but when fever and flank pain are present and the patient is nauseated, consideration of a brief hospital admission or an initial intravenous dose of antibiotics may be necessary (Chapter 284). The possibility of pelvic inflammatory disease should also be entertained.

In the initial evaluation of a patient with a more chronic, persistent fever, a careful history and physical examination provide important diagnostic clues, directing further investigation. The initial goal is to characterize the illness accurately, in addition to eliciting important host and epidemiologic factors. A careful review of systems is necessary to understand the extent of involvement of various organ systems as well as to note previous medical conditions. The examination should be broader than for an acute febrile illness with localizing symptoms and signs. Laboratory tests may also play a more important role in guiding further investigation. Repeated evaluations are the norm rather than the exception in these cases.

Blindly initiating empirical therapy in febrile patients with no imminent risk of serious clinical harm or death should be discouraged because it may impede a timely diagnosis affording definitive care. Procalcitonin, which is a precursor of calcitonin, is an acute phase reactant that is more likely to be elevated with bacterial than with viral infections, and its use may reduce unnecessary antibiotics in some situations, such as patients with respiratory infections. However, procalcitonin distinguishes sepsis from nonseptic systemic inflammation poorly (71% sensitivity, 71% specificity, receiver operating characteristic curve 0.63),[11] and it appears to be less useful in such settings.

INITIAL MANAGEMENT OF SUSPECTED NOSOCOMIAL INFECTION

Determination of the nature of a febrile illness in a hospitalized patient must take into account the host, the setting, and the timing of recent trauma or type and duration of surgery, in addition to the general approach taken for ambulatory patients. A classic mnemonic—the six *w*'s—may help guide the evaluation: wind, water, wound, walk, wonder drug, and what we did. "Wind" refers to fever within the first 24 hours of surgery, when it is unusual to have an infection. A fever at this time is often thought to be related to the anesthetic agent, atelectasis, or surgical trauma. The only bacteria believed to cause significant infections within 24 hours of surgery are *S. pyogenes* and *Clostridium* species, both of which are unusual in the typical hospital patient. "Water" refers to a urinary tract infection occurring after the third day of urinary tract catheterization. Because nearly all nosocomial urinary tract infections occur in patients with indwelling urinary catheters or in those who have undergone urologic instrumentation, urinalysis or culture (or both) should be performed routinely only in febrile patients with such risk factors. There is a high prevalence of bacteriuria in patients who have been catheterized for 3 days or longer, and there is a relatively low incidence of true infection attributable to bacteriuria. "Wound" infections commonly occur about 5 to 7 days postoperatively, whether they are surface wounds or complications of dehiscence of gastrointestinal anastomoses. Some of the highest rates of skin and soft tissue infections in the National Nosocomial Infection Surveillance database are seen with gastrointestinal procedures. Toxin-producing *C. difficile* is the only significant nosocomial gastrointestinal infection seen in hospitalized patients, so a routine bacterial stool culture is not necessary. "Walk" refers to possible deep venous thrombosis or pulmonary embolism in someone who has not received appropriate prophylaxis or who is otherwise at risk for thrombosis. Fever induced by a "wonder drug" is typically seen after approximately 7 to 10 days of use if the patient does not already have an allergy to that medication, in which case it recurs immediately. An exception to this rule is sulfamethoxazole, for which approximately half of hypersensitivity reactions occur within 3 days of initiation. Finally, "what we did" alerts the clinician to the possibility of an iatrogenic infection, such as intravenous catheter–related bacteremia.

CONCLUSION

The initial management of patients with febrile illnesses requires three major considerations. First, is the illness more likely to be infectious or more likely to be related to some other process? Excessive antibiotic use when it is not warranted, such as for viral infections or collagen vascular disease, may cause an adverse reaction, in addition to contributing to the worldwide increase in antimicrobial resistance. However, an empirical antibiotic is appropriate in many cases of fever and localizing signs of bacterial infection. Second, the clinician must rapidly assess the severity of the illness and determine whether it is likely to cause significant organ damage or even death. In a febrile patient with signs of sepsis, the clinician must quickly decide which specific therapy is indicated because a delay in initiating antimicrobial therapy is correlated with increased morbidity and mortality.[12] Finally, the clinician needs to determine whether supportive care alone, including antipyretic therapy, is warranted.

The nearly universal prevalence of febrile adaptive responses to microbial challenge suggests that fever has a net benefit to the host. In addition to clinical studies correlating elevated core temperature and improved prognosis during infection, investigations of principal endogenous mediators have provided evidence of a protective effect of pyrogenic cytokines. Although the use of antipyretic medications is a long-established and widespread practice, the actual benefit of temperature reduction in febrile patients is uncertain. Antipyretic therapy does not protect against the recurrence of childhood febrile seizures, nor has its risk-benefit ratio been determined in patients with cardiopulmonary and other underlying disorders. In summary, fever is usually not harmful, and antipyretics may confuse the clinical picture by dampening it, although their anti-inflammatory effects are often beneficial.

REVIEW QUESTIONS

1. A 72-year-old man was admitted with exacerbation of his chronic obstructive pulmonary disease (COPD) symptoms and temperature of 38.3° C. His respiratory symptoms improved and he defervesced with antibiotics; but on his third hospital day, he became extremely agitated, requiring haloperidol, a major tranquilizer and central nervous system dopamine-depleting agent. Within hours his temperature rose to 42° C, and he developed muscle rigidity and dysautonomia. What is the most likely etiology of his worsening clinical picture?

A. Aspiration pneumonia due to his agitatio
B. Pulmonary embolism
C. COPD exacerbation
D. Nosocomial infection
E. Neuroleptic malignant syndrome due to haloperidol

Answer: E Temperatures exceeding 41° C are often due to drug-induced imbalance in thermoregulatory mechanisms and may cause direct cellular damage (Chapter 434).

2. A 46-year-old female immigrant had returned to her work as a day-care teacher for a month after visiting her family in Central America at Thanksgiving when she developed watery diarrhea. She was otherwise well and afebrile. Her complete blood count and electrolyte panel were normal. Several of her pupils had similar illness. What is the most likely etiology of her illness?

A. *Plasmodium vivax* infection
B. Traveler's diarrhea due to toxigenic *E. coli*
C. Amebiasis
D. Shigellosis
E. Viral gastroenteritis

Answer: E No laboratory abnormalities accompany typical benign acute viral infections. The first consideration in evaluating such a patient is that an infection unrelated to travel is more likely to be the cause of the illness. Common viral respiratory infections and gastroenteritis are accompanied by temperatures below 102° F.

3. A 36-year-old man developed low-grade fever, sore throat, and a rash. He had pharyngeal erythematous-based vesicles and ulcerations as well as vesicles on his hands and palms, feet, and buttocks. His 2-year-old child was recovering from a similar illness. What is the most likely etiology of his illness?

A. Epstein-Barr virus infection
B. Herpes simplex virus infection
C. Leptospirosis
D. Lyme disease
E. Enteroviral hand-foot-and-mouth disease

Answer: E See Tables 280-3 and 280-4. The presence of fever and rash involving the palms and soles allows considerable narrowing of the differential diagnosis.

4. For which of the following ambulatory adult patients should an antibiotic be prescribed?

A. A 47-year-old woman with no underlying medical conditions who has had a persistent cough for 2 weeks.
B. A 28-year-old woman with 10-day illness and now with unilateral face pain, maxillary toothache, and worsening symptoms after initial improvement.
C. A 31-year-old woman with pharyngitis but no fever, tonsillar exudates, tender anterior cervical adenopathy, or cough.
D. A 54-year-old man with no fever and prolonged coughing lasting 6 weeks.
E. A 65-year-old man with COPD and yellow-green mucopurulent discharge and no other new symptoms.

Answer: B See section on initial management of suspected infection in the ambulatory setting.

5. A 76-year-old woman admitted for community-acquired pneumonia, treated empirically with moxifloxacin, developed severe watery diarrhea, abdominal pain, fever, and leukocytosis (white blood cell count of 30,000) on day 4 of hospitalization. What is the likely etiology of her nosocomial infection?

A. *C. difficile* infection
B. Urinary tract infection
C. Intravenous catheter–related infection
D. *Legionella* infection
E. Drug fever

Answer: A Toxin-producing *C. difficile* is the only significant nosocomial gastrointestinal infection seen in hospitalized patients.

281

APPROACH TO FEVER AND SUSPECTED INFECTION IN THE COMPROMISED HOST

KIEREN A. MARR

DEFINITION

This chapter focuses on the approach to suspected infection and fever in compromised hosts.[1] Multiple conditions, including burns, critical illness, and inherited immunodeficiencies (to name only a few), can compromise the immune system and render a person at risk for different infections, but this chapter focuses primarily on hosts who have acquired defects in immune function secondary to medical therapies, or the "medically immunosuppressed." Examples include treatment of neoplastic diseases (particularly hematologic disorders such as leukemia and lymphoma), organ transplantation, and treatment of collagen vascular or autoimmune diseases. Management of people with the acquired immunodeficiency syndrome (AIDS) is discussed in Chapters 384 through 395, and a more thorough discussion of primary immunodeficiency is provided in Chapter 250.

TABLE 281-1 CONDITIONS, INTERVENTIONS, AND IMMUNE DEFECTS TYPICALLY ENCOUNTERED IN COMPROMISED HOSTS

UNDERLYING CONDITION	INTERVENTION	TYPE OF DEFECT
Treatment of neoplastic diseases (particularly hematologic malignant neoplasms)	Underlying disease (without intervention)	Defects in production of bone marrow cells associated with defects in cellular immunity and phagocytic function (e.g., cytopenias associated with bone marrow infiltration with malignant cells)
	Cytotoxic chemotherapies	Bone marrow suppression; defects in primary and secondary humoral and cellular immunity; breach in mucosal barriers (skin, gut); impairment in mucociliary clearance; defects in other organ function (e.g., kidney, liver)
Hematopoietic stem cell transplantation	Underlying disease, without intervention (e.g., hematologic malignant neoplasms)	Defects in primary and secondary humoral and cellular immunity; defects in phagocytic cell quantity and function
	Cytotoxic conditioning therapy (± total body irradiation)	Bone marrow suppression; defects in primary and secondary humoral and cellular immunity; breach in mucosal barriers; defects in organ function
	Stem cell manipulation (e.g., T-cell depletion)	Delay in cellular engraftment
	Prophylaxis and treatment of graft-versus-host disease (e.g., corticosteroids, calcineurin inhibitors, antimetabolites, TNF-α antagonists)	Defective function in phagocytic cells and dysfunction of primary and secondary humoral and cellular immunity
Solid organ transplantation	Underlying disease, without intervention (e.g., diabetes, end-stage liver disease)	Organ dysfunction and miscellaneous immune dysfunction
	Induction therapies (e.g., corticosteroids, antilymphocyte globulin, splenectomy, anti–interleukin-2 Ab, anti-CD52 Ab, calcineurin inhibitors	Depletion and impairment in primary and secondary cellular and humoral immunity
	Surgical intervention and altered anatomy	Breach in mucosal barriers; defects in organ function
	Acute and chronic rejection prophylaxis and treatment (e.g., corticosteroids, calcineurin inhibitors, antimetabolites and alkylating agents, plasmapheresis, antithymocyte globulin, monoclonal antibodies to B and T cells, anticytokine therapies, T-cell costimulation blockers)	Defective function in phagocytic cells, primary and secondary humoral and cellular immunity
Treatment of collagen vascular and autoimmune diseases	Anti-inflammatory and immunosuppressive agents (corticosteroids, nonsteroidal anti-inflammatory drugs, calcineurin inhibitors, sirolimus, mycophenolate mofetil)	Defective function in phagocytic cells, primary and secondary humoral and cellular immunity
	Antimetabolite and alkylating agents	Bone marrow suppression, defects in primary and secondary humoral and cellular immunity
	Biologic immune response modifiers (e.g., antithymocyte globulin, monoclonal antibodies to B and T cells, anticytokine therapies, T-cell costimulation blockers)	Defective function in primary and secondary humoral and cellular immunity

Ab = antibody; TNF = tumor necrosis factor.

APPROACH TO THE PATIENT

The approach to the immunosuppressed patient requires detailed knowledge of the type of immune defect and related risks. Table 281-1 outlines general defects in host responses with the types of conditions that characterize groups of medically immunosuppressed patients discussed in the context of this chapter (treatment of neoplastic diseases, hematopoietic stem cell and solid organ transplantation, and treatment of autoimmune and collagen vascular diseases). As the management of many of these conditions becomes more and more complex and dependent on biologic agents that affect immune responses at both broad and focused targets, knowledge of prior therapies received has become critically important in developing an informed approach to fever.

Patients with Malignant Disease

In patients with neoplastic diseases, particularly hematologic malignancies, the underlying condition plays a role in dictating infectious risks. For instance, the absolute number of phagocytic cells belonging to the polymorphonuclear leukocyte series may be reduced or the function of those cells impaired in the setting of specific malignancies (e.g., acute or chronic leukemias). In conditions such as acute leukemia, in which the cells are abnormal in morphology and function and only a small proportion of normally functioning cells circulate, risks for bacterial infections are enhanced, even in the absence of administered cytotoxic therapies. In certain conditions, such as in the setting of chronic lymphocytic leukemia, there may be quantitative defects in humoral factors that are critical in host defense, such as circulating immunoglobulin G and immunoglobulin M antibodies, secretory immunoglobulin A antibodies, and components of the complement cascade that can directly lyse some bacteria. Another component of the population of phagocytic cells includes circulating monocytes and tissue macrophages and the fixed mononuclear cells of the reticuloendothelial system. These cells collaborate with helper T cells in defense against pathogens that can survive intracellularly, such as mycobacteria, fungi, and some viruses and parasites. The spectrum of infectious risks is further enhanced and prolonged after treatment with cytotoxic drugs. These therapies affect other organ functions that are critical to defense, especially the integrity of the gastrointestinal tract mucosal barrier and airway innate clearance mechanisms, posing additional susceptibilities to bacterial and fungal pathogens. In this manner, the neoplastic disorder itself and the specific therapies used to treat it combine to define both acute and chronic risks for infection.

Transplant Recipients

Hematopoietic stem cell transplantation (HSCT) (Chapter 178) posits additional risks to the patient as a result of the agents used for conditioning therapy in preparation for the stem cell transplantation, variable rate and magnitude of cellular engraftment, and, in recipients of allogeneic HSCT, administration of additional agents to modulate risks for and treatment of graft-versus-host disease (GVHD). Thus, risks for specific infections can be roughly divided on a time scale relative to engraftment. Organ dysfunction, loss of natural barriers (skin and gut), and neutropenia dictate enhanced early risks for bacteria and fungi that inhabit the gastrointestinal tract; impaired humoral and secondary immunity enhance late risks for infections caused by viruses, fungi, and encapsulated bacteria, especially in people treated aggressively for GVHD.

Immunodeficiency in solid organ transplant recipients (Chapter 49) is largely related to the acute initiation and chronic maintenance requirements of therapies to suppress T- and B-cell function to minimize the impact of allosensitization and to decrease risks for early and late graft rejection. Therapies have evolved over time, with increased use of targeted biologic therapies, but in general, risks are largely related to those associated with acute and chronic cellular and humoral dysfunction. The type and amount of therapy differ according to immunologic risk of recipients. Additional variables modulating overall risks for infection include the altered anatomy, surgical intervention, and potential of infection transmitted from the graft itself (i.e., donor derived).

Transplant recipients have increased risks both for acute infection and for reactivation of latent infections after initiation of immunosuppression. Hence, pretransplantation evaluation should be focused on detection of latent herpes viruses (e.g., cytomegalovirus [CMV]) and other pathogens (e.g., *Mycobacterium tuberculosis*) that can be transferred or reactivated with transplantation and immunosuppression.

Two important concepts regarding immunosuppression that have emerged from the field of transplantation include observations of the immunomodulatory effects of viral reactivation and infection and the "net state of immunosuppression."[2] It was long ago noted that viral infections (both reactivation and disease) enhance risks for other infections. This has been particularly well documented for CMV (Chapter 376), which is recognized as a risk for other infections in recipients of both hematopoietic stem cell and solid organ transplant grafts. Overall risks for infection are related to epidemiologic exposures and the net state of immunosuppression, dictated by multiple host, donor, and medical variables. This net state is variable in both quantity and changes in character over time, largely influenced by therapies to prevent rejection or GVHD, and other complications, such as viral reactivation. This concept, which originated from an understanding of solid organ transplantation, can perhaps be applied to the care of all immunosuppressed patients.

Patients Treated for Autoimmune Disease

Table 281-1 also outlines the types of immunosuppressive therapies frequently administered to patients for the control of connective tissue diseases and autoimmune conditions. This is detailed here to emphasize that this group of patients is growing in importance in both hospitalized and outpatient populations, with increased use of biologic immune response modifiers (Chapters 35 and 36) enhancing risks for both reactivation of latent infection (e.g., *M. tuberculosis* and *Histoplasma capsulatum*) and severe manifestations of acute infection. Infectious risks should be considered in balancing need for these therapies, designing preventive regimens, and creating differential diagnoses of suspected infection.

FEVER IN THE COMPROMISED HOST

The onset of fever in a compromised patient can be an ominous development, and depending on the nature and magnitude of the impaired host defenses, a febrile response can herald the onset of a life-threatening systemic infection. A diagnostic approach should be derived by careful consideration of the patient's signs and symptoms of infection, immunosuppression, and whether the patient is at heightened risk for reactivation of latent infection. Because infection can progress rapidly, empirical antimicrobial therapy may be indicated even before an infection is definitively diagnosed. In this situation, empirical antimicrobial therapy may be indicated even before an infection is definitively diagnosed. Here, the common scenario of fever in the neutropenic host is discussed in depth.

Fever during Neutropenia: Diagnostic Considerations

If fever occurs in the setting of chemotherapy-induced neutropenia, the risk for bacterial infection increases proportionally with the decline in neutrophil count, especially with prolonged durations of significant neutropenia. Early pivotal studies documented that infection rates increase with neutrophil levels lower than 1000 cells/mm^3, progressively increasing as counts decline to less than 100 cells/mm^3. The duration of significant neutropenia is also an important determinant of the type of infection most likely to occur, with the risk for bacterial and fungal infections increasing with each successive week in which leukocyte counts are less than 500 cells/mm^3. In these studies, neutropenia and lymphopenia played significant roles in influencing infection rates in the setting of acute leukemia; however, neutropenia alone was more important than lymphopenia alone. These studies marked some of the earliest efforts that laid the foundation for our current approach to treatment of fever during neutropenia.

Historically, the most common causes of fever during neutropenia were gram-negative bacteria arising from the gastrointestinal tract. These observations drove establishment of empirical and prophylactic antibiotic practices designed to prevent and to treat unrecognized infection caused by the most common predicted pathogens. In the 1990s, concurrent with increased use of prophylactic and empirical antibiotics, especially quinolones and extended-spectrum β-lactams, reported rates of gram-negative bacteremias declined, with proportional increases in the numbers of bacteremias caused by gram-positive organisms. Why the change in epidemiology occurred is a matter of debate, but it is likely multifactorial; in addition to increased use of effective preventive antibacterials, there may be a role played by increased use of indwelling intravascular devices, positing higher risks for gram-positive bacteremias. It has also been recognized that fever that persists despite administration of broad-spectrum antibacterial therapy may herald the onset or presence of undiagnosed invasive fungal infections.

TABLE 281-2 APPROACH TO FEVER DURING CHEMOTHERAPY-INDUCED NEUTROPENIA

PAST AND CURRENT CLINICAL CONSIDERATIONS
What is the type and duration of immunologic deficiency?
Does the patient have any organ dysfunction that would predispose to particular infection?
Does the patient have any unique environmental or epidemiologic exposures?
What are the patient's prior infections and colonizing organisms?
What are the current and recently administered antimicrobial agents?
Are there any specific presenting signs or symptoms that suggest a particular type of infection or syndrome?

The importance of mucositis in driving inflammation and leading to development of bacterial or fungal infection through mucosal barrier injury cannot be overemphasized in patients administered cytotoxic therapies. Studies have shown that mucositis can produce inflammation adequate to drive development of fever. It is also likely that some people develop fever by transient seeding of the blood stream with colonizing bacterial or fungal pathogens. Some of these infections may be caused by organisms that are less well adapted to growth with standard microbiologic methods. These concepts support liberal use of empirical antimicrobials in the febrile neutropenic setting, with the focus on administration of a compound that is active against the most likely pathogens, considering the patients' epidemiologic exposures and colonizing organisms, especially in the gastrointestinal tract.

Table 281-2 lists multiple questions and considerations that the clinician should entertain when approaching fever in the neutropenic patient. The differential diagnosis of fever in the setting of chemotherapy-induced neutropenia is influenced by local and hospital exposure and the type of preventive antibiotics administered to the patient, which serve to alter microbial epidemiology within the gastrointestinal tract (see Table 281-2). Importantly, the type and the duration of immunodeficiency can alter overall risks, with "latent" infections presenting at development of first fever. Specific organ dysfunction, such as underlying pulmonary disease or renal impairment, can predispose to unique infectious syndromes (see later). Epidemiologic exposures should be thoroughly solicited; for instance, diagnostic evaluation should consider whether the patient previously or currently resides in areas endemic for *M. tuberculosis* or other infections that become latent. Current and previously administered antimicrobial drugs both affect risks for specific infections and can alter host microbial epidemiology. With this in mind, it is useful to have some information on colonizing organisms that may display complex resistance profiles, such as vancomycin-resistant enterococci and bacteria that express extended-spectrum β-lactamases or other resistance determinants (carbapenemases). Knowledge of recent colonization with these organisms should tailor initial antibiotic management, especially in patients who present severely ill.

One early consideration in treatment of fever during neutropenia is whether the patient requires hospitalization for therapy.[3] Risk assessment is an integral part of early evaluation to determine whether outpatient therapy is feasible. Two risk assessment systems have been developed, with the Multinational Association of Supportive Care in Cancer score validated to serve as a useful predictor of outcome, potentially assisting in identifying patients who can be treated with oral antibiotics and close monitoring rather than with inpatient therapy. Although the score is useful as a general guide to risk stratification, other variables that are important to consider in making risk assessment are underlying disease (e.g., lymphoma vs. leukemia), past and anticipated duration of neutropenia, symptoms and signs of infection foci, other comorbidities, and, perhaps most important, whether the patient has access to immediate and reliable medical attention if discharged from the medical facility. Recent guidelines suggest that febrile neutropenic patients can be managed as outpatients, provided the risk index is low enough and empirical antibacterial therapy is administered within an hour of triage, with close monitoring for stability to ensure safety in outpatient management.

The onset of fever should trigger a prompt and thorough bedside evaluation of the patient. Beginning with examination of the head and neck, there should be a specific examination for evidence of central nervous system (CNS) infection as well as a general evaluation of mental status. The

oropharynx must be examined for evidence of pharyngitis and focal tenderness. Sinus membranes should be evaluated for the presence of erythema or necrosis. Complete examination of the heart, lung fields, and abdomen is critical, with attention to the potential presence of new murmurs, pneumonia, and intra-abdominal tenderness. The perirectal area and the entire integument should be examined. Intravenous catheter exit sites and tunnels should be carefully examined, and blood should be drawn through all catheter channels for culture. Because catheter exit sites and tunnels can be infected in neutropenic patients without showing early signs of inflammation and erythema and with classic signs of infection presenting only after recovery of neutrophils, examination should be performed daily and with close scrutiny for evolving localized infection that may necessitate catheter removal.

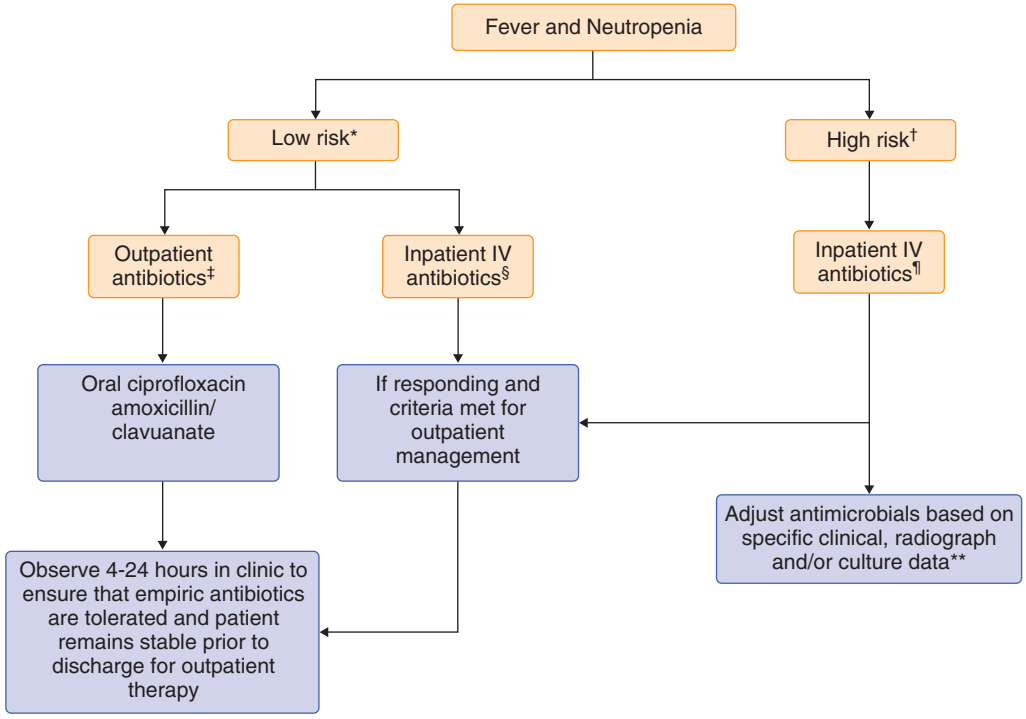
Laboratory studies should be undertaken, with emphasis placed on procedures that can yield prompt results, such as Gram stain of body fluids, exudates, or aspirates. Routine blood work should include a complete blood count with differential, serum creatinine concentration, and screening liver function studies. A chest radiograph should be part of the initial evaluation, as should routine urinalysis. Because routine radiographs are insensitive for detection of small nodular lesions, especially those caused by filamentous fungi, computed tomography (CT) should be performed in evaluating persistent fever, especially in the presence of airway symptoms. No biomarker has yet to be proved reliable in discriminating between severe infection or other causes of fever during neutropenia, although studies have focused attention on the utility of lipopolysaccharide-binding protein, interleukins 6 and 8, procalcitonin, and C-reactive protein, to name only a few.

Although fever is the hallmark of infection, it is not specific for the presence of an infectious process. The development of fever may be a result of multiple causes, including medications, reaction to blood components, Sweet's syndrome, and GVHD. The fundamental principle is that infection should be suspected as the most likely cause of fever in a compromised host, and therapy should be applied empirically, even as diagnostic tests are being performed. Multiple episodes of fever during prolonged hospitalization and neutropenia are not uncommon; each episode requires comprehensive assessment. After a documented infection, it should not be assumed that a subsequent episode of fever is caused by the same recrudescent pathogen; the law of diagnostic parsimony tends to be less reliable in immunosuppressed patients.

Fever during Neutropenia: Management

Progression of infection can occur rapidly in neutropenic hosts. Very high mortality rates associated with bacteremia, especially that caused by gram-negative bacteria, triggered the introduction of routine empirical therapies (i.e., treatment of fever before diagnosis of infection). There are now many options for initial antibiotic therapy; choice should be tailored according to patient and institutional variables, as outlined in Table 281-1 and Figure 281-1. The first therapeutic distinction is whether a patient is at high risk, warranting inpatient management and intravenous antibiotic therapy, or low risk, potentially treated with oral regimens as an outpatient. In low-risk patients, the combination of a fluoroquinolone such as ciprofloxacin with amoxicillin-clavulanate has been shown to be effective. In high-risk patients, admission for treatment and prompt administration of a broad-spectrum antibiotic regimen is necessary. An international guideline panel of the Surviving Sepsis Campaign recommends starting antibiotics as soon as possible, preferably within an hour of recognition of fever during neutropenia. Although these recommendations were not specifically developed for this population, recent outcomes studies suggest that delays in administering antibiotics may be associated with prolonged hospital stays.[4]

Early studies demonstrated that the combination of an antipseudomonal β-lactam and an aminoglycoside is effective, but a recent meta-analysis showed that monotherapy with one of the new broad-spectrum β-lactams is associated with better outcomes compared to the combination therapy. Extended-spectrum agents, such as third- and fourth-generation cephalosporins and



* Low Risk = anticipated neutropenia ≤7 days and clinically stable and no medical comorbidities.
† High Risk = anticipated neutropenia >7 days, *or* clinically unstable, *or* any medical comorbidities.
‡ If able to tolerate and absorb; caregiver, access, and transportation are available; patient and physician decide.
§ If there is documented infection requiring IV antibiotics; there is gastrointestinal intolerance; patient and physician decide.
¶ Empiric antibiotic monotherapy with any of the following: Piperacillin/tazobactam, *or* Carbapenem, *or* Ceftazidime, *or* Cefepime.
** For example: vancomycin and linezolid for cellulitis or pneumonia; add aminoglycoside and switch to carbapenem for pneumonia or gram negative bacteremia; metronidazole for abdominal symptoms of suspected *C. difficile* infection.

FIGURE 281-1. Initial management of fever (≥38.3°C) and neutropenia (≤0.5 × 10^9 cells/mL). Limited data to support recommendation. (Modified from Freifeld AG, Bow EJ, Sepkowitz KA, et al. Clinical practice guideline for the use of antimicrobial agents in neutropenic patients with cancer: 2010 update by the Infectious Diseases Society of America. *Clin Infect Dis.* 2011;52:e56-e93.)

carbapenems, were then shown to be effective options administered as monotherapy. Meta-analyses have now shown that the routine use of an aminoglycoside in combination may result in more toxicities and no better outcomes.

One major decision point in early therapy involves when to initiate vancomycin in high-risk patients. Advocates point to the risk for gram-positive infections that may carry a higher morbidity in neutropenic patients, including those caused by *Staphylococcus aureus* and viridans streptococci. However, because initiation of vancomycin with fever does not affect outcomes except in the case of treating breakthrough viridans streptococcal infection, in a setting where toxicities may offset benefits, most guidelines do not support its administration except in the case of documented or suspected catheter-related infection, colonization with penicillin- and cephalosporin-resistant pneumococci or methicillin-resistant *S. aureus*, positive blood cultures for gram-positive bacteria, or hemodynamic instability.

The median time to defervescence is shorter (2 days) in low-risk patients and longer (5 to 7 days) in high-risk patients. Clinical response to the first few days of therapy is a critical determinant of the course of extended antimicrobial therapy. Therapy should be tailored to the diagnostic findings. If patients are stable yet still febrile during a period of prolonged and severe neutropenia, clinical judgment must be used in deciding whether to maintain the initial regimen or to switch to an alternative regimen. If patients become afebrile after 3 to 5 days of antibacterial treatment but cultures are negative, some authorities recommend continuing the broad-spectrum intravenous coverage until recovery of the neutrophil count. This, however, may not be practical for patients with leukemia in blast crisis or refractory aplastic anemia, in whom periods of aplasia lasting weeks or more are common. Others believe that a switch to oral treatment is justifiable (e.g., a fluoroquinolone possibly paired with a β-lactam) if the patient becomes afebrile and appears to be clinically stable. If the patient remains afebrile, there is rapid improvement in the underlying condition, such as with recovery of the circulating neutrophil count to higher than 500 cells/mm^3, and no focus of infection is identified, discontinuation of treatment is an option. If the neutrophil count recovers to above 500 cells/mm^3 and fever persists, clinical judgment must be used to define needs for antimicrobial therapy while a search for the cause of the fever is continued. If the patient was initially treated with vancomycin and no confirmatory cultures supporting continued vancomycin use are obtained after 3 days (e.g., no coagulase-negative staphylococci from blood or methicillin-resistant *S. aureus*), intravenous vancomycin therapy should be discontinued.

Clinical deterioration should trigger consideration of infections resistant to the empirical regimen. Classic examples include breakthrough streptococcal bacteremia in patients not receiving vancomycin; vancomycin-resistant enterococci; breakthrough extended-spectrum β-lactamase–producing gram-negative bacteria in patients taking single-agent β-lactams; *Stenotrophomonas* species infections occurring in the setting of carbapenem monotherapy; and infections with multidrug-resistant pathogens, such as *Acinetobacter* species and organisms that produce carbapenemases.

There are many causes of persistent fever, both noninfectious and infectious. Noninfectious causes include hematomas, drug reactions, transfusion reactions, pulmonary emboli, splenic infarcts, and the underlying malignant disease. The possibility of infection caused by nonbacterial pathogens, such as fungi (especially *Candida* and *Aspergillus* species), should prompt evaluation and consideration of antifungal empirical therapies in the setting of fever that persists more than 4 to 7 days. Many drugs have been evaluated and shown to be effective in this setting, including azole drugs, echinocandins, and polyenes. Choice should be tailored to current antifungal prophylaxis, diagnostic findings, suspicion of *Candida* versus *Aspergillus* infection, and organ function. Current efforts are focused on developing reliable screening methods to negate the need for potentially toxic antifungals and to derive "preemptive" strategies for guiding use.

There are no hard and fast rules for duration of therapies; the simplest recommendation is to treat documented pathogens until the signs and symptoms of infection subside. On the other hand, persistently compromised hosts may remain febrile for weeks without identification of the cause. For a patient with persistent fever in whom no pathogen is identified, the duration of therapy must be based on integration of clinical data and the best estimate of the direction of the host's status. As mentioned previously, therapy can be discontinued in stable, afebrile patients, assuming that the absolute neutrophil count exceeds 500 cells/mm^3. Clearly, if broad-spectrum antibacterial therapy is to be discontinued, the patient must be monitored carefully thereafter. For patients whose neutrophil counts remain at levels less than 500 cells/mm^3, particularly the subset with severe profound neutropenia of less than 100 cells/mm^3, it is prudent to continue empirical antibacterial and antifungal therapy, with reappraisal of all diagnostic measures. The decision to stop therapy at whatever arbitrary interval may be justified if the patient's condition is stable.

The use of granulocyte colony-stimulating factors for the prevention of febrile neutropenia is discussed in Chapter 167. For the management of established fever in neutropenic patients, evidence-based guidelines have been published by the American Society of Clinical Oncology and by the Infectious Diseases Society of America. The National Comprehensive Cancer Network and the German Society for Haematology and Medical Oncology have likewise published recommendations for the use of myeloid growth factors in the oncology setting. [5,6] The guidelines generally agree, and they support the use of colony-stimulating factors in similar circumstances that indicate high risk for infection-associated complications and poor clinical outcomes, such as in patients with anticipated long and profound durations of neutropenia, age older than 65 years, uncontrolled primary disease, pneumonia, hemodynamic compromise, and invasive fungal infections.

The remainder of this chapter discusses diagnosis and evaluation of specific syndromes that are common in individuals who are immunocompromised because of multiple conditions, including transplantation. Table 281-3 summarizes some of the most common infectious and noninfectious syndromes that involve the skin, lungs, gastrointestinal tract, and nervous system, as discussed next.

CUTANEOUS SYNDROMES

Cutaneous abnormalities can provide a clue to bacteremia, and aspiration and culture of suspicious lesions can be as valuable as a blood culture. Ascending streptococcal or staphylococcal cellulitis can occur in both immunocompromised and non-compromised patients. Metastatic abscesses are a well-recognized part of the *S. aureus* bacteremia syndrome. Necrotizing vasculitis is classically associated with *Pseudomonas aeruginosa* infections; its cutaneous lesion of ecthyma gangrenosum is an erythematous, indurated target or "bull's-eye" lesion with an area of central necrosis that can appear in crops (Fig. 281-2). However, other gram-negative endotoxin-producing bacteria have been associated with similar cutaneous lesions.

In the neutropenic host, disseminated fungal infections may be initially recognized by characteristic cutaneous lesions. Disseminated candidiasis in neutropenic patients can be manifested with diffuse maculopapular, erythematous, and sometimes tender lesions. The appearance of cutaneous lesions typically changes in character with engraftment of neutrophils (Fig. 281-3). Disseminated infections caused by filamentous organisms such as *Aspergillus* species cause similar lesions, but usually fewer in number and more often with some component of central necrosis. Other filamentous fungi, namely, those with which infection is characterized by a high fungal burden, such as *Fusarium* species, typically cause more skin lesions in multiple stages of evolution, ranging from papules to larger erythematous lesions with central necrosis. Multiple filamentous fungi such as *Aspergillus* species and Zygomycetes can also cause primary cutaneous lesions, especially with a breech in skin integrity associated with catheter sites, trauma, and surgery. Infection with *Cryptococcus neoformans* can be accompanied by cutaneous involvement, with manifestations ranging from molluscum-like lesions to primary cutaneous cellulitis, which may be especially common in solid organ transplant recipients. Cutaneous lesions are an opportunity to establish diagnosis through aspiration, biopsy, and culture.

Morbilliform eruptions or maculopapular exanthems are frequent in neutropenic patients and transplant recipients, and they can be caused by drug reactions, GVHD, and numerous viral infections. Primary infection and reactivation with herpes viruses such as CMV and Epstein-Barr virus can be accompanied by rashes, and diagnostics should be considered in the appropriate context. Human herpesvirus 6, the primary cause of roseola infantum in childhood, leads to latency and can cause disease in immunocompromised hosts both by reactivation and by primary infection. Disease can be accompanied by fever, rash, myelosuppression, and involvement of other organ systems (e.g., CNS). In immunocompromised patients, adenovirus can be both primarily acquired, usually through the respiratory tract, and reactivated; it causes fever, rash, and potentially disease involving multiple organ systems (lungs, gastrointestinal tract, kidneys, liver, CNS). In HSCT recipients, the constellation of fever, rash, diarrhea, and hepatitis may be confused for severe GVHD. Parvovirus B19 infection can be severe in immunocompromised hosts and associated with fever, rash, and manifestations of hemophagocytosis, although there are other infectious causes of hemophagocytic syndromes as well (Chapter 169). The characteristic vesicular rashes of

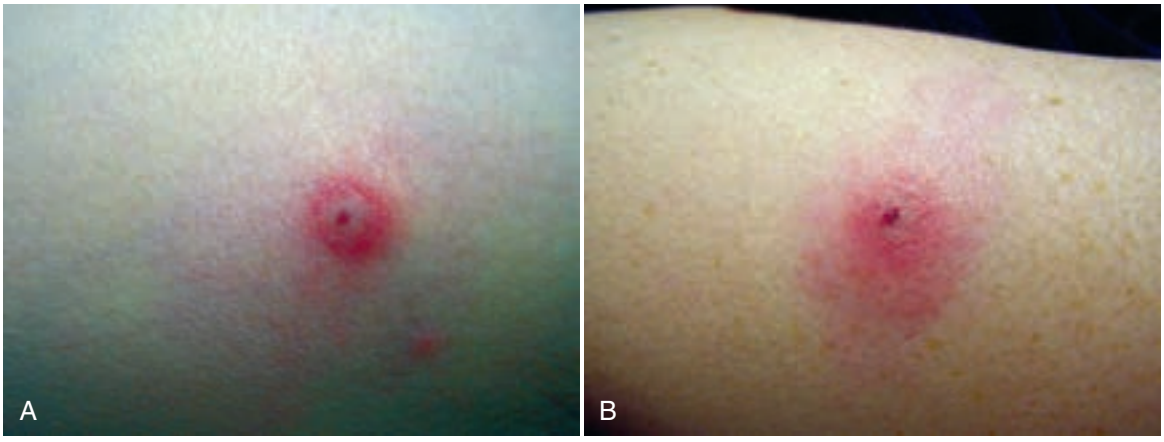


FIGURE 281-2. Ecthyma gangrenosum. A 28-year-old woman with fever and neutropenia while receiving chemotherapy for acute leukemia developed several tender edematous papules on her thighs. A, Central crust and surrounding erythema are shown. B, The papules became necrotic during 1 to 2 days, with the formation of black, well-demarcated eschar. Cultures from blood and the necrotic eschar grew *Pseudomonas aeruginosa*. (© DermAtlas; http://www.DermAtlas.org.)

CMV, cytomegalovirus; EBV-PTLD = Epstein-Barr virus–post-transplantation lymphoproliferative disorder; GVHD = graft-versus-host disease; HHV-6 = human herpes virus 6; HSV = herpes simplex virus; MMF = mycophenolate mofetil; PRES = posterior reversible encephalopathy syndrome; RSV = respiratory syncytial virus; VZV = varicella-zoster virus.

varicella reactivation are frequent in stem cell and solid organ transplant recipients with chronic T-cell deficiencies, especially in the absence of antiviral prophylaxis; an important therapeutic consideration is to recognize and aggressively treat disease that involves viscera because disseminated disease is associated with high mortality rates. Antivirals administered as prophylaxis in high-risk HSCT and solid organ transplant recipients can decrease both early morbidity and late mortality associated with herpes simplex virus (HSV), varicella-zoster virus (VZV), and CMV disease, although drug-related toxicities need to be measured in risk-benefit calculations.

There are numerous noninfectious causes of rashes and lesions that are common in immunocompromised individuals. Drug-induced hypersensitivity syndromes can be both mild and severe, potentially associated with life-threatening toxic epidermal necrolysis. As in other populations, antimicrobial agents are frequently implicated as causative agents. GVHD, especially during the acute phase, frequently is manifested as suspected infection, with fever, nonspecific rashes, and frequently disease involving the gastrointestinal tract (diarrhea, hepatitis).

Sweet's syndrome, or acute febrile neutrophilic dermatosis, is characterized by skin lesions with neutrophilic infiltration in the dermis (see Fig. 440-22). This presents a diagnostic dilemma in neutropenic patients and has been described in the setting of impending neutrophil recovery or treatment with granulocyte colony-stimulating factor. It is also associated with numerous drugs and can appear as a paraneoplastic phenomenon. Biopsy with appropriate microbial stains and culture is essential to distinguish these lesions from infectious causes of ecthyma gangrenosum and other disseminated infections, such as those caused by fungi.

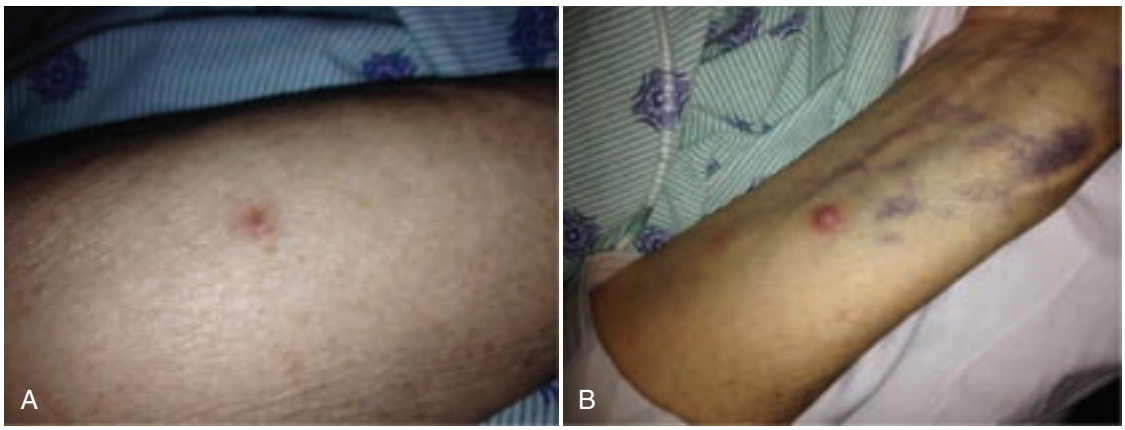

FIGURE 281-3. Disseminated candidiasis. A 60-year-old woman with fever during neutropenia that developed after receipt of therapy for acute leukemia developed tender papular lesions on her extremities, trunk, and back. **A,** Blood cultures returned positive for *Candida tropicalis*. **B,** After resolution of neutropenia, lesions developed a more pustular appearance.

RESPIRATORY SYNDROMES

The lungs are a challenging site in evaluating fever in a compromised patient because detection of abnormalities is easy but obtaining lung secretions or infected tissues can be difficult. Pneumonia should be suspected in a patient who has respiratory symptoms as manifested by cough, shortness of breath, chest pain, and hypoxia. In the early stages of pneumonitis, routine chest radiographs may be normal, whereas more expensive imaging procedures such as CT can reveal pulmonary infiltrates or abscesses. Both community-acquired pathogens such as pneumococci and *Haemophilus influenzae* can cause lobar or diffuse pneumonia. Gram-negative bacilli can cause pneumonia of a necrotizing type in severely neutropenic patients. All patients who are receiving ventilator support are at risk for secondary gram-negative bacillary pneumonia or staphylococcal pneumonia. Clusters of outbreaks of *Legionella pneumophila* infection have occurred in immunocompromised patients maintained in dialysis, transplant, or intensive care units; these outbreaks reflect institutional environmental contamination.

Opportunistic fungi have been increasingly recognized as causes of lung infection in compromised neutropenic patients and transplant recipients. A travel history is essential in a compromised patient who has evidence of lung disease; epidemic mycoses such as blastomycosis, coccidioidomycosis, and histoplasmosis may be manifested as acute pneumonia after recent exposure (although more typically, initial exposure in a normal host leads to containment in an initial focus of fungal lung disease). After immune suppression, the primary focus can be the source of reactivated disease. *Candida* species, in contrast, are uncommon primary lung pathogens. Although *Candida* species commonly colonize indwelling vascular and urinary catheters, candidal pneumonia is unusual in the absence of systemic candidiasis. Systemic candidiasis usually originates from the gastrointestinal tract if it is not secondary to vascular catheter infection, but *Candida* lung nodules can occur after systemic infection, especially with high fungal burden. Although traditionally associated with an "interstitial pattern" of lung infiltration, *Pneumocystis* species pneumonia can be manifested as local consolidation or pulmonary nodules, exhibiting granulomatous inflammation on pathologic examination. Filamentous fungi, which include *Aspergillus*, Zygomycetes, and less frequently diagnosed *Fusarium* species and *Scedosporium* species, are difficult to treat. These infections may be accompanied by chest pain and occasionally hemoptysis. From an initial focus, *Aspergillus* infection can spread through the pulmonary vasculature, which sets the stage for localized hemorrhage, creating a halo sign on CT scan, and infarction and necrosis, which can progress to cavitary lesions. Non-neutropenic hosts frequently also develop less specific radiographic findings, such as bronchopneumonia. These organisms can also cause primary airway disease, presenting with features typical of tracheobronchitis, with or without findings apparent on CT scan. This infection is particularly well described in lung transplant recipients, who may also have involvement of the bronchial anastomosis.

Attention has recently been drawn to the high risks for severe pulmonary infection caused by reactivation of *M. tuberculosis* in people who are treated with biologic immune response modifiers (Chapter 36) in the setting of autoimmune or other inflammatory diseases, such as with rheumatoid arthritis, psoriasis, and inflammatory bowel diseases. High risks are particularly well described in the setting of treatment with tumor necrosis factor antagonists, justifying enhanced vigilance, including routine screening for prior infection, and consideration of preventive chemotherapy.[7] These patients are also at increased risk for invasive fungal infections, including reactivation of endemic infections such as histoplasmosis, warranting enhanced screening and high suspicion for disease.

Viral infections that involve the lung are difficult to diagnose in immunocompromised patients. A particularly common concern is reactivation pneumonitis caused by members of the herpesvirus family, especially CMV, which occurs most frequently in the setting of chronic T-cell depression associated with transplantation. Respiratory viruses, which infect immunocompromised hosts with the same frequency as in the general population, cause lower tract disease and pneumonitis more frequently in hosts with suppressed cellular immunity. Essentially any respiratory virus can cause upper and lower tract disease, depending on geographic and seasonal epidemiology; most frequently recognized are respiratory syncytial virus, parainfluenza viruses, influenza viruses, and adenoviruses. Patients who have defects in cellular immunity typically exhibit higher viral loads and prolonged shedding, presenting considerations with regard to enhanced therapy, emergence of antiviral resistance, and infection control. The transplant population has served as a sentinel population in recognizing multiple emerging viral pathogens, including human metapneumovirus, bocavirus, and the KI and WU polyomaviruses.

There are numerous recognized noninfectious causes of pulmonary infiltrates in immunosuppressed hosts. These include early complications of chemotherapy administration, such as diffuse alveolar damage and hemorrhage, and late complications of GVHD and organ rejection (e.g., bronchiolitis obliterans syndromes). Certain drugs that are frequently administered in these populations of patients can cause direct lung toxicity; one classic example is the proliferation signal inhibitor sirolimus.

GASTROINTESTINAL SYNDROMES

There are multiple causes of diarrhea in a compromised host, including conventional enteric pathogens such as *Salmonella* (Chapter 308), *Shigella* (Chapter 309), and *Campylobacter* (Chapter 303). More recently, attention has been drawn to the frequency of noroviruses as an important cause of chronic gastroenteritis in immunocompromised patients, in whom diagnoses have been classically elusive and misapplied to noninfectious syndromes (e.g., GVHD), and outcomes can be poor.[8] In patients who have been in the hospital and have been receiving multiple courses of antibiotic treatment, *Clostridium difficile* (Chapter 296) is a common occurrence, and colitis can be both severe and persistent in immunosuppressed hosts. Two acid-fast staining parasites are *Isospora belli* and *Cryptosporidium* species, and they are associated with predisposing impairments in cell-mediated immunity. More recently recognized are the microsporidians. *Giardia lamblia* is classically associated with hypogammaglobulinemia. Individuals who have received long courses of chemotherapy, radiation, and antibiotics commonly experience *Candida* mucosal overgrowth in the mouth and esophagus. HSV and CMV can cause symptoms identical to those of *Candida* esophagitis. In severely neutropenic patients, anaerobic streptococci and gram-negative pathogens such as *P. aeruginosa* can cause severe mucositis and pharyngitis. In cancer patients, these organisms take advantage of the cytotoxic effects of chemotherapy, which promotes sloughing of mucosal surfaces and subsequently predisposes to infection.

Neutropenic patients may develop enterocolitis that can be of mixed anaerobic and aerobic bacterial origin. Neutropenic enterocolitis, also known as

typhlitis or *ileocecal syndrome*, results from chemotherapeutic damage to the intestinal mucosa in the setting of neutropenia. Presentation usually includes fever, abdominal pain, nausea, vomiting, and diarrhea. Because neutropenic enterocolitis can rapidly progress to intestinal perforation, sepsis, and multisystem organ failure, prompt diagnosis and aggressive medical or surgical intervention are required.

CMV colitis can be focal or diffuse; in some solid organ transplant recipients, disease can be present without demonstration of a positive blood polymerase chain reaction for CMV, so endoscopy is required for diagnosis. Because the differential diagnosis of colitis and diarrhea is broad and includes multiple infections, focal Epstein-Barr virus–associated post-transplantation lymphoproliferative disorder, GVHD, and drug-induced toxicity such as that caused by mycophenolate mofetil, these patients should be evaluated with endoscopy to reach definitive diagnosis.

NEUROLOGIC SYNDROMES

Both gram-positive and gram-negative bacteria (including anaerobes) can cause brain abscess or meningitis. *Listeria monocytogenes* is a common cause of meningitis in a compromised host. This pathogen is a gram-positive pleomorphic bacillus that may be difficult to identify on routine Gram stain of cerebrospinal fluid. Encapsulated bacteria such as pneumococci and staphylococci can cause metastatic CNS disease and meningitis. In patients with impaired cell-mediated immunity, *C. neoformans* is also a leading cause of CNS infection. Other fungal pathogens, such as *Aspergillus* and other molds, can invade the CNS, both by direct sinus invasion and by hematogenous spread. Focal brain lesions and meningoencephalitis in individuals who have chronic deficiency in cellular immunity can be caused by reactivation or acute severe infection by typically latent organisms such as *Toxoplasma gondii*, *M. tuberculosis,* and *H. capsulatum*. Reactivated or quiescent CNS syphilis should also be considered in patients with severe immunologic impairment.

There are numerous viral causes of meningoencephalitis. Similar to other populations, one needs to consider enteroviruses, measles, and neurotropic herpesviruses (HSV-1, CMV, VZV). Human herpesvirus 6 is a common cause of encephalitis and post-transplantation acute limbic encephalitis in transplant recipients, characterized by seizures, anterograde amnesia, and neuroimaging abnormalities involving the temporal lobes. Progressive multifocal leukoencephalopathy caused by JC polyomavirus occurs in patients with chronic CD4 deficiency, such as with human immunodeficiency virus (HIV) type 1 infection. Studies have emphasized that transplant recipients are at increased risk for meningoencephalitis caused by West Nile virus compared with the general population. Anyone presenting early after transplantation should be considered at risk for potentially severe infections acquired from the donor; West Nile virus, rabies, HIV, HSV, and multiple other viruses have been documented to be transmitted through organ donation.

There are multiple noninfectious causes of neurologic symptoms, which include drug toxicities and immunologic disorders, such as paraneoplastic syndromes and Guillain-Barré syndrome. Particularly relevant in the transplant recipient, patients with autoimmune diseases, and recipients of high doses of cancer chemotherapy is the *posterior reversible encephalopathy syndrome*. The classic presentation of the posterior reversible encephalopathy syndrome encompasses a sudden onset of severe "thunderclap" headache, seizures, confusion, and visual disturbance, accompanied by a CT or magnetic resonance imaging pattern of predominantly posterior cerebral edema and angiographic evidence of reversible vasoconstriction. It may be caused by endothelial injury, vasospasm, or edema associated with drugs such as calcineurin inhibitors (cyclosporine, tacrolimus).

CONCLUSION

Infections are a major cause of mortality in immunocompromised hosts. The approach to fever and suspected infection requires knowledge of specific risks inherent to the type and duration of immunodeficiency, diagnostic diligence, and tailored therapeutics designed to avoid rapid progression and poor outcomes.

REVIEW QUESTIONS

1. A patient who has an absolute neutrophil count below 500 cells/mm^3 for 2 weeks after induction therapy for acute myelogenous leukemia is at increased risk for

A. *E. coli* bacteremia from the gastrointestinal tract
B. Influenza infection involving the upper respiratory tract
C. Varicella-zoster virus reactivation
D. Cytomegalovirus disease involving the lungs
E. *Cryptococcus neoformans* meningoencephalitis

Answer: A These patients do not have increased risk for influenza involving the upper respiratory tract compared with the population in general but have increased risk for complications (such as pneumonitis). Answers C to E are correct only for people with advanced deficits in T-cell immunity.

2. Early antibiotic therapy would be appropriate before documenting a microbial diagnosis in

A. A neutropenic patient who has developed fever, with normal hemodynamics
B. A heart transplant patient who has a new left lower lobe consolidation, fever, and leukocytosis
C. A kidney transplant patient with pyuria, fever, and elevated creatinine concentration
D. None of the above
E. All of the above

Answer: E These all outline high-risk situations in which empirical antibiotic therapy would be appropriate before documentation of disease to avoid rapid progression with sepsis.

3. A man presents with diffuse papular skin lesions 20 days after receipt of bone marrow transplantation, with fever. He has been receiving fluconazole, moxifloxacin, and acyclovir prophylactically. The least likely cause of his skin lesions is

A. *Candida glabrata*
B. Sweet's syndrome
C. *Aspergillus fumigatus*
D. Herpes simplex virus
E. A vasculitic reaction to a drug

Answer: D Herpes simplex virus rarely disseminates to cause these types of skin lesions, especially in people receiving acyclovir.

4. People who have received tumor necrosis factor inhibitors as biologic therapy for an autoimmune disease have heightened risks for infections caused by which of the following?

A. Viruses
B. Bacteria
C. Fungi
D. All of the above
E. None of the above

Answer: D Tumor necrosis factor inhibition may alter immune responses to multiple arms of the immune system.

5. What is the most likely cause of neutropenic enterocolitis that developed after receipt of cytotoxic therapy for acute myelogenous leukemia?

A. Cytomegalovirus
B. *Clostridium difficile*
C. Norovirus
D. Mixed anaerobic and aerobic bacteria
E. Adenovirus

Answer: D These infections are typically caused by organisms that are "native" in the gastrointestinal tract during episodes of mucosal injury.

282 PREVENTION AND CONTROL OF HEALTH CARE–ASSOCIATED INFECTIONS

DAVID P. CALFEE

THE BURDEN OF HEALTH CARE–ASSOCIATED INFECTIONS

The Centers for Disease Control and Prevention (CDC) defines health care–associated infections (HAIs) as infections that patients acquire during the course of receiving health care treatment for other conditions. *Nosocomial infection* is a term that refers specifically to an HAI that develops in association with hospital care. The development of infection during the course of health care is not, however, limited to the acute care hospital setting. Thus, *health care–associated infection* is the preferred term in referring to the broader spectrum of infections that develop during the course of health care, wherever that care may be provided, including acute care hospitals, long-term care facilities, rehabilitation facilities, dialysis facilities, and even the patient's home during the receipt of home care services.

The most extensive data regarding the incidence of and outcomes associated with HAIs come from the acute care hospital setting. On the basis of data reported by U.S. hospitals to the CDC in 2002, it has been estimated that 1.7 million HAIs occur in U.S. hospital patients each year, with almost 99,000 associated deaths (Table 282-1). A point prevalence survey conducted in 2010 in 183 U.S. hospitals that the prevalence of HAI was 4%.[1] Previous European studies have estimated that 4.1 million HAIs occur in European acute care hospitals each year. Thus, approximately one of every 14 to 20 patients admitted to U.S. and European hospitals develops an HAI, making HAI one of the most common complications associated with the receipt of health care. Moreover, these data indicate that HAIs are one of the top 10 causes of death in the United States. Whereas many of these HAI-associated deaths occur among patients who are already severely ill and who have a high likelihood of death due to their underlying disease, a substantial proportion of HAI-related deaths occur among persons who were otherwise expected to survive their hospitalization. In a single-center study, 31% of unexpected in-hospital deaths were determined to be possibly or probably related to an HAI. In addition to an increased risk of death, patients who develop HAI suffer a number of other adverse outcomes, including prolonged hospital stays, additional medical interventions and antibiotic treatment, discomfort, and loss of function and income. It has been estimated that these HAIs cost U.S. hospitals between $28.4 billion and $45 billion each year.[2] These statistics are particularly concerning when they are considered with the knowledge that many of these infections are preventable. In fact, a systematic review found that 55 to 70% of four of the most common types of HAIs are preventable through the use of currently available, evidence-based preventive strategies (see Table 282-1).

Although the majority of HAI statistics come from acute care hospitals, there are data to demonstrate that HAIs are significant problems in other health care settings as well. Point prevalence surveys conducted in European and the U.S. Veterans Affairs system long-term care facilities found that the prevalence of HAI among long-term care facility residents ranged from 2.4 to 5.2%. The overall burden of HAI among long-term care facility residents has been estimated to be 1.64 to 3.83 million infections per year in the United States and at least 2.6 million infections per year in Europe. Vascular access–related infections are the most common HAIs among patients requiring

TABLE 282-1 ESTIMATES OF THE BURDEN, COSTS, AND PREVENTABILITY OF HEALTH CARE–ASSOCIATED INFECTIONS IN U.S. HOSPITALS

TYPE OF INFECTION	NUMBER OF INFECTIONS PER YEAR[a]	AVERAGE ATTRIBUTABLE COST* PER INFECTION[b]	NUMBER OF DEATHS (CASE-FATALITY RATE)[a]	PROPORTION PREVENTABLE[c]
Urinary tract infection	561,667	$749-$1007	13,088 (2.3%)	65-70%
Catheter-associated urinary tract infection	449,334			
Surgical site infection	290,485	$11,087-$34,670	8205 (2.8%)	55%
Pneumonia	250,205	$14,806-$28,508	35,967 (14.4%)	55%
Ventilator-associated pneumonia	52,543			
Blood stream infection	248,678	$6461-$29,156	30,665 (12.3%)	65-70%
Central line–associated blood stream infection	92,011			
Other	386,090	$5682-$9124	11,062 (2.9%)	
C. difficile infection	178,000

chronic hemodialysis for end-stage renal disease, with approximately 37,000 catheter-related blood stream infections occurring in U.S. end-stage renal disease patients each year. The magnitude of HAIs related to care provided in other settings, such as ambulatory surgery and endoscopy centers, has not been as thoroughly studied, but such infections have been well described.

Pathogenesis

HAIs can be caused by organisms that are a part of the patient's normal flora (i.e., endogenous infection) or by pathogens acquired during exposure to health care (i.e., exogenous infection) through the contaminated hands of health care workers, the environment, contaminated medical equipment, other patients, or visitors. A variety of factors can contribute to the development of an HAI, and in many cases, HAIs are multifactorial in nature. These factors can be related to the pathogen, the host, the specific health care interventions that a patient receives, the setting in which health care is received, and the methods by which these interventions are made. HAI prevention strategies focus on eliminating, reducing, or modifying one or more of these risk factors.

Pathogen-Related Factors

A variety of pathogen-related factors contribute to the ability of an organism to cause infection. These factors include the organism's normal reservoir, mode of transmission (e.g., direct or indirect contact transmission, respiratory droplets, airborne particles), ability to survive on inanimate objects and surfaces, ability to produce biofilm, virulence factors, and resistance to antimicrobial agents and, for some organisms (e.g., *Clostridium difficile*), disinfectants.

Host-Related Factors

Many host-specific factors are associated with an inherent increased risk of one or more types of infection, regardless of the receipt of health care; however, when a patient with one or more of these risk factors enters the health care system, these factors contribute to an increased risk of HAI. Such risk factors include age (with neonates and older adults having an increased risk of infection because of incomplete development or senescence of the immune system, respectively), obesity, smoking, severity of illness, and certain medical conditions (e.g., burns, end-stage liver or renal disease, poorly controlled diabetes, some cancers, congenital or acquired immune deficiency). These factors reflect suppression of the immune system or breaches of other normal host defense mechanisms. Whereas many of these factors are not amenable to intervention or cannot be effectively modified in the short term, interventions that address remediable risk factors (e.g., obesity, smoking, poorly controlled diabetes mellitus) have the potential to reduce the risk of HAI during future episodes of health care.

Health Care–Related Factors

Health care–related HAI risk factors are those resulting from interventions that are intended to treat or otherwise provide benefit for a patient's existing medical conditions but that also introduce an increase in the risk of infection. These factors may disrupt normal host defenses or alter the patient's normal microbiologic flora. Health care–related risk factors include the use of invasive devices (e.g., central venous catheters, urinary catheters, endotracheal tubes), surgical procedures, exposure to antibiotics, receipt of immunosuppressive medications, and prolonged hospitalization. Because each of these interventions poses at least some degree of increased risk of infection, the risk-to-benefit ratio of each intervention must frequently be reassessed so that patients are not exposed to unnecessary risk. For example, central venous catheters and indwelling urinary catheters are major risk factors for primary blood stream infection and urinary tract infection, respectively. In a patient who has a true medical need for one of these devices, the benefits of the catheter exceed the risk of infection. However, once the patient recovers from the condition that necessitated the catheter, the risks associated with the device then outweigh the benefits.

Exposure to antibiotics is a well-established risk factor for colonization and infection with multidrug-resistant organisms (MDROs) and development of *C. difficile* infection (CDI) through a mechanism known as antibiotic selection pressure. Antimicrobial use is common in acute care hospitals and other health care settings, such as long-term care and dialysis facilities and ambulatory care practices. A 2009 point prevalence survey of hospitals in 25 European countries found that 29% of hospitalized patients receive one or more antimicrobials during their hospital stay. Among 70 academic hospitals in the United States, 49.6 to 76% of hospitalized adults received at least one dose of an antibacterial drug, and mean total antimicrobial use was 839 days of therapy (range, 594 to 1109) per 1000 patient-days in 2009. Even more important, studies have shown that a large proportion of antimicrobial use is inappropriate. Inappropriate antimicrobial use includes administration of antimicrobial regimens that are broader in spectrum or longer in duration than necessary, use of antibiotics that do not provide activity against the causative pathogen, treatment for test results that do not reflect the presence of infection (e.g., specimen contamination, asymptomatic colonization), use of antibacterial agents for treatment of conditions that are not due to bacterial infection (e.g., viral respiratory tract infections), and prescription of inappropriate doses of an antibiotic. Other studies have found that approximately 30% of antimicrobial use in acute care hospitals is inappropriate. Similar proportions of inappropriate antimicrobial use have been reported among long-term care facility residents and chronic hemodialysis patients. Misuse and overuse of antimicrobial agents in the outpatient setting are also well-recognized problems in the United States and other countries, including many countries where antimicrobials can be obtained without a prescription. This inappropriate use of antimicrobial agents introduces unnecessary risk for the development of complications of antibiotic therapy, including CDI, MDRO infection, and toxicity, and represents an important target for intervention.

Health Care Delivery–Related Factors

This group of risk factors includes those that are introduced as a result of the way in which health care is delivered. These risk factors do not offer any potential benefit to patients but rather are associated only with risk. Health care delivery–associated risk factors include, among other things, failure to perform hand hygiene when indicated or to use aseptic or sterile technique during invasive procedures, unsafe injection practices (e.g., entering

TABLE 282-2 RATES OF ANTIMICROBIAL RESISTANCE AMONG PATHOGENIC ISOLATES FROM HEALTH CARE–ASSOCIATED INFECTIONS

ORGANISM	ANTIBIOTIC CLASS	PROPORTION OF ISOLATES RESISTANT TO ANTIBIOTIC		
		United States (2009-2010)[a]	*ICUs in 36 Developing Countries (2004-2009)*[b]	*ICUs in 13 European Countries (2007)*[c]
Staphylococcus aureus	Anti-staphylococcal penicillins (e.g., oxacillin, methicillin)	44-59%	71-84%	34.5%
Klebsiella species	Extended-spectrum cephalosporins	13-29%	72-76%	22%

a multidose vial with a used needle), and failure to adequately clean and disinfect or to sterilize the patient environment and medical equipment and instruments. These risks are all potentially modifiable and are thus important targets for HAI prevention initiatives. Antibiotic use, which has already been discussed as a patient-specific health care–related risk factor, can also be considered a health care delivery–related risk factor. Unlike with other types of drugs, use and misuse of antibiotics in one patient or population can introduce risks among the larger population through changes in microbial ecology (i.e., selection and increased prevalence of antimicrobial-resistant pathogens).

Many of these health care delivery–related factors are the result of poor adherence to recommended, evidence-based infection prevention practices. Despite recognition that poor hand hygiene practice is a leading cause of pathogen transmission, the existence of major national and international guidelines, and initiatives to improve hand hygiene practices among health care workers, compliance with recommended hand hygiene practices among health care personnel remains unacceptably low. In the United States, average rates of health care worker compliance with recommended hand hygiene practices have been reported to be less than 50%, with some individual studies reporting rates as low as 20% in some intensive care units (ICUs). Similarly, unsafe injection practices continue to be identified as the cause of health care–related transmission of blood-borne pathogens, such as hepatitis B and C viruses.

In recent years, there has been an increasing recognition of the role of environmental contamination in the transmission of health care–associated pathogens. Environmental contamination with these organisms is common, and many of these organisms can persist in the health care environment for prolonged periods. For example, environmental contamination with *C. difficile* has been detected in 100% of hospital rooms occupied by patients with CDI, whereas methicillin-resistant *Staphylococus aureus* (MRSA) has been detected on environmental surfaces in approximately 70% of hospital rooms housing patients infected and colonized with MRSA. Some but not all studies have identified similarly high rates of environmental contamination with multidrug-resistant gram-negative pathogens. This contamination can result in patient-to-patient transmission through transient contamination of health care workers' hands and equipment or by direct contact of the patient with the contaminated environment. Studies have shown that admission to a hospital room in which the prior occupant was colonized or infected with one of several MDROs is a significant risk factor for acquisition of that organism. Environmental contamination is, however, a potentially modifiable risk factor for HAI. Cleaning and disinfection of the environment and portable medical equipment that is shared among patients are often suboptimal. For example, one multicenter study conducted in 36 acute care hospitals in the United States found that at baseline, only 48% of high-risk environmental surfaces were cleaned during routine cleaning after discharge of the patient. Improvement in cleaning practices and other interventions to reduce the microbiologic burden in the health care environment has been shown to reduce the microbiologic burden of organisms in the environment and has been associated with a reduction in the risk of acquisition of MDROs and CDI. In addition to cleaning and disinfection of environmental surfaces and disinfection or sterilization of shared medical equipment, environmental infection control interventions are important for preventing patients from acquiring pathogens due to exposure to water (e.g., *Legionella* species) and air (e.g., environmental fungi) within the health care setting.

Pathogens in Health Care–Associated Infections

The organisms most commonly identified in device- and procedure-associated infections (i.e., central line–associated blood stream infection, catheter-associated urinary tract infection, ventilator-associated pneumonia, and surgical site infection) vary somewhat among the different types and sites of infection. Overall, eight pathogen groups accounted for more than 80% of pathogens identified in device- and procedure-related infections reported to the CDC through the National Healthcare Safety Network in 2009 and 2010.[3] These pathogen groups and the proportion of reported pathogens that they represented include *Staphylococcus aureus* (16%), *Enterococcus* species (14%), *Escherichia coli* (12%), coagulase-negative staphylococci (11%), *Candida* species (9%), *Klebsiella* species (8.0%), *Pseudomonas aeruginosa* (8%), and *Enterobacter* species (5%). Whereas many of these pathogens represent patients' endogenous flora, further discussion of several of the organisms that may be acquired during exposure to health care is warranted.

Multidrug-Resistant Organisms

An increasingly concerning problem is the emergence of acquired antimicrobial resistance among many of the bacterial pathogens that are common causes of HAIs (Table 282-2). MDROs represent a significant health threat because infections caused by many of these MDROs have been associated with worse outcomes than those caused by antimicrobial-susceptible strains of the same organism, including excess length of hospital stay, increased health care costs, and higher mortality, with mortality rates approaching 50% in some studies. Possible explanations for the observed increased rate of adverse outcomes associated with MDRO infections include the presence of more severe underlying disease, delays in initiating effective therapy, and the use of more toxic or less effective therapy for treatment of the infection. Regardless of their cause, the poor outcomes associated with MDRO infections highlight the critical need for effective preventive measures and development of new antibiotics with activity against these MDROs, particularly multidrug-resistant gram-negative bacilli (MDR-GNB).

Organisms can develop resistance to antimicrobial agents to which they were previously susceptible through a variety of mechanisms, including induction, genetic mutation, and acquisition of new genetic material (e.g., conjugation with cell-to-cell transfer of genetic material by plasmids or transposons). In the health care setting, however, patient-to-patient transmission of MDROs is more common than de novo development of resistance in a previously susceptible organism within the patient's existing flora. Identified risk factors for acquisition of MDROs include exposure to antibiotics, frequent or prolonged exposure to health care facilities (e.g., hospitals, nursing homes), poor infection control practices among health care workers,

environmental contamination with MDROs, and prevalence of MDROs among other patients within a health care facility.

Among the pathogens reported to the CDC between 2009 and 2010 as causes of device-associated infections and surgical site infections, approximately 20% had antimicrobial susceptibility profiles that met the CDC's definition of multidrug resistance (see Table 282-2). Of note, 62 to 83% of *Enterococcus faecium* isolates were vancomycin resistant (VRE), and 44 to 59% of *S. aureus* isolates were resistant to methicillin (MRSA). These multidrug-resistant gram-positive pathogens have been recognized as significant health care–associated pathogens for several decades. More recently, the emergence of multidrug resistance among several gram-negative pathogens has been identified as a growing global health threat among persons receiving health care. For example, 65% of *Acinetobacter baumannii* isolates reported to the CDC in 2009 and 2010 demonstrated acquired resistance to at least one drug in three or more antibiotic classes. Such multidrug resistance definitions were also met by 15% of *Klebsiella* isolates and 14% of *P. aeruginosa* isolates. Antimicrobial resistance is an important problem in many regions of the world. For example, International Nosocomial Infection Control Consortium data from 36 developing countries in Asia, Africa, Europe, and Latin America collected between 2004 and 2009 demonstrated methicillin resistance in 84% of *S. aureus* isolates and extended-spectrum cephalosporin resistance in 76.3% of *Klebsiella pneumoniae* isolates and 66.7% of *E. coli* isolates.[4] The lack of use of a standardized definition of multidrug resistance limits direct comparisons of resistance data from different populations. Standardized definitions for multidrug resistant, extensively drug resistant, and pandrug resistant have recently been proposed.[5] Adoption of these or other standardized definitions is needed to allow a more thorough understanding of the global burden of antimicrobial resistance among health care–associated pathogens.

One example of the emergence and rapid dissemination of MDR-GNB is carbapenem-resistant Enterobacteriaceae (CRE), particularly *K. pneumoniae* (Chapter 305). Carbapenem resistance among these organisms was rare in the United States before the year 2000, at which time less than 1% of *K. pneumoniae* isolates reported to the CDC demonstrated such resistance. By 2009-2010, 8 to 13% of *K. pneumoniae* isolates from hospital-associated infections were resistant to carbapenems. In the United States, carbapenem resistance among the Enterobacteriaceae is most commonly due to the production of *K. pneumoniae* carbapenemase (KPC), a class A serine β-lactamase enzyme that hydrolyzes all β-lactam antibiotics. The KPC enzyme, which was first described in 2001, is encoded by the bla_{KPC} gene carried on a transmissible plasmid that also carries additional genes that confer resistance to several other classes of antimicrobial agents. Thus, in addition to carbapenem resistance, these organisms demonstrate resistance to other β-lactam antibiotics and to several other classes of antibiotics. Other mechanisms of carbapenem resistance among the Enterobacteriaceae, including other carbapenemases such as New Delhi metallo-β-lactamase-1 (NDM-1), OXA, VIM, and IMP, contribute to the growing threat of CRE around the world.

Asymptomatic carriage of MDROs is relatively common among persons with health care exposures. In fact, patients with clinically apparent MDRO infections represent a relatively small proportion of the total burden of these pathogens. Reported rates of MRSA carriage have ranged from 4.6 to 13.6% among hospital patients, 2 to 22% among U.S. ambulatory dialysis patients, and 10 to 100% among residents of long-term care facilities. The prevalence of VRE carriage among hospital patients and ambulatory dialysis patients has been reported to range from 6.3 to 67% and 0 to 16%, respectively. It is more difficult to describe the prevalence of MDR-GNB carriage because of use of different definitions of multidrug resistance and the inclusion of multiple and different organisms (e.g., *P. aeruginosa*, *A. baumannii*, *K. pneumoniae*) among reported studies. Studies that have included a variety of MDR-GNB have reported carriage rates of 19 to 32% in ICU patients and hospital patients with diarrhea, 25% among residents of long-term care facilities, and 16% among chronic hemodialysis patients. Studies that have focused specifically on carbapenem-resistant Enterobacteriaceae have demonstrated prevalence rates ranging from 2 to 5.4% among high-risk hospital patients in the United States and 2 to 49% among post–acute care facility patients in Israel. These asymptomatic carriers play an important role in the epidemiology of MDRO infections. First, they are at substantial risk of subsequent infection with the colonizing organism, with up to one third of carriers of MRSA, VRE, and MDR-GNB developing symptomatic infection within 12 months. Second, asymptomatic MDRO carriers can contribute to MDRO transmission within the health care system through contamination of their surrounding environment and of health care workers' hands, clothing, and medical equipment. In fact, several studies have demonstrated that the risk of acquiring an MDRO, such as MRSA, VRE, and MDR-GNB, during hospitalization is related to the prevalence, or colonization pressure, of that MDRO among other patients. Finally, admission to a hospital room in which the prior patient was colonized or infected with the MRSA, VRE, or MDR-GNB has been associated with an increased risk of acquisition of those organisms.

There are, however, some encouraging data related to the incidence of some MDROs, particularly MRSA. In the United States, the incidence of hospital-onset invasive MRSA infections decreased 9.4% per year between 2005 and 2008.[6] During a similar period (2005 to 2011), the incidence of invasive MRSA infections among dialysis patients, a group with a rate of invasive MRSA infection that is approximately 100 times greater than that of the general population, was also observed to have significantly decreased in the United States, with annual decreases of 6.7% for health care–associated community-onset cases and 10.5% for hospital-onset cases.[7] These changes occurred despite the emergence of community-associated MRSA as a significant cause of skin and soft tissue infections among persons without typical health care–associated risk factors and the introduction of community-associated MRSA as a health care–acquired pathogen. In England, a 56% reduction in the number of cases of MRSA bacteremia reported through a mandatory reporting system was observed between 2004 and 2008. The specific cause of these observed decreases in MRSA HAIs is uncertain and may be the result of improvements in basic infection control practices, introduction of specific MRSA prevention practices, or other changes in the epidemiology of this pathogen.

Clostridium Difficile

C. difficile, the etiologic agent of pseudomembranous colitis, is the most common cause of health care–associated infectious diarrhea (Chapter 296). Although community-associated CDI occurs, most cases are associated with receipt of health care. Analysis of CDC data from 2010 found that 94% of cases of CDI were associated with health care exposure but that 75% of cases had their onset outside of the hospital (e.g., in the community or in long-term care facilities). Clinical manifestations of CDI range from asymptomatic carriage to mild diarrhea to life-threatening colitis, toxic megacolon, and sepsis. The overall mortality associated with CDI has been reported to range from 2 to 6%, with substantially higher mortality among patients who develop toxic megacolon and other severe manifestations of the disease. Compared with patients without CDI, hospital patients who develop CDI experience an extended duration of hospitalization of 2.8 to 6.4 days, and approximately 15 to 30% of these patients will experience at least one recurrence of the disease, typically within 1 to 2 months of the initial episode. Persons who experience one recurrence have a 50 to 60% chance of additional recurrences. U.S. data from 2009 indicate that 4.8% and 12.8% of hospital patients with CDI are readmitted to the hospital with a principal diagnosis or any diagnosis of CDI, respectively, within 30 days and that by 90 days, rates of hospital readmission increase to 6.8% and 17.2%, respectively. Estimates of CDI-attributable hospital costs range from $5682 to $9124 per case (in 2007 U.S. dollars), amounting to a total cost of $1 billion to $4.8 billion per year.

C. difficile has become one of the most common health care–associated pathogens, and several studies have suggested that more HAIs are now due to *C. difficile* than to MRSA. The incidence of CDI among hospitalized patients in the United States more than doubled between 2000 and 2009. Reported rates of hospital-onset CDI in the United States and Europe are 7.4 and 4.1 per 10,000 patient-days, respectively. In addition to an increased incidence of CDI, the rate of *C. difficile*–related death increased more than four-fold in the United States during the past decade, causing approximately 14,000 deaths per year. The observed increases in the incidence of and mortality associated with CDI were temporally associated with the emergence and dissemination of the 027/NAP1/BI strain of *C. difficile*, which has been associated with greater mortality and higher rates of recurrence than other circulating strains. Initially identified in North America, this epidemic strain has now disseminated globally. Data from England show a 50% reduction in CDI between the fourth quarter of 2009 and the first quarter of 2013 after the introduction of a national CDI surveillance and prevention program. In the United States, however, *C. difficile* remains a challenge, and reductions like those reported in the United Kingdom have not been observed. In fact, between 2008 and 2012, *C. difficile* hospitalizations increased by 11.2%, and from 2010 to 2012, the incidence of hospital-onset CDI increased by 28%.

The problem of *C. difficile* extends beyond the acute care hospital setting. For instance, data from Ohio indicate that 62% of CDI cases in 2006 occurred in nursing homes. Another study conducted in Montgomery County, New York, found that 52% of cases of CDI in long-term care facility residents developed within 4 weeks of discharge from an acute care hospitalization.[8] Data from the CDC's Emerging Infections Program showed that 20% of

hospital-onset CDI occurred among persons with recent (i.e., <12 weeks) residence in a nursing home and that 67% of nursing home–onset CDI cases occurred among residents who had been recently discharged from an acute care hospital. These latter findings demonstrate the complex epidemiology of CDI.

The development of CDI is a two-step process that first requires acquisition of *C. difficile* through fecal-oral transmission and then the presence or introduction of factors that allow progression to symptomatic disease. Although some healthy individuals without health care exposure are intestinal carriers of *C. difficile*, acquisition of the organism during contact with the health care system plays a critical role in the epidemiology of CDI. Transmission in the health care setting can occur as the result of exposure to organisms on health care workers' hands, environmental surfaces, or medical equipment. Hand contamination of health care workers is common after contact with the skin or environment of persons with CDI. For example, a prospective study of 30 CDI patients found that hand contamination occurred in 50% of health care workers after contact with patients' skin and in 50% of health care workers after contact with the patient's immediate environment, particularly the bed rails.[9] In the absence of effective hand hygiene practices, contaminated health care workers may transmit the organism to other patients. Contamination of the environment and medical equipment with *C. difficile* is also common. Testing performed in hospital rooms has identified *C. difficile* on environmental surfaces in up to 100% of rooms housing patients with active CDI and in as many as 33% of non-CDI patient rooms. Commonly contaminated surfaces include bed rails, bedside tables, telephones, call buttons, and blood pressure cuffs. *C. difficile* spores are resistant to killing by many common hospital disinfectants and can persist in the environment for long times, further contributing to the risk of exposure to a contaminated environment. Patients who are admitted to a hospital room in which the previous occupant had CDI have been found to be at greater risk for development of CDI than patients admitted to hospital rooms in which the previous occupant did not have CDI. The risk for development of CDI has also been demonstrated to be directly related to the prevalence, or colonization pressure, of *C. difficile* among other patients in a health care facility. This likely reflects an increased risk of exposure to the organism through contaminated hands of health care workers, environment, or medical equipment as the number of persons with CDI increases.

Once *C. difficile* has been ingested, several factors are known to be associated with development of symptomatic CDI. The major risk factor is receipt of antibiotics. Such exposures disrupt the normal intestinal flora and allow *C. difficile* to multiply to larger numbers and to produce toxins that result in disease. Although exposure to any antimicrobial agent may increase the risk for development of CDI, clindamycin, third-generation cephalosporins, penicillins, and fluoroquinolones may present the highest risk. Other factors that have been associated with an increased risk for development of CDI include receipt of cytotoxic chemotherapeutic agents and gastric acid suppressive medications such as proton pump inhibitors, failure to develop an antibody response to *C. difficile*, and older age (i.e., age older than 64 years).

Viruses

Respiratory Viruses

Common respiratory viruses, such as influenza, can be transmitted in the health care setting by health care workers, visitors, and patients, resulting in health care–acquired disease. Higher rates of morbidity and mortality have been observed among those who acquire infection during hospitalization, probably due to the presence of significant underlying medical illness. Despite several studies that have associated higher influenza immunization rates of health care workers with lower rates of nosocomial influenza transmission, the uptake of influenza vaccination among health care workers remains relatively low. This has led many public health agencies and professional societies to call for mandatory influenza vaccination policies for all eligible health care workers. The health care–associated transmission of newly emerged respiratory viruses, such as the severe acute respiratory syndrome coronavirus (SARS-CoV) in 2003, pandemic influenza in 2009, and the Middle East respiratory syndrome coronavirus (MERS-CoV) in 2013, highlights the importance of syndromic surveillance to allow rapid identification of patients with potentially communicable diseases and implementation of appropriate infection control precautions.

Blood-borne Viruses

Although routine screening of the blood supply for the blood-borne pathogens (BBPs) hepatitis B virus, hepatitis C virus, and human immunodeficiency virus has dramatically decreased the incidence of health care–associated BBP infections, transmission of these pathogens within health care settings continues to occur. Most health care–associated BBP transmission that occurs now is due to failure to adhere to recommended basic infection control practices. Unsafe injection practices (e.g., reuse of syringes, contamination of multidose vials, improper use and disinfection of blood glucose monitoring devices that are used for multiple patients) and inadequate cleaning, disinfection, and sterilization of medical equipment and the health care environment (e.g., dialysis facilities) have been identified in several recent outbreaks of patient-to-patient transmission of BBPs. Between 2001 and 2011, an estimated 130,198 patients from 17 U.S. states were notified of possible health care–associated exposures to BBPs as the result of 35 reported unsafe injection practice events.[10] A large proportion of documented health care–associated hepatitis B virus and hepatitis C virus transmission events has occurred in outpatient settings and long-term care facilities, highlighting the importance of infection prevention programs throughout the entire health care system. Transmission of BBPs from health care worker to patient is uncommon but can occur, typically in the setting of "exposure-prone" invasive procedures. Guidelines are available to assist health care workers and health care facilities in minimizing the risk posed to patients by a BBP-infected health care worker while allowing most such health care workers to remain involved in patient care activities (E-Table 282-1).

Fungi

Candida albicans and other *Candida* species accounted for approximately 9.5% of all pathogens reported to the CDC between 2009 and 2010 as causes of device-associated infections and surgical site infections, placing them among the most common pathogens implicated in HAIs. *Candida* species were particularly common causes of catheter-associated urinary tract infection and catheter-associated blood stream infection, accounting for 12.7% and 14.6% of pathogens reported among these types of infection, respectively. Exposure to environmental fungi, such as *Aspergillus* species, in the health care setting can result in HAI, particularly in immunocompromised hosts. Such exposure and resulting infection are most commonly associated with inadequate environmental control measures during construction, demolition, or water damage within the health care facility. A recent multistate outbreak of invasive fungal infections in the United States, mostly due to *Exserohilum rostratum*, associated with contaminated methylprednisolone injections demonstrates that contaminated medications and other medical products are additional potential sources of exposure to fungal pathogens during health care.

Device-Associated Infections

Central Line–Associated Blood Stream Infections

Central line–associated blood stream infections (CLABSIs) are blood stream infections that occur in patients with a central venous catheter and in whom there is no other identified source of the infection. Development of CLABSI has been associated with longer hospital stays, increased risk of death, and greater hospital costs than those observed among otherwise similar patients who do not develop CLABSI (see Table 282-1). Rates of morbidity and mortality, however, vary substantially, depending on the causative pathogen and characteristics of the patient in whom the infection occurs. The CLABSI definition was developed for epidemiologic surveillance purposes rather than for medical decision making for individual patients. It differs in definition from that of a catheter-related blood stream infection, a term that may be used for research or clinical purposes, in which more specific testing, such as catheter segment cultures, quantitative blood cultures, or differential time to positivity of paired blood cultures, is done to definitively determine that the catheter is the true source of a blood stream infection. Although CLABSIs are often thought of as a complication that occurs among ICU patients, the use of central venous catheters in non-ICU hospital wards has expanded substantially during the past few decades. Thus, the incidence of and the overall burden of CLABSI in some non-ICU wards now often exceeds that in ICUs. CLABSIs are also important problems among nonhospitalized persons with central venous catheters, such as persons receiving chronic total parenteral nutrition, chemotherapy, or dialysis in the outpatient or home care setting. In 2008, for example, approximately 37,000 CLABSIs occurred among outpatient hemodialysis patients in the United States.

Blood stream infections due to central venous catheters are largely the result of contamination or colonization of the external surface or the intraluminal surface of the catheter. This contamination can occur either during catheter insertion or after insertion, related to a number of aspects of catheter use and care. Research has identified a number of effective strategies to reduce the risk of catheter contamination during insertion and throughout the time that the catheter remains in situ. This research has led to the development

of evidence-based guidelines for prevention of vascular catheter–related infections (see E-Table 282-1). A review of the scientific literature concluded that 65 to 70% of CLABSIs are preventable with the use of currently available strategies and technologies.[11] The "central line bundle" refers to a small number of evidence-based practices that, when used together, can reduce the risk of CLABSI even more than would be expected when the components are introduced individually. The central line bundle includes hand hygiene, maximal barrier precautions during insertion (i.e., use of sterile gown and gloves and a surgical cap and mask by the operator and covering the patient with a sterile, full-body drape), chlorhexidine skin antisepsis, optimal insertion site selection (i.e., avoidance of the femoral site in adult patients), and daily review of catheter necessity with immediate removal of catheters that are no longer necessary. Other interventions that have been associated with reductions in CLABSI rates include the use of antimicrobial or antiseptic catheters, covering of the insertion site with a sterile gauze or semipermeable transparent dressing, cleansing of the catheter insertion site with an antiseptic such as chlorhexidine, use of aseptic technique to access and to manipulate the catheter, scrubbing of the catheter hub with a disinfectant before accessing the catheter lumen for administration of medications or other products or for aspiration of blood, use of antimicrobial- or antiseptic-coated catheters, and use of chlorhexidine rather than regular soap and water for daily bathing of ICU patients.

Widespread adoption of the central line bundle and other CLABSI prevention strategies has been associated with a substantial reduction in the incidence of CLABSI in U.S. hospitals. Data from the CDC demonstrate a 58% decrease in the incidence of CLABSI in ICUs between 2001 and 2009. More recent data from the CDC's National Healthcare Safety Network show a further 41% reduction in CLABSI in U.S. acute care hospitals between 2008 and 2011, with reductions noted in both ICU and non-ICU settings. In these most recent data, the incidence of CLABSI ranged from 0.9 to 3.7 per 1000 catheter-days in ICUs. The highest rate was observed in burn units.[12] Most other types of ICUs had rates ranging from 1.0 to 1.6 per 1000 catheter-days. In non-ICU wards, the highest CLABSI rates were reported from hematopoietic stem cell units and hematology-oncology wards.

Catheter-Associated Urinary Tract Infections

A catheter-associated urinary tract infection (CAUTI) is a urinary tract infection that develops in a patient who has or who recently had an indwelling urinary catheter. Similar to the pathogenesis of catheter-related blood stream infections, CAUTIs develop by the introduction of pathogens into the bladder as a result of contamination and colonization of the internal or external surface of the catheter. Among patients with indwelling urinary catheters, the incidence of bacteriuria is 3 to 8% per day, and 10 to 25% of those with bacteriuria will subsequently develop symptoms consistent with a urinary tract infection. Compared with the mortality and costs associated with many other HAIs, those associated with individual CAUTI events are substantially lower (see Table 282-1). CAUTI, however, occurs 5 to 10 times more frequently than CLABSI and ventilator-associated pneumonia, and thus the total burden of suffering and expense due to CAUTI is substantial. It has been estimated that 65 to 70% of CAUTIs that occur in acute care hospitals are preventable. Data reported to the CDC's National Healthcare Safety Network in 2011 show that the mean incidence of CAUTI in U.S. ICUs ranged from 1.2 to 4.5 per 1000 catheter-days, with substantial variation between different types of ICUs. In non-ICU inpatient wards, the mean rate ranged from 0.2 to 3.2, with the highest rates being observed on rehabilitation units. These data demonstrate a small but statistically significant 7% reduction in CAUTI between 2009 and 2011. The large reductions observed among many published studies of CAUTI prevention initiatives compared with the relatively small overall reduction observed in U.S. hospitals suggest that substantial opportunities remain for additional CAUTI prevention.

A number of basic practices, such as aseptic technique during insertion, maintenance of proper cleanliness and hygiene, securement of the catheter to avoid piston-like movement of the catheter within the urethra, and maintenance of a closed system with unobstructed flow of urine from the bladder into the collection system, are recommended to reduce the risk of CAUTI. Several studies have demonstrated that indwelling urethral catheters are often inserted for inappropriate reasons and that many catheters that were initially inserted for an appropriate indication remain in place even after the initial indication for catheterization has resolved. This may be due in part to lack of familiarity with appropriate indications for catheter insertion or with options that exist regarding alternatives to the use of indwelling urethral catheters. Additional studies have found that physicians are often unaware that their patient has a urinary catheter. Thus, perhaps the greatest opportunity for CAUTI prevention is avoidance of unnecessary catheter insertion and prompt removal of catheters that are no longer necessary. Development of protocols that explicitly define appropriate indications for insertion of urinary catheters, introduction of interventions that remind clinicians to reassess the appropriateness of a patient's urinary catheter, and nurse-driven protocols that allow nurses to remove unnecessary urinary catheters have been associated with reduced catheter use and lower rates of CAUTI.

Ventilator-Associated Pneumonia

In hospitalized patients, mechanical ventilation is one of the most common risk factors for the development of pneumonia. Mechanical ventilation and the interventions required to provide mechanical ventilation (e.g., endotracheal intubation, sedation) increase the risk of pulmonary infection through a variety of mechanisms, including an increased risk of aspiration of oropharyngeal and gastrointestinal secretions and impairment of the cough reflex. From both a clinical and epidemiologic standpoint, ventilator-associated pneumonia (VAP) is a difficult diagnosis to establish with certainty because of the subjective nature of many of the variables considered (e.g., chest radiograph findings, changes in the characteristics of respiratory tract secretions), alternative explanations for clinical and radiographic abnormalities (e.g., acute respiratory distress syndrome, atelectasis), and difficulty in determining whether the results of respiratory tract cultures represent true infection or colonization of the airway.

In 2011, the incidence of VAP in U.S. hospital ICUs ranged from 0.2 to 3.2 per 1000 ventilator-days, with the highest rates observed in trauma and burn units.[12] These infections are associated with mortality rates and health care costs that are among the highest observed among all HAIs (see Table 282-1). Studies suggest that at least 55% of VAP cases are preventable. As with other device-associated infections, avoiding the use of the device is the most effective means of preventing infection. For preventing VAP and other complications of mechanical ventilation, the use of noninvasive methods of ventilation, daily sedation interruption and assessment of readiness to be weaned, and early mobilization can eliminate or at least reduce the duration of mechanical ventilation. For patients who do require mechanical ventilation, the following are routinely recommended for VAP prevention: proper cleaning, disinfection, sterilization, use, and maintenance of respiratory equipment; elevation of the head of the bed (unless it is medically contraindicated); and routine oral hygiene care, typically with an antiseptic such as chlorhexidine. In some randomized, controlled trials, selective oropharyngeal or digestive decontamination has been associated with a significant reduction in VAP, but this approach has not yet been widely adopted as a standard of care in the United States, at least in part because of concerns that this intervention may lead to selection of antimicrobial-resistant organisms.

Other Device-Related Infections

With the advances that have occurred in medical technology in recent years, there have been substantial improvements in the capabilities of existing medical devices and the development of new implantable devices to treat and to manage a variety of medical conditions, particularly of the cardiovascular and nervous systems. These devices include cardiovascular implantable electronic devices such as pacemakers and implantable cardioverter-defibrillators, ventricular assist devices, deep brain stimulators, and intrathecal pumps. The potential benefits that these devices may offer to patients come with at least some degree of risk of device-related infection.

Surgical Site Infections

Surgical site infections (SSIs) are infections that develop at the site of an operative procedure. Although only a relatively small proportion of patients who undergo surgery subsequently develop SSI and the overall mortality rate associated with SSI is relatively low, the absolute number of SSIs that occur and the overall cost and burden of morbidity and mortality associated with SSI are large because of the volume of surgical procedures performed each year (see Table 282-1). A number of factors contribute to the risk of SSI: the specific site and type of surgical procedure; duration of the procedure; tissue hypoxia at the surgical site; wound contamination with endogenous or exogenous organisms; surgical technique; perioperative infection prevention practices; environmental controls related to temperature, humidity, and air purity within the operating room; and the patient's underlying medical conditions, smoking status, and other factors that may increase the inherent risk of infection. Although some of these factors are not amenable to corrective intervention, many of them are, and a number of interventions have been proved to reduce the risk of SSI. In fact, through routine application of evidence-based

preventive measures, it has been estimated that 55% of SSIs could be prevented. The use of sterile technique, preoperative skin preparation with an antiseptic agent, administration of antimicrobial prophylaxis within 60 minutes before the surgical incision, and perioperative glucose control are practices that have been demonstrated to reduce the risk of infection associated with a wide variety of surgical procedures. There is also evidence that at least in some types of surgeries, maintenance of normothermia and the use of supplemental oxygen (e.g., 80% fraction of inspired oxygen) in the perioperative period may reduce the risk of SSI. Although substantial opportunities for improvement remain, a report from the CDC's National Healthcare Safety Network that compares SSI data from 2008 and 2011 shows during that 4-year period a statistically significant 17% reduction in the incidence of SSI occurring in association with several common surgical procedures.[13]

HEALTH CARE–ASSOCIATED INFECTION PREVENTION STRATEGIES

As noted in the preceding paragraphs, many HAIs are preventable. This has been recognized since at least as early as the mid-1800s, when Semmelweiss demonstrated a dramatic reduction in sepsis-related deaths among maternity ward patients after an intervention to improve hand hygiene among health care workers. The degree to which HAIs are preventable was more clearly quantified in a multicenter study conducted in the 1970s. In that study, it was found that 32% of HAIs could be prevented through establishment of an effective infection control program. More recent estimates that take into account newer research and the technology that has been developed during the following three decades suggest that at least 55 to 70% of some of the most common HAIs can be prevented. Scientific research and clinical experience have led to the publication of evidence-based guidelines for the prevention of HAIs (see E-Table 282-1).[14]

Strategies to prevent HAI are designed to interrupt one or more of the factors associated with pathogen transmission or the development of infection due to endogenous or exogenous organisms. HAI prevention strategies are sometimes described by one of two categorization schemes that classify the intervention on the basis of either the applicability of the intervention for the prevention of a variety of HAIs or the priority an intervention should be given with regard to the overall HAI prevention program within a health care facility. The first categorization scheme classifies interventions as either "horizontal" or "vertical" infection prevention strategies. Horizontal prevention strategies are those that have the potential to prevent a wide variety of HAIs or to prevent transmission of a variety of pathogens. Vertical strategies, on the other hand, are those that target a specific pathogen. Examples of horizontal prevention strategies include hand hygiene, education of health care workers, environmental cleaning and disinfection, antimicrobial stewardship, and use of aseptic technique for invasive procedures. Vertical or pathogen-specific prevention strategies include the use of transmission-based precautions that are applied to patients known or suspected to be colonized or infected with a specific pathogen to prevent transmission of that pathogen. Preventing its transmission could involve interrupting its normal routes of transmission (e.g., contact, droplet, airborne), active surveillance testing for the pathogen (e.g., MRSA) to detect asymptomatic carriers who may serve as unrecognized reservoirs for its transmission, targeted decolonization therapy for persons identified as carriers of the pathogen of interest (e.g., MRSA), and vaccination programs (e.g., health care worker influenza vaccination campaigns).

The second categorization scheme classifies interventions as either basic or advanced (or special) preventive practices. Basic practices are those that should routinely be implemented in all health care facilities. Basic practices for acute care hospitals include most of the horizontal approaches described before as well as a few vertical approaches, such as transmission-based precautions. Special or advanced interventions are additional interventions that a facility may implement when basic practices fail to adequately control or prevent HAIs or transmission of one or more specific pathogens within the facility. This approach is consistent with recommendations and guidelines from the CDC and several professional societies that promote a tiered approach to the implementation of various HAI prevention strategies (see E-Table 282-1). The selection of specific strategies to be implemented within a specific health care facility should be based on an assessment of risk, local data and epidemiology, scientific evidence and guidelines, regulatory and accreditation requirements, and facility-specific cost-benefit calculations. Many of the prevention strategies that have been proven effective for prevention of device-associated infections and SSIs have already been discussed. Several additional preventive strategies are discussed in more detail here.

Antimicrobial Stewardship

Antimicrobial stewardship refers to interventions designed to improve the appropriateness of antimicrobial use by promoting the selection of an optimal antimicrobial regimen (i.e., the most appropriate drug, dose, duration, and route of administration) for a specific patient. The goals of an antimicrobial stewardship program are to optimize clinical outcomes (e.g., cure of infection related to antimicrobial use, minimize toxicity and other adverse events) and to limit the antimicrobial selection pressure that drives the emergence of antimicrobial-resistant strains. Multidisciplinary antimicrobial stewardship programs have been associated with several desirable outcomes, including significant reductions in antimicrobial use, reduced rates of antimicrobial resistance among health care–associated pathogens, reduced incidence of adverse outcomes associated with antibiotic use (e.g., toxicity, *C. difficile* infection), and significant reductions in hospital antimicrobial-associated costs. Thus, antimicrobial stewardship can be considered a horizontal infection prevention strategy.

A variety of approaches have been used by successful antimicrobial stewardship programs, and guidelines describing these strategies have been published (see E-Table 282-1). One of the most commonly used and most effective strategies includes formulary restriction and requirement of preauthorization before prescribing of certain antibiotics (e.g., antibiotics that are broad in their antimicrobial spectrum, are associated with significant toxicity, or are expensive). A second approach that has been considered to be a core strategy for antimicrobial stewardship activities is prospective audit of the appropriateness of prescribed antimicrobial therapy with provision of feedback to the prescribing clinician if opportunities for further optimization of therapy are available (e.g., narrowing or broadening spectrum of therapy, discontinuing antimicrobial therapy, or altering drug dose or dosing interval on the basis of available clinical data). Additional approaches that have been included in successful antimicrobial stewardship programs include education, development of guidelines and clinical pathways, computer-assisted decision support, and protocols to optimize conversion from the parenteral to the oral route of administration when appropriate.

Despite a substantial amount of data indicating that antimicrobial stewardship activities are an effective means of reducing inappropriate antimicrobial use and the clinical and financial consequences of excessive antimicrobial use, many acute care hospitals do not yet have formal antimicrobial stewardship programs in place, and many of those that do are not adequately resourced to reach their full potential. In addition to the standard challenges associated with implementation of interventions that require a change in human behavior and clinical practice, antimicrobial stewardship programs must also address the complex and constantly changing problems and issues associated with antimicrobial resistance. Antimicrobial stewardship programs are most commonly found in academic hospitals and large community hospitals, but there is a recognized need for development of such programs in smaller community hospitals, long-term care facilities, dialysis facilities, and outpatient practices.

Decolonization Therapy

Decolonization refers to the administration or application of antimicrobial or antiseptic agents to a person to eliminate or to reduce the burden of carriage of one or more pathogens. Perhaps most commonly recognized as a vertical measure that has been used in some MRSA control programs, decolonization therapy has also been used as a horizontal preventive measure. For example, selective oropharyngeal or digestive decontamination has been used for prevention of VAP and SSI after colorectal surgery. More recently, topical decolonization has been studied as a horizontal intervention for prevention of a variety of HAIs and prevention of transmission of a variety of pathogens. Several quasi-experimental, before-after studies have associated the use of chlorhexidine, compared with nonantimicrobial soap, for daily bathing of patients with significant reductions in rates of blood stream infections, including CLABSI, acquisition of MDROs, blood culture contamination, and contamination of the environment and health care workers. Thus far, two higher quality studies of daily chlorhexidine bathing have been completed and published. A multicenter, cluster-randomized trial conducted in eight adult ICUs and one bone marrow transplant unit in the United States found that daily bathing with chlorhexidine, compared with nonmedicated soap, was associated with a 23% reduction in the combined outcome of MRSA and VRE acquisition. A similar study in pediatric ICUs showed a significant reduction in the incidence of bacteremia in the per-protocol analysis, although the difference observed in the intention-to-treat analysis did not

reach statistical significance.[A1] A third cluster-randomized trial conducted in 74 adult ICUs in the United States found that providing all ICU patients with decolonization therapy that consisted of intranasal application of mupirocin for 5 days and daily chlorhexidine bathing significantly reduced the MRSA-positive clinical cultures attributable to the ICU by 37% and was associated with a lower incidence of all-cause blood stream infections compared with the use of active surveillance and contact precautions for MRSA-colonized patients without decolonization therapy.[A2] Selective decontamination of the digestive tract reduces ICU-acquired bacteremia even more than does selective oropharyngeal decontamination, but it also increases carriage of aminoglycoside-resistant gram-negative bacteria.[A4] Most of the data supporting the use of universal decolonization come from studies conducted in ICUs, and the role of this intervention in preventing infection and pathogen transmission in other settings is not well established.

Active Surveillance Testing

Active surveillance testing is a vertical intervention that identifies asymptomatic carriers of a pathogen of interest (e.g., MRSA, VRE, MDR-GNB) with the intention to introduce additional interventions for identified carriers to prevent infection in the carrier or transmission to others. The interventions that may be applied to the identified carriers include transmission-based precautions (e.g., contact precautions), decolonization therapy (mostly applicable to *S. aureus*), and altered antimicrobial therapy (e.g., surgical antimicrobial prophylaxis). The role of active surveillance has long been the subject of debate and investigation. It is commonly used in outbreak control efforts in conjunction with other interventions. In the non-outbreak setting, there are numerous reports of use of active surveillance as part of a comprehensive program to reduce transmission of or infection with MDROs in individual hospitals, large hospital systems, and health care facilities within specific geographic regions, such as a number of northern European countries. A cluster-randomized trial conducted in U.S. ICUs found that there was not a significant difference in the incidence of colonization or infection with MRSA and VRE in ICUs that performed active surveillance testing with introduction of contact precautions for patients found to be carriers of MRSA or VRE compared with ICUs that did not conduct active surveillance testing.[A3] However, there was a delay in reporting the results of surveillance testing that was longer than would be anticipated in normal clinical practice, which may limit the ability to generalize the study findings to all settings. A comparative effectiveness review of MRSA screening strategies concluded that the strength of evidence for universal screening to prevent MRSA HAIs was low and that there was insufficient evidence to assess other outcomes associated with universal screening or to assess the comparative effectiveness of other MRSA screening strategies (e.g., targeted screening).[15]

As previously mentioned in the discussion of decolonization therapy, a more recently published cluster-randomized trial found that providing universal decolonization to all ICU patients without the use of active surveillance testing was associated with a significantly greater reduction in MRSA clinical cultures attributable to the ICU than was active surveillance testing with isolation of MRSA-positive patients. Although data from these recent, cluster-randomized trials of active surveillance testing and the emergence of data supporting the use of horizontal measures such as universal decolonization therapy have contributed substantial new data regarding the control of multidrug-resistant gram-positive pathogens (e.g., MRSA and VRE) in the ICU in non-outbreak situations, additional study of these interventions in other settings and for other pathogens, such as MDR-GNB, is needed.

Interfacility and Regional Collaboration

Given the frequency with which patients are shared among hospitals and other health care settings within geographic regions and the evidence of interfacility patient transfer as a risk factor of introduction of MDROs and *C. difficile* into a health care facility, implementation of comprehensive prevention programs in all facilities within a region may be more effective in preventing HAIs and MDRO transmission than implementation of the same interventions in a single health care institution. The establishment of regional infection prevention initiatives offers several potential benefits, including the ability to more effectively address the complex epidemiology of HAIs that involve multiple health care facilities (e.g., MDRO acquisition, transmission, and infection) than single-institution interventions and opportunities for collaboration and sharing of information, experiences, and resources. A number of successful regional and national initiatives for the prevention of HAI, including CLABSI, dialysis-related blood stream infections, MRSA, VRE, CRE, and *C. difficile*, have been described.

GOALS AND INCENTIVES FOR HEALTH CARE–ASSOCIATED INFECTION PREVENTION

In addition to the obvious altruistic incentive of preventing harm to the patient, there are a number of additional incentives for health care providers and health care facilities to prevent HAIs. In the United States, the amount of attention given to HAIs and their prevention has greatly increased since the 1999 release of the Institute of Medicine report *To Err Is Human: Building a Safer Health System*. With this attention has come increasing pressure from the public, regulatory and accreditation agencies, and health care payers for the health care industry to improve its efforts and outcomes related to HAI prevention. Hospital accreditation agencies such as the Joint Commission have established standards for infection prevention programs and periodically survey hospitals to determine if such programs are in place. Similarly, the Centers for Medicare and Medicaid Services (CMS) Conditions of Participation list specific requirements for infection prevention and control processes in health care facilities that receive funding from CMS. Hospitals found to be deficient in the implementation of the requirements are at risk of losing the funding that they receive from the agency.

During the past decade, several legislative acts in the United States, such as the Medicare Prescription Drug, Improvement, and Modernization Act of 2003, the Deficit Reduction Act of 2005, and the Patient Protection and Affordable Care Act of 2010, have included requirements related to HAI reporting and accountability. In an effort to address the important public health and patient safety issue of HAIs, the U.S. Department of Health and Human Services developed the National Action Plan to Prevent Healthcare-Associated Infections. Among other things, the Action Plan sets specific goals and targets for improvement during a 5-year period. Introduced in 2009, phase I identified nine national targets for HAI prevention in U.S. acute care hospitals. These nine targets addressed five specific HAIs and health care–associated pathogens, including CLABSI, CAUTI, SSI, MRSA, and *C. difficile*. Phase II of the Action Plan added targets for end-stage renal disease facilities, ambulatory surgery centers, and health care worker influenza vaccination. Phase III introduced targets for long-term care facilities.

In recent years, CMS has introduced several initiatives that provide new incentives for hospitals to demonstrate success in HAI prevention. One of these incentives is the hospital-acquired condition (HAC) program. HACs are conditions that are determined to be high cost or high volume, which result in higher hospital payment by CMS, and that are deemed to be reasonably preventable with application of evidence-based guidelines. In the HAC program, administrative data (i.e., *International Classification of Diseases, Ninth Revision* diagnosis codes assigned at the time of hospital discharge) are used to identify HACs, and as of October 2008, hospitals participating in the CMS Inpatient Prospective Payment System no longer receive additional reimbursement for these conditions when they occur. The HACs currently identified for inclusion in this program are vascular catheter–associated infection, CAUTI, and some SSIs.

In 2011, the CMS Inpatient Quality Reporting Program began to require reporting of CLABSIs that occur in ICUs in acute care hospitals with use of clinical infection surveillance data. Since 2011, more HAI-related process and outcome measures have been added to the program. As of November 2013, reporting requirements include CLABSI and CAUTI in ICU patients, SSI related to colon surgery and abdominal hysterectomy, MRSA bacteremia, *C. difficile* infection, and health care worker influenza vaccination data. Requirements for reporting additional HAI-related outcome will likely be added in subsequent years. Some of these metrics will be used along with other quality measures to determine a hospital's annual reimbursement from CMS through its value-based purchasing program. In addition to being used to determine hospital reimbursement, much of this HAI-related data is being made available to the public through the Hospital Compare website (www.hospitalcompare.hhs.gov). In addition to financial consequences for hospitals with the highest rates of HAIs, in 2011, CMS introduced the Partnership for Patients program, which provides resources to assist hospitals to improve patient safety with the goal of reducing specific hospital-associated conditions, including CAUTI, CLABSI, SSI, and VAP, by 40% by the end of the year 2013. More than 3300 U.S. hospitals elected to participate in this voluntary program.

Several individual U.S. states have introduced mandatory reporting programs for one or more HAI-related outcomes. Many of those states' mandatory reporting programs include public reporting of HAI data. Some states have also mandated implementation of specific infection prevention strategies, such as antimicrobial stewardship, active surveillance testing for MRSA, and mandatory influenza vaccination or use of masks for health care workers during influenza season. Although the reported intention of these programs is to prevent HAIs, some data suggest that mandated public reporting and nonpayment programs do not result in improved HAI-related processes or outcomes.

REVIEW QUESTIONS

1. What percentage of device- and procedure-associated health care–associated infections that occur in U.S. hospitals are potentially preventable?

A. 0-15%
B. 20-30%
C. 40-50%
D. 55-70%
E. 85-100%

Answer: D A systematic review of published studies found that 55 to 70% of central line–associated blood stream infections, catheter-associated urinary tract infections, ventilator-associated pneumonia, and surgical site infections are preventable with the use of currently available evidence-based prevention strategies and technologies. Unfortunately, many of these strategies are not consistently implemented.

2. Bathing of intensive care unit (ICU) patients with chlorhexidine on a daily basis has been associated with which of the following outcomes?

A. Reduction in MRSA-positive clinical cultures attributable to the ICU
B. Reduction in overall blood stream infection rates in ICU patients
C. Reduction in central line–associated blood stream infection rates in ICU patients
D. Reduction in environmental contamination with VRE
E. All of the above

Answer: E Several quasi-experimental studies and three cluster-randomized controlled trials have demonstrated the potential for daily bathing with chlorhexidine to reduce a variety of health care–associated infection outcomes in ICU patients. This intervention has generally been well tolerated. Further study of the risk of development of chlorhexidine resistance among common health care–associated pathogens as the use of chlorhexidine becomes more common is warranted. Daily chlorhexidine bathing in other settings has not been subject to such extensive study, and thus the role of the horizontal infection control intervention in the non-ICU setting is not yet known.

3. The increased rates of morbidity and mortality associated with health care–associated infections caused by multidrug-resistant organisms (MDROs), compared with those caused by susceptible organisms of the same species, are likely due to all *except* which of the following?

A. Greater virulence of antimicrobial-resistant organisms compared with antimicrobial-susceptible organisms
B. Delays in initiating effective antimicrobial therapy
C. The presence of more severe underlying disease in patients who develop MDRO infections
D. The availability of only less effective or more toxic antimicrobial agents for treatment of some MDRO infections compared with agents available for the treatment of more susceptible organisms

Answer: A The higher rates of morbidity and mortality associated with MDRO infections, compared with infections caused by susceptible organisms of the same species, are likely to be multifactorial in nature. In general, however, MDROs are not more virulent than susceptible organisms of the same species.

4. Which of the following scenarios does *not* represent an avoidable health care–associated risk factor for health care–associated infection or MDRO acquisition?

A. The presence of an indwelling urinary catheter in an otherwise healthy patient who underwent elective knee replacement surgery 2 days earlier
B. Insertion of a central venous catheter for administration of cytotoxic chemotherapy
C. Insertion of an indwelling urinary catheter to reduce the need for nursing assistance in a 73-year-old patient with urinary incontinence
D. Administration of antimicrobial prophylaxis for 48 hours after an elective colectomy
E. Continuation of empirically prescribed piperacillin-tazobactam therapy for a patient admitted in septic shock who has now demonstrated a clinical response to current therapy and from whom pan-susceptible *E. coli* has been isolated from blood and urine specimens obtained at the time of admission

Answer: B The appropriateness of indwelling invasive devices and ongoing antimicrobial therapy should be assessed on a regular (i.e., at least once daily) basis with discontinuation of the device when an appropriate indication is not present and adjustment of antimicrobial therapy based on the results of diagnostic testing and clinical assessments.

5. Recommendations for the prevention of central line–associated blood stream infections (CLABSIs) include all of the following *except*

A. Use of maximal barrier precautions during catheter insertion (e.g., use of a cap, mask, sterile gown, sterile gloves, and sterile full-body drape)
B. Routine replacement of central venous catheters every 7 days
C. Preparation of the catheter insertion site with an antiseptic agent (e.g., >0.5% chlorhexidine preparation with alcohol) before catheter insertion
D. Daily review of catheter necessity with immediate removal of catheters that are no longer necessary
E. Scrubbing of the access port with an antiseptic before accessing the port

Answer: B Currently available evidence-based guidelines for prevention of CLABSI provide recommendations for catheter insertion, use, and maintenance. Routine catheter replacement is not a recommended strategy for CLABSI prevention.

283

APPROACH TO THE PATIENT WITH SUSPECTED ENTERIC INFECTION

HERBERT L. DUPONT

EPIDEMIOLOGY

Enteric infections are second only to respiratory tract infections as common infectious medical problems. In certain populations, enteric infections are hyperendemic: poorly nourished infants living in developing tropical countries showing excessive rates of mortality; infants in certain daycare centers; unhygienic residents of custodial institutions for the mentally retarded; immunosuppressed persons; and visitors from industrialized areas to developing regions with traveler's diarrhea.

ETIOLOGY

In approaching a patient with an enteric infection, epidemiologic (Table 283-1) and clinical features (Table 283-2) are used to identify the type of etiologic agent responsible for illness and to develop a plan for evaluation (Table 283-3) and management (Table 283-4).

Recent travel (Chapter 286) to mountainous regions or recreational lakes of North America should raise the suspicion of infection caused by *Giardia* species.[1] When diarrhea occurs during or after travel to a developing tropical region, a bacterial enteropathogen should be suspected.[2] The leading causes of traveler's diarrhea worldwide are the diarrheogenic *Escherichia coli*[3]: enterotoxigenic *E. coli* (ETEC) and enteroaggregative *E. coli* (EAEC). The invasive bacteria (*Shigella*, *Salmonella*, and *Campylobacter* species) cause diarrhea among travelers to all regions but are more common in Asia. Infection with *Cyclospora* species should be suspected when persistent or recurrent diarrhea follows travel to Nepal, Haiti, or Peru or other regions of the developing world (travel-related infections are discussed in detail in Chapter 286).

A specific food or water vehicle cannot be suspected unless multiple cases of illness with a common exposure occur. All too frequently, persons assume that food consumed during their last meal before an illness onset is responsible for the symptoms. The highly variable incubation period for diarrheal disease, which may be as short as 2 hours after eating a food, for preformed toxins, to a week or even longer for microbial enteropathogens, makes the determination of a specific food or beverage in a single case of illness impossible. When an outbreak of diarrhea results in multiple cases, a category of etiology (preformed toxin versus enteric infection) can be determined by calculating the incubation period after looking at timing of the common exposure and the time of first symptoms. Short incubation periods are characteristic of food poisoning associated with enterotoxins (2 to 7 hours for cases caused by *Staphylococcus aureus*, 2 to 4 hours for *Bacillus cereus* enterotoxin food poisoning). Longer incubation periods (usually 12 to 72 hours or longer) are associated with most cases of intestinal infection.

The clinical expression of diarrheal illness will give clues to the etiologic agent involved in disease (see Table 283-2). In the patient with diarrhea who is receiving or recently has completed a course of an antimicrobial drug, a proton pump inhibitor, or an anticancer drug, particularly with recent or

current hospitalization, *Clostridium difficile* infection (Chapter 296) should be suspected. An increasing number of cases of *C. difficile* diarrhea are occurring in the community. When a person has close contact with an infant or infants attending a daycare center, a number of low-dose pathogens found in this setting (e.g., *Giardia*, *Cryptosporidium*, or *Shigella* species or viral pathogens, particularly norovirus) should be suspected. Some homosexuals may show high rates of enteric infection acquired through fecal-oral contamination, often associated with infection by multiple pathogens or through the practice of unprotected receptive anal intercourse leading to proctitis due to sexually transmitted organisms. When persons experience advanced acquired immunodeficiency syndrome (AIDS) or other forms of severe immunodeficiency associated with metastatic malignant disease or chronic use of immunosuppressive drugs, depressed intestinal immunity may lead to enteric infection with a variety of parasitic, bacterial, or viral pathogens (see Table 283-1) (Chapter 281). Infants with malnutrition may develop persistent diarrhea and substantial long-term morbidity due to protozoal parasites, including *Giardia* and *Cryptosporidium*.

TABLE 283-1 EPIDEMIOLOGIC FEATURES IMPORTANT IN DETERMINING POTENTIAL CAUSE OF ENTERIC INFECTION IN A PERSON OR PERSONS WITH DIARRHEA

EPIDEMIOLOGIC FEATURE	ETIOLOGIC AGENT TO SUSPECT
Travel to mountainous areas of North America	*Giardia* spp
Travel to Russia (especially St. Petersburg)	*Cryptosporidium*, *Giardia* spp
Travel to Nepal	*Cyclospora* spp
Travel to the developing tropical/semitropical world from an industrialized region	Enterotoxigenic *Escherichia coli*, enteroaggregative *E. coli*; *Shigella*, *Campylobacter*, *Salmonella* spp; other bacterial causes; *Giardia*, *Cyclospora*, *Cryptosporidium* spp and noroviruses
Presence of associated cases (an outbreak)	Use incubation period and clinical features to determine probable cause
Antibiotic, chemotherapy, or proton pump inhibitor use in the past 2 months, particularly with a history of recent or current hospitalization	*Clostridium difficile*
Contact with daycare centers	Any enteropathogen, often the low-dose organisms: *Giardia*, *Cryptosporidium*, *Shigella* spp or viral pathogens
Homosexual person practicing unprotected sex	Any organism spread by fecal-oral route; in those with proctitis, suspect *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, herpes simplex, or *Treponema pallidum*
Immunosuppressed person	Any agent, especially *Cryptosporidium*, *Cyclospora*, *Isospora*, *Shigella*, and *Salmonella* spp; *C. jejuni*, *C. difficile*, *Mycobacterium avium-intracellulare*, microsporidia, herpes simplex virus, and cytomegalovirus
Recent or current cruise ship travel	Norovirus, less frequently enterotoxigenic *E. coli*

Enteric infection syndromes may be divided into at least five groups on the basis of the clinical presentation: (1) febrile systemic disease (enteric fever); (2) acute watery diarrhea (secretory diarrhea); (3) recurrent vomiting as the primary manifestation of enteric disease (gastroenteritis); (4) passage of many small-volume stools containing blood and mucus (dysentery); and (5) diarrhea lasting 2 weeks or longer (persistent diarrhea). Table 283-2 lists the major syndromes along with the expected cause.[4]

Noroviruses (Chapter 380) have become the major cause of food-borne gastroenteritis and the most commonly identified cause of waterborne enteric disease.[5] They have been identified as causes of persistent diarrhea in immunocompromised patients, especially in those undergoing hematopoietic stem cell transplantation. *Campylobacter* species (Chapter 303) is a commonly reported bacterial enteropathogen in industrialized countries and is the most important definable cause of Guillain-Barré syndrome (Chapter 420), often resulting in severe disease requiring assisted ventilation, intensive care unit confinement, and permanent neurologic sequelae. *E. coli* O157:H7 and other Shiga toxin–producing *E. coli* (STEC) (Chapter 304) are important causes of food-borne and waterborne colitis complicated by hemolytic-uremic syndrome in children and occasionally in elderly people.

The most commonly detected pathogens in endemic diarrhea in the United States in one study were noroviruses (26%), rotavirus (18%), and *Salmonella* species (5.3%). EAEC strains are being shown to be important causes of pediatric diarrhea in the United States as diagnostic methods improve.[6] In May and June of 2011, there was a large outbreak of diarrhea and hemolytic-uremic syndrome reported from Germany and France due to an *E. coli* O104:H4 strain of EAEC that had picked up the STEC phage controlling production of Shiga toxin. In the future, with improved diagnostic tools, we are likely to see more of these hybrid superpathogens with multiple virulence properties.

DIAGNOSIS

Laboratory Findings

Laboratory tests (Fig. 283-1; see Table 283-3) can be useful and are of particular value in the more severely ill patients, when subjects are forced by their illness to alter activities or are totally disabled and confined to bed or when many patients are afflicted during an outbreak. In each of these situations, the laboratory may help establish cause and allow development of a proper plan of treatment (see Table 283-3). Useful laboratory tests include procedures looking for fecal inflammatory markers, such as microscopic detection of fecal leukocytes or the more sensitive, commercially available test, fecal lactoferrin or calprotein. These tests are particularly helpful to suggest the presence of the invasive bacterial pathogens *Shigella*, *Salmonella*, and *Campylobacter* species or the noninvasive but inflammatory *C. difficile*. Stool culture is performed in more severe cases of sporadic diarrhea and in disease outbreaks

TABLE 283-2 CLINICAL FEATURES OF ENTERIC INFECTION

CLINICAL SYNDROME	ETIOLOGIC AGENTS SUSPECTED	SPECIAL CONSIDERATIONS
Sustained fever, often with systemic toxicity (enteric or typhoid fever)	*Salmonella typhi*, nontyphoid *Salmonella* spp, *Campylobacter* spp, *Shigella* spp, *Yersinia enterocolitica*	Stool and blood cultures; empirical antibiotics generally indicated
Acute watery (secretory) diarrhea	Any agent. Consider *Vibrio cholerae* (if water losses are major), enterotoxigenic or enteroaggregative *Escherichia coli*, *Shigella* spp, *Salmonella* spp, *Campylobacter jejuni*, viral or parasitic protozoal pathogen	Fluid and electrolyte therapy crucial for recovery in dehydration
Recurrent vomiting (gastroenteritis)	Viral agents (rotavirus or noroviruses) or preformed toxin (*Staphylococcus aureus* or *Bacillus cereus*)	In case of an outbreak, incubation period suggests the etiology
Bloody diarrhea (dysentery)	*Shigella* spp, *C. jejuni*, *Salmonella* spp, Shiga toxin–producing *E. coli* (e.g., O157:H7 or other serotype) or invasive *E. coli*, *Aeromonas hydrophila*, noncholera *Vibrio* spp, *Yersinia enterocolitica*, *Entamoeba histolytica*, or inflammatory bowel disease	Stool culture and occasionally parasite examination important to determining cause; hemolytic-uremic syndrome may complicate diarrheal disease caused by Shiga toxin–producing *E. coli* or rarely *Shigella dysenteriae*
Diarrhea lasting ≥2 weeks (persistent diarrhea)	*Giardia* spp and other protozoal parasites, bacterial overgrowth, bacterial diarrhea, lactase deficiency, Brainerd diarrhea, postinfectious irritable bowel syndrome (PI-IBS), unmasked inflammatory bowel disease (IBD), or celiac sprue	Stool culture and parasite examination indicated; empirical anti-*Giardia* therapy may be useful; remove milk from diet; prior raw milk or untreated (well or surface) water consumption or international travel may predispose to Brainerd diarrhea; with illness lasting >30 days, consider Brainerd diarrhea, PI-IBS, celiac disease, or IBD

TABLE 283-3 LABORATORY TESTS AND PROCEDURES USEFUL IN THE DIAGNOSIS OF INFECTIOUS DIARRHEA

SPECIFIC TEST OR PROCEDURE	WHEN INDICATED	CLINICAL SIGNIFICANCE
Fecal leukocyte test	For moderate to severe cases	When present, indicates diffuse colonic inflammation, often due to *Shigella*, *Salmonella*, *Campylobacter* spp, Shiga toxin–producing *Escherichia coli*, or *Clostridium difficile*
Fecal lactoferrin	For moderate to severe cases to help identify inflammatory forms of enteric infection, to use in health care–associated diarrhea to help determine whether *C. difficile* toxin test should be performed	More sensitive test than fecal leukocytes and will pick up the same pathogens as fecal leukocytes but also pathogens associated with less striking degrees of inflammation (enteroaggregative *E. coli* and *C. difficile*)
C. difficile toxins A and B	Diarrhea associated with use of antibiotics, chemotherapy, or proton pump inhibitors, especially associated with current or recent hospitalization	Most sensitive tests are culture and tissue culture assay. Polymerase chain reaction is sensitive but lacks specificity. Most specific tests are enzyme immunoassay for toxins A and B; a two-step procedure can be used: sensitive but nonspecific *C. difficile* glutamate dehydrogenase antigen test followed by toxin assay
Stool culture for *Shigella*, *Salmonella*, *Campylobacter* spp, and Shiga toxin–producing *E. coli* (O157:H7 and others)	Moderate to severe diarrhea and when stools are positive for inflammatory markers or contain gross blood and mucus (dysentery)	The four mucosa-inflammatory bacteria are the only bacteria routinely sought by most laboratories.
Specialized stool culture for *Vibrio* spp	For cases of profuse watery diarrhea in cholera-endemic areas and outbreaks of seafood-associated diarrhea or dysentery	Cholera cases may need aggressive fluid therapy. Non-cholera vibrios can cause dysentery.
Parasite examination: (1) enzyme immunoassay for *Giardia* spp, *Cryptosporidium* spp, or *Entamoeba histolytica*; (2) acid-fast stain for *Cyclospora* or *Cryptosporidium* spp or *Isospora*; or (3) trichome stain and microscopic examination	In any patient with persistent diarrhea and when diarrhea follows visits to mountainous or recreational lakes in North America, Nepal, Haiti, Peru, or Russia (particularly St. Petersburg)	If microscopic evaluation is performed, experience of the laboratory personnel is important. The commercially available enzyme immunoassay tests are sensitive.
Esophagogastroduodenoscopy and flexible sigmoidoscopy	Persistent diarrhea in patients without evidence of cause of illness	Identified cause of diarrhea is treated; without diagnosis, subjects may be treated symptomatically.

TABLE 283-4 THERAPY FOR AND PREVENTION OF INFECTIOUS DIARRHEA

THERAPEUTIC OPTION	INDICATION	PHARMACOLOGIC AGENT
Oral fluid and electrolyte therapy	For infants, elderly patients, and anyone with profuse watery diarrhea	Soups, soft drinks, and saltine crackers are sufficient; formal oral replacement therapy may be needed with dehydrating forms of diarrhea
Diet	In all forms of diarrhea to facilitate enterocyte renewal and recovery	Soups and broth, saltine crackers, steamed vegetables, baked or broiled meats
Nonspecific therapy	For temporary (≤48 hours) control of diarrhea in older children and adults without evidence of severe diarrhea caused by an invasive or inflammatory bacterial or parasitic pathogen	Loperamide is the most effective symptomatic treatment and will decrease number of stools passed by 60%; bismuth subsalicylate is much less effective and will reduce number of stools by 40%; the antisecretory agent crofelemer is of value in HIV-associated diarrhea
Empirical antibacterial drugs	Enteric fever with toxicity Febrile dysenteric diarrhea Traveler's diarrhea	Fluoroquinolones for 7-10 days Azithromycin is recommended when fever or dysentery complicates illness Rifaximin for 3 days, fluoroquinolone for 1-3 days, or azithromycin 1000 mg in single dose
Specific antibacterial therapy	Shigellosis, campylobacteriosis, cholera	See Chapters 302, 303, and 309
Antiparasitic drugs	Giardiasis, amebiasis, cryptosporidiosis, cyclosporiasis	See Chapters 350, 351, and 353
Prophylaxis in traveler's diarrhea	Persons traveling to developing areas on tight schedules, those with history of prior traveler's diarrhea, persons with unstable underlying medical disorders, and those interested in prophylaxis	Rifaximin, 200 mg twice daily with meals, while in a high-risk region

and is carried out with blood culture in a patient with fever and systemic toxicity. Other indications for stool culture are presence of dysentery (passage of grossly bloody stools) and when fecal inflammatory markers are found. In dysenteric diarrhea, particularly in the presence of an outbreak, the laboratory should also be instructed to look for *E. coli* O157:H7 and other Shiga toxin–producing *E. coli*. Parasite examination is indicated by diarrhea and persistent (≥14 days) illness; a recent trip to Nepal, Haiti, Peru, or Russia; evidence that the subject practices oral-anal sex or unprotected receptive anal intercourse; or associated immunosuppression. Other tests are indicated in special situations, including stool culture for *Vibrio cholerae* in a patient with severe watery diarrhea with excessive fluid losses in a cholera-endemic area and culture for *Mycobacterium avium* complex, herpes simplex virus, and cytomegalovirus in those with immunosuppression. For patients with persistent diarrhea without etiologic diagnosis when routine tests are employed, endoscopy (esophagogastroduodenoscopy and flexible sigmoidoscopy or colonoscopy) may be indicated in attempting to determine the nature and cause of illness.

The broad range of conventional diagnostic approaches currently available to identify enteropathogens associated with infectious diarrhea will be increasingly supplemented by or replaced with new molecular methods, including real-time polymerase chain reaction, quantitation of pathogen load, and next-generation sequencing.[7]

TREATMENT

Rx

Treatment of diarrhea should be tailored to the clinical syndrome. Oral rehydration therapy with fluids and electrolytes is used to treat acute watery diarrhea and gastroenteritis and all forms of enteric infection, especially when complicated with any degree of dehydration. Oral rehydration therapy is particularly important in infants; it can be life-saving in developing countries for infants with severe diarrhea. Patients with diarrhea should be fed easily digestible foods to facilitate enterocyte renewal and to speed up disease recovery.

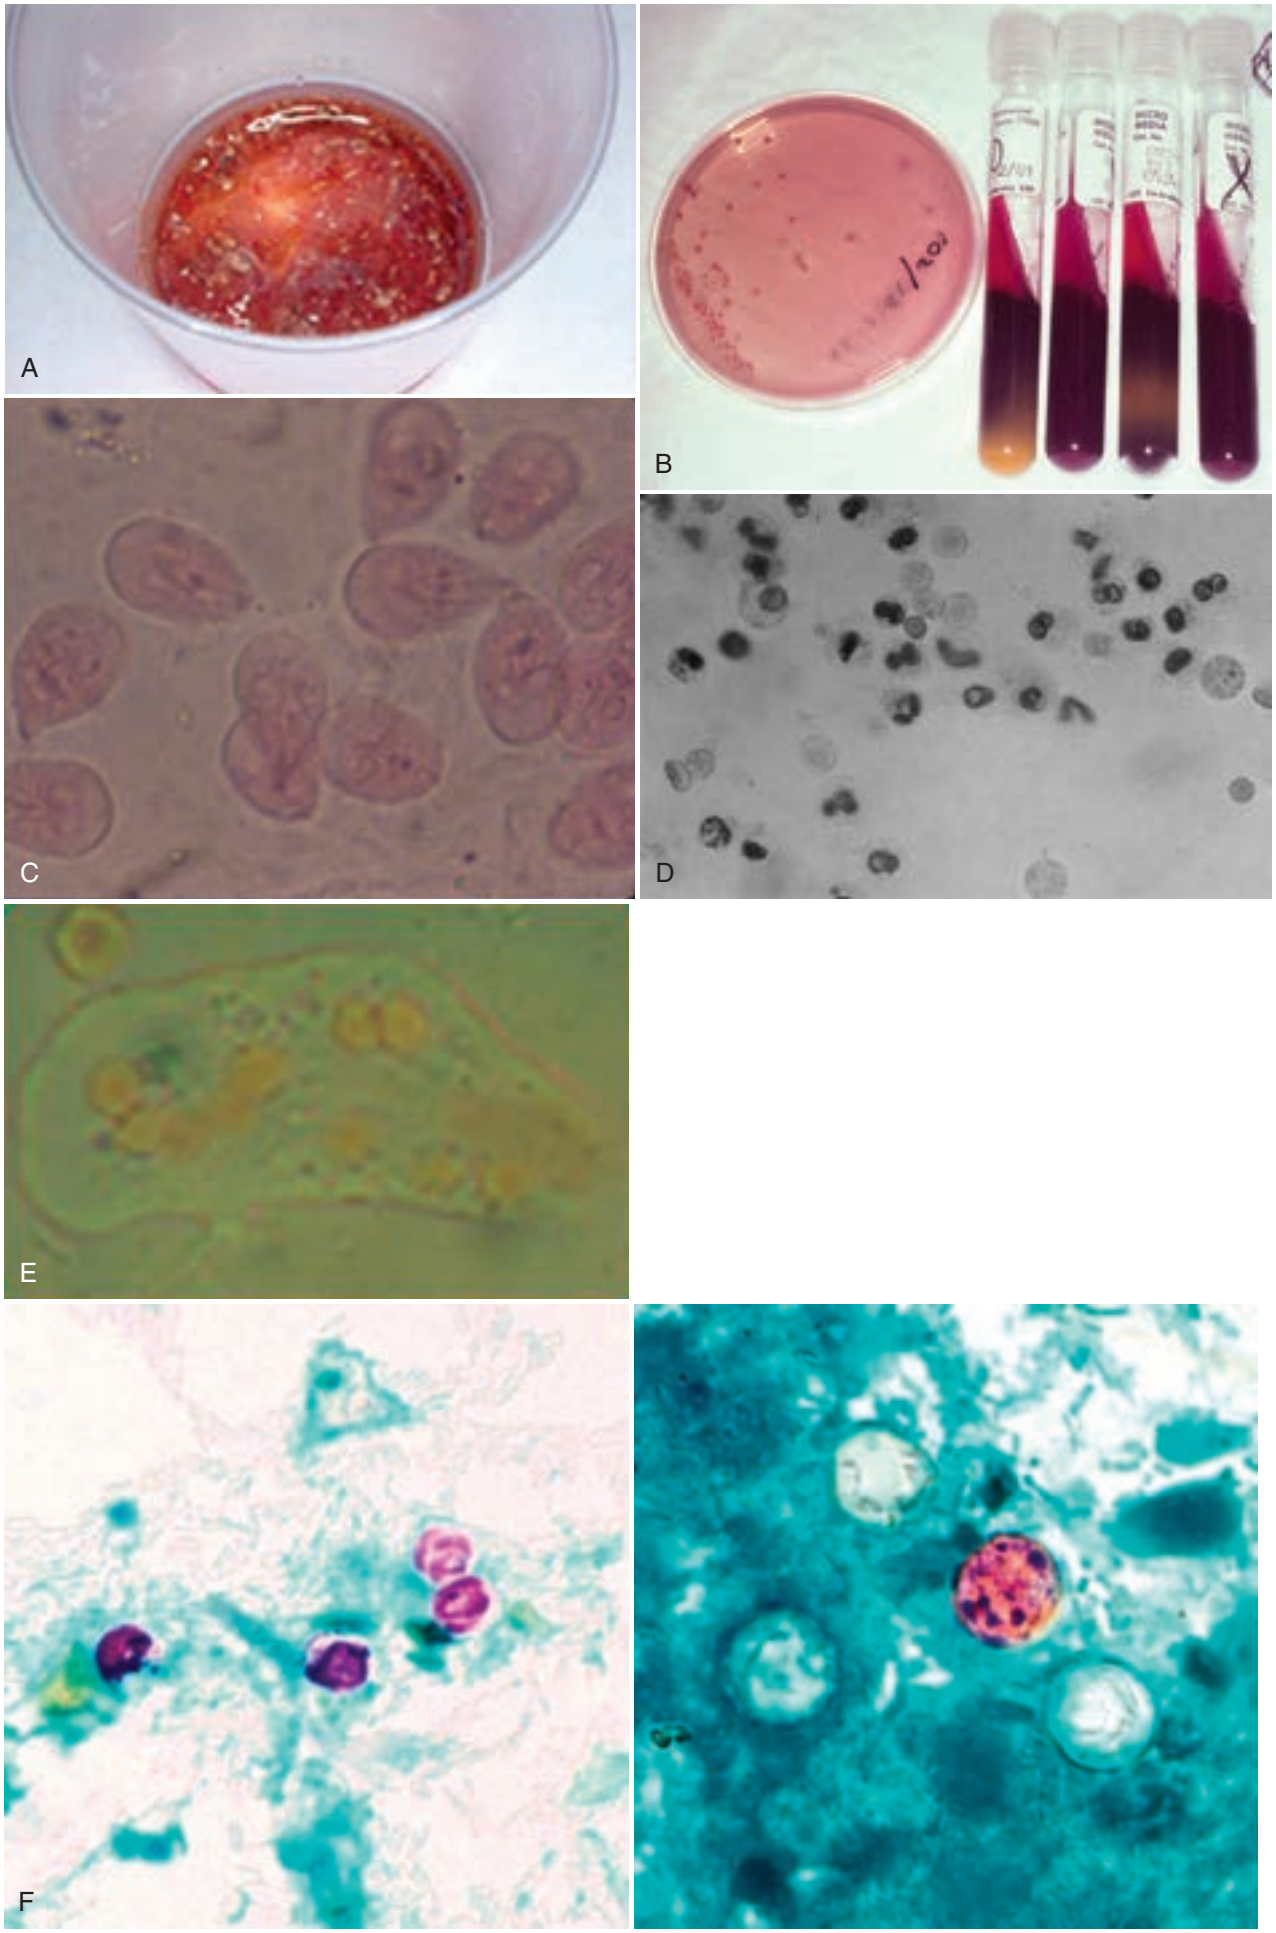

FIGURE 283-1. Laboratory tests to diagnose causes of diarrhea. A, Dysenteric stool. **B,** Stool culture and biochemical tests confirm *Salmonella*. **C,** *Giardia* trophozoites. **D,** Many leukocytes in diffuse colonic inflammation. **E,** *Entamoeba histolytica* trophozoite with ingested red blood cells. **F,** Oocysts of *Cryptosporidium* (*left*) and *Cyclospora* (*right*). (From the CDC Public Health Information Library. http://phil.cdc.gov/phil/home.asp: images 7829 and 7827.)

TABLE 283-5 NONINFECTIOUS CAUSES OF DIARRHEA

Running	Small bowel bacterial overgrowth
Fecal impaction	Systemic mastocytosis and eosinophilic gastroenteritis
Drugs and laxatives	Tropical sprue
Enteral feeding	Celiac sprue
Irradiation	Dermatitis herpetiformis
Pancreatic insufficiency	Whipple's disease
Intestinal lymphangiectasia	Thyrotoxicosis
Foods (especially dietetic)	Adrenal insufficiency
Cirrhosis and biliary obstruction	Factitious
Diabetic diarrhea	Inflammatory bowel disease
Alcoholism	Food allergy
Collagenous colitis	Carcinoid
VIPoma	Villous adenoma
Ischemic bowel disease	Stress with autonomic stimulation
Irritable bowel syndrome	

In afebrile, nondysenteric diarrhea, symptomatic drugs may allow older children and adults with illness to return earlier to school or work. Loperamide is the most active drug for improvement of symptoms. Bismuth subsalicylate can reduce diarrhea and is mildly effective in reducing nausea and vomiting associated with viral gastroenteritis.

For enteric fever, febrile dysenteric disease, and moderate to severe cases of traveler's diarrhea, empirical antimicrobial therapy is indicated (see Table 283-4).[8] For outbreaks of dysenteric diarrhea, particularly in children in whom fever is not significant, antibacterial and antimotility drugs should be initially withheld while the etiology of the outbreak is being established to prevent patients infected by STEC strains from being predisposed to hemolytic-uremic syndrome. For bacterial and parasitic pathogen-specific diarrhea, antimicrobial therapy is often advised (see other chapters in the text for specific treatments). Because of the importance of diarrhea when persons travel from industrialized regions to developing countries, prophylaxis with the orally administered, poorly absorbed rifaximin can be employed for some groups (see Table 283-4), with expected protection rates exceeding 70%.

In sporadic cases of acute or persistent diarrhea, infectious agents are not always responsible. Table 283-5 offers a partial list of the noninfectious causes of diarrhea that should be considered.

REVIEW QUESTIONS

1. A 30-year old traveler to Goa, India, for vacation develops diarrhea and fever on the fifth day at the resort. After 36 hours of diarrhea, stools begin to contain bright red blood. She visited a U.S. travel medicine clinic before heading for India and was given two antibiotics, one for the common watery diarrhea and a second in the less likely event that she developed bloody diarrhea and fever. Which of the following antibiotics would she have correctly received from the clinic to treat dysenteric traveler's diarrhea?

A. Oral ciprofloxacin, 500 mg twice a day for 3 days
B. Azithromycin, 1000-mg single dose
C. Levofloxacin, 500 mg once a day for 3 days
D. Metronidazole, 500 mg three times a day for 10 days
E. Rifaximin, 200 mg three times a day for 3 days

Answer: B The invasive pathogens (*Shigella*, *Salmonella*, and *Campylobacter*) occur more commonly in travelers to Asia compared with destinations in Africa and Latin America. Ciprofloxacin and levofloxacin would not be the best choice in this patient because of the importance of fluoroquinolone-resistant *Campylobacter* as a causative agent of dysenteric traveler's diarrhea occurring in Asia. Metronidazole would be appropriate for persistent diarrhea caused by *Giardia* or *Entamoeba histolytica* but would not be useful in most patients with traveler's diarrhea where the typical enteropathogenic agents are bacterial in origin. Rifaximin is of value for the common watery diarrhea of travelers but is of no value for the treatment of mucosally invasive enteropathogens as the drug is poorly absorbed (<0.4%). Azithromycin has the broadest spectrum of activity against the causes of traveler's diarrhea and should be preferentially used for dysenteric traveler's diarrhea or when breakthrough diarrhea occurs in a patient taking rifaximin to prevent traveler's diarrhea.

2. Two families eat a common meal and five people from the two families develop diarrhea the next afternoon, of whom two are passing grossly bloody stools. A sixth person eating the meal without diarrhea develops motor weakness and decreased reflexes 11 days later, progressing to quadriplegia. She is confined to a hospital intensive care unit requiring mechanical ventilation. What probably caused the outbreak of diarrhea and the case of quadriplegia?

A. *Campylobacter jejuni*
B. *Shigella flexneri*
C. *Vibrio cholerae*
D. *Aeromonas sobria*
E. *Vibrio vulnificus*

Answer: A The most common causes of dysentery (passing grossly bloody stools) in the United States are *Shigella* and *Campylobacter*. *Campylobacter* is the most important definable cause of Guillain-Barré syndrome (GBS), occurring during the 2 months after *Campylobacter* infection in fewer than 2 per 10,000 cases. GBS is an example of molecular mimicry with antibodies directed to *Campylobacter* lipooligosaccharides and peripheral nerve gangliosides. The complication can occur in asymptomatic *Campylobacter* infection as was seen in this case. *Campylobacter* can be suspected by searching for serologic evidence of past infection in subjects with GBS.

3. You receive a call from your office. One of your patients has developed watery diarrhea 2 hours after eating at a local restaurant. No other persons are known to be ill. What should you tell your office?

A. Obtain a sample of food if possible for *S. aureus* enterotoxin.
B. Have the office draw a blood culture sample.
C. Do a complete clinical and epidemiologic history.
D. Recommend ciprofloxacin therapy for the patient.
E. Collect a stool sample for studies of enteric pathogens.

Answer: C A meal or beverage can be implicated as a cause of an enteric disease if there are associated cases of illness occurring with a common exposure. The only exception to this is a case of classic botulism occurring shortly after consumption of a food. The incubation period of an enteric infection/intoxication can be as long as 9 days and as short as 2 hours. Thus, the problem could have resulted with an exposure during this broad time range. By taking a careful history, it would have been learned that this patient had diarrhea as well as vomiting and a temperature of 102° F. By obtaining more information, an infectious agent is more likely than a preformed toxin of *Staphylococcus aureus* or *Bacillus cereus*, which could produce illness with this short incubation period. Clearly, the meal was not responsible because an enteric infection has a minimum incubation period of 14 hours. In this subject, a stool culture revealed a *Salmonella* spp, and he gave a history of eating a turkey meal the day before.

4. In January 2010, local authorities in Maryland were notified of a large cluster of gastroenteritis involving more than 100 persons, 24 to 36 hours after consumption of raw oysters in three Baltimore restaurants. The median incubation period was 30 hours. Vomiting and watery nonbloody diarrhea with abdominal pain were common. Some subjects complained only of nausea and vomiting. Fever was seen in approximately 30% of the affected persons. Approximately 20 subjects had stool studies performed, which were negative for bacterial and parasitic pathogens. Clinical recovery was complete in 72 hours, and there were no long-term sequelae. Which of the following organisms likely caused the outbreak?

A. *Shigella sonnei*
B. *Vibrio cholerae*
C. *Giardia*
D. Norovirus
E. *Staphylococcus aureus* enterotoxin

Answer: D In the United States each year, more than 20 million cases of acute norovirus gastroenteritis occur, with half being reported to be foodborne. The reservoir of norovirus is infected persons who may be asymptomatic. With fecal contamination of an oyster bed, norovirus contamination occurs readily. Outbreaks of norovirus gastroenteritis from oysters are not rare. The illness seen here meets the Kaplan criteria for norovirus illness: (1) median duration of illness is 12 to 60 hours; (2) median incubation period is 24 to 48 hours; (3) more than 50% of affected persons complain of vomiting; and (4) no bacterial agent is found. Norovirus is more common in winter months, which fits with the timing of the outbreak. *Shigella*, *V. cholerae*, and *Giardia* produce a different disease (febrile dysentery, dehydrating diarrhea, persistent illness). *Staphylococcus* food poisoning associated with concentration of an enterotoxin in improperly handled food has a shorter incubation period (2 to 7 hours) and is not likely to be seen in oyster-associated outbreaks.

5. On June 15, 2010, local physicians reported 11 pediatric cases of diarrhea to a county health department. A preliminary investigation found that nine of the persons recently had visited a large city park with a wading pool. The health department performed an evaluation of persons who used the park or wading pool and found that of 89 children interviewed, 69 met the case definition. Secondary spread of illness to family members and contacts was found to be common. One third of the children had temperature above 102° F; half had bloody diarrhea. A pathogen was isolated from three children providing a stool sample. Which of the following is likely to be the cause of the outbreak?

A. *Shigella sonnei*
B. Enteroinvasive *E. coli*
C. *Campylobacter jejuni*
D. *Vibrio cholerae*
E. Enterotoxigenic *E. coli*

Answer: A Outbreaks of infectious diarrhea have been reported among infants and children in wading pools where chlorine levels are not monitored and fecal contamination is expected. The likely causes of the illness are the low-dose pathogens: norovirus, *Shigella* spp, Shiga toxin–producing *E. coli*, *Giardia*, and *Cryptosporidium*. Secondary spread of enteropathogens commonly occurs only for low-dose organisms. *Salmonella* and *Campylobacter* in most patients (outside the very young infant stage) are moderate-dose pathogens. *V. cholerae* and ETEC are high-dose pathogens. The moderate- and high-dose pathogens would be rare causes of outbreaks in this setting and would not have been associated with secondary transmission. If Shiga toxin–producing *E. coli* (STEC) would have been given as an option, two answers could have been correct. STEC is a low-dose pathogen seen in wading pool outbreaks and with secondary cases. The high fever is more compatible with shigellosis than with STEC diarrhea, however. *V. cholerae*, EAEC, and ETEC are each high-dose pathogens not associated with wading pools; secondary spread does not occur for them, and none causes dysenteric illness.

284 APPROACH TO THE PATIENT WITH URINARY TRACT INFECTION

LINDSAY E. NICOLLE AND S. RAGNAR NORRBY

DEFINITIONS

Urinary tract infection (UTI) is bacterial or fungal infection of the normally sterile urine. The clinical presentation varies from asymptomatic bacteriuria, when the urine culture is positive but there are no symptoms, to cystitis (bladder or lower tract infection), pyelonephritis (renal or upper tract infection), and urosepsis (systemic inflammatory response syndrome or septic shock from a urinary source). Urethritis caused by *Chlamydia trachomatis*, *Ureaplasma urealyticum* (Chapter 285), or *Neisseria gonorrhoeae* (Chapter 299) and prostatitis (Chapter 129) and renal tuberculosis (Chapter 324) are addressed elsewhere in this text.

Uncomplicated UTI occurs in women with a normal genitourinary tract. Most episodes are manifested as cystitis; acute nonobstructive pyelonephritis also occurs in these women, at a lower frequency. Complicated UTI occurs in patients with functional or structural abnormalities of the urinary tract. Complicating factors are host factors facilitating the establishment and persistence of bacteriuria or infection (Table 284-1). Uncomplicated UTI occurs rarely in young men. Men presenting with UTI should be assumed to have complicated infection until it is proved otherwise. Recurrent infection is considered a reinfection when it is caused by a new bacterial strain and relapse when the same strain that caused preceding infections is isolated. It is clinically important to classify UTIs by site of infection, presence or absence of symptoms, tendency to recur, and presence or absence of complicating factors.

TABLE 284-1 HOST FACTORS ASSOCIATED WITH COMPLICATED URINARY TRACT INFECTION

	EXAMPLES
Obstruction	Urethral or ureteric strictures, tumor Diverticula Pelvicalyceal junction obstruction Prostate enlargement Urolithiasis Extrinsic compression
Functional	Neurogenic bladder Vesicoureteral reflux Anatomic defects Pregnancy Turbulent urethral urine flow Cystocele
Urologic interventions	Indwelling or suprapubic catheters Endourologic surgery Ureteric stents Nephrostomy tubes Cystoscopy Neobladders
Metabolic or congenital diseases	Urethral valves Polycystic kidneys Nephrocalcinosis Medullary sponge kidney
Immunologic abnormalities	Renal transplantation

EPIDEMIOLOGY

UTI is the most common bacterial infection. It is somewhat more common in boys than in girls in the newborn period because of the higher frequency of urethral malformations in boys. Later in childhood, symptomatic UTIs and asymptomatic bacteriuria are more common in girls. More than half of all healthy women experience at least one symptomatic UTI in their lifetime, and each year, 2 to 10% of women experience at least one episode. UTI is uncommon in men with a normal genitourinary tract but increases after the age of 65 years, primarily attributable to prostate hypertrophy and prostatitis. The frequency of infection in patients with complicated infection varies by the abnormality promoting infection. For instance, patients with spinal cord injury and neurogenic bladder have continuing high rates of infection, but patients with abnormalities that can be corrected will no longer be at risk of infection. UTI is also one of the most common hospital-acquired infections; about 80% of these are a consequence of the use of an indwelling bladder catheter.

Asymptomatic bacteriuria is common. The prevalence increases from 1 to 2% of schoolgirls to 3 to 5% of sexually active premenopausal women, 10 to 20% of healthy postmenopausal women, and 40 to 50% of elderly women in nursing homes. It is infrequent in men until older ages, with 5 to 10% of elderly men in the community and 35 to 40% in nursing homes having bacteriuria. Some patients with genitourinary complications also have a very high prevalence. For instance, 50% of spinal cord–injured patients with a neurogenic bladder and without an indwelling catheter and 100% of patients with chronic indwelling urethral catheters have bacteriuria.

PATHOBIOLOGY

Acute uncomplicated UTI follows ascension into the bladder or kidney of uropathogenic organisms in the normal gut flora that have colonized the vagina and periurethral mucosa. The ability of these organisms, usually *Escherichia coli*, to colonize and to persist within the urinary tract is dependent on an array of virulence factors that include adhesins, toxins, and iron-scavenging proteins. Organism virulence is a major determinant of whether infection is asymptomatic or symptomatic or is manifested as cystitis or pyelonephritis. All strains causing uncomplicated infection express the FimH adhesin, but this adhesin is not specific for UTI. *E. coli* isolated from uncomplicated pyelonephritis are characterized by the presence of the P fimbria adhesin Gal(α1-4) Galβ disaccharide globoside, which initiates mucosal inflammation. Adherence of organisms in the bladder or kidney activates the innate immune

response leading to release of cytokines, particularly interleukin-6 and interleukin-8, and mobilizes leukocytes. This results in pyuria and local or systemic symptoms, including fever in patients with pyelonephritis.

The occurrence of acute uncomplicated UTI in healthy premenopausal women is determined by both genetic and behavioral factors. A genetic predisposition is supported by observations that a history of prior UTI is consistently one of the strongest associations with recurrent uncomplicated UTI, and women who experience these infections report a higher proportion of first-degree female relatives with recurrent UTI than do those without infection. One established genetic association is being a nonsecretor of the ABH blood group antigen. There is more avid binding of uropathogenic organisms to the vaginal epithelium in nonsecretors. Genetic polymorphisms affecting the innate immune response have been correlated with increased frequency of infection as well as with specific presentations.[1] The strongest behavioral factors associated with uncomplicated UTI are sexual intercourse and spermicide use. For sexually active premenopausal women, 75 to 90% of episodes are attributed to intercourse. The normal lactobacillus flora of the vagina maintains an acid environment that prevents colonization by potential uropathogens, and spermicide suppresses these organisms. Use of the birth control pill or condoms, postcoital voiding, type of underwear used, personal hygiene after voiding or defecating, and taking a bath rather than a shower are not associated with an increased risk for recurrent episodes of UTI, despite popular perceptions. Behavioral risk factors are similar for women for all clinical presentations—asymptomatic bacteriuria, cystitis, or pyelonephritis. Sexual intercourse is not a major contributor to UTI in postmenopausal women. The most important determinants of infection in these women are having a history of UTI at a younger age and nonsecretory status.

The risk of complicated UTI is determined by the underlying abnormality. Genitourinary abnormalities facilitate infection through increased entry of organisms into the bladder, such as intermittent catheterization or urologic procedures, and persistence of organisms within the urinary tract because of incomplete voiding or in biofilm on urologic devices. The determinants that promote symptomatic rather than asymptomatic infection are not well characterized. However, obstruction and mucosal trauma with bleeding are well-recognized antecedents for bacteremia and sepsis in patients with preexisting bacteriuria. Although it is generally accepted that patients with diabetes have an increased incidence of UTI, this correlates with long-term complications of diabetes, such as neurogenic bladder, rather than with diabetes.[2] Patients with poorly controlled diabetes, however, are at risk for more severe manifestations of infection.

Acquisition of bacteriuria in individuals with indwelling urinary devices, including indwelling catheters, stents, and nephrostomy tubes, is primarily attributable to biofilm development along the device.[3] Biofilm is composed of an extracellular polysaccharide material produced by the organisms that incorporates urine components including Tamm-Horsfall protein and magnesium or calcium ions. After insertion of the device, a conditioning layer composed of proteins and other host components immediately coats the device. Organisms adhere to this conditioning layer and initiate biofilm formation. Colonization usually begins at the urethral orifice or in the drainage bag, and the biofilm then ascends the catheter. Organisms growing in the biofilm persist in an environment relatively protected from antibiotics or host defenses. For patients with an indwelling catheter, the acquisition of bacteriuria occurs at a rate of 3 to 7% per day. The initial episode that follows indwelling catheter insertion is usually with a single organism, but polymicrobial flora is the norm in mature biofilms on chronic indwelling devices. *Proteus mirabilis* is a particularly important organism for biofilm formation on chronic devices. These strains may produce copious biofilm, and urease production creates an alkaline environment leading to precipitation of calcium and magnesium ions. This creates a "crystalline biofilm" that is similar to the material causing infection stones and may cause catheter obstruction. About 80% of episodes of urinary catheter obstruction are attributed to *P. mirabilis*.

ETIOLOGY

Table 284-2 summarizes the most common infecting organisms. In all types of UTI, *E. coli* is the dominant bacterial species, causing up to 85% of all symptomatic UTIs in women with community-acquired infections.[4] The second most common species causing uncomplicated cystitis is *Staphylococcus saprophyticus*, which is isolated more frequently in later summer and early fall. In patients with recurrent complicated UTI, species such as *Enterococcus faecalis*, *Enterococcus faecium*, *Klebsiella* species, *Proteus* species, *Providencia stuartii*, and *Morganella morganii* become more common. Patients with very frequent recurrences or with bladder catheters, particularly those in hospitals and nursing homes where antimicrobials are frequently used, may have *Pseudomonas aeruginosa*, *Acinetobacter baumannii*, *Serratia marcescens*, and *Stenotrophomonas maltophilia* isolated. In such patients, *E. coli* accounts for less than 50% of infections. Urolithiasis attributed to infection stones is associated with urease-producing organisms; the alkaline urine created facilitates struvite formation.[5] Patients with frequent recurrent complicated UTI, including those with chronic indwelling catheters, often acquire organisms of increased antimicrobial resistance because of repeated exposure to antimicrobials. In health care facilities, the catheterized urinary tract is the most common site of isolation of multiply drug–resistant gram-negative organisms, including extended-spectrum β-lactamase–producing and carbapenemase-producing Enterobacteriaceae. *Candida* sp is the most common fungal UTI. Patients with *Candida* infection are characterized by the presence of diabetes or of an indwelling urinary catheter and broad-spectrum antimicrobial exposure.[6]

TABLE 284-2 MICROBIAL ETIOLOGY OF URINARY TRACT INFECTIONS

ORGANISMS	CLINICAL CHARACTERISTICS
GRAM-NEGATIVE BACTERIA	
Escherichia coli	Typical
Klebsiella pneumoniae	Often reinfection
Enterobacter spp	Often reinfection or health care–associated infection*
Proteus spp	May indicate calculi; frequent with devices
Providencia stuartii	Often reinfection or health care–associated infection*
Morganella morganii	Often reinfection or health care–associated infection*
Serratia marcescens	Often health care–associated infection*
Acinetobacter baumannii	Often health care–associated infection*
Burkholderia spp	Often health care–associated infection*
Pseudomonas aeruginosa	Often health care–associated infection*
Stenotrophomonas maltophilia	Often health care–associated infection*
GRAM-POSITIVE BACTERIA	
Staphylococcus saprophyticus	Most common during late summer and fall
Staphylococcus aureus	May indicate focus outside the genitourinary tract
Enterococcus spp	Often reinfection
Other gram-positive bacteria	In most cases contaminants or colonizers
FUNGI	
Candida spp	May indicate focus outside the genitourinary tract

*Includes hospital and nursing home care.

CLINICAL MANIFESTATIONS

Typical symptoms of cystitis, pyelonephritis, and urosepsis are listed in Table 284-3. The onset of cystitis is rapid, and symptoms usually develop during less than 24 hours. Clinically, the lack of vaginal discharge differentiates cystitis from urethritis caused by chlamydia, ureaplasma, or gonococci. Women who experience recurrent episodes of acute uncomplicated UTI are more than 90% reliable for self-diagnosis.

Pyelonephritis may also have a rapid onset and may or may not be associated with cystitis symptoms. Bacteremia occurs in 10 to 30% of patients but does not have prognostic significance. The typical flank pain and tenderness, resulting from inflammation and edema of the renal parenchyma, may be masked by the intake of analgesic drugs such as acetaminophen, which may also reduce the fever. An important differential diagnosis is renal calculus. This may have a similar location of pain but does not cause fever unless it is complicated by infection.

Complicated UTI is manifested across a clinical spectrum from minimal voiding abnormalities to symptoms consistent with cystitis, pyelonephritis, or severe sepsis. Urosepsis is a life-threatening condition, usually associated with bacteremia.[7] Obstruction or trauma to the mucosa from an indwelling catheter or with urologic surgery may precipitate bacteremia. Patients who present with urosepsis invariably have complicated UTI rather than nonobstructive pyelonephritis.

TABLE 284-3 CLINICAL SYMPTOMS OF URINARY TRACT INFECTIONS

TYPE OF URINARY TRACT INFECTION	TYPICAL SIGNS OR SYMPTOMS
Cystitis	Frequency Dysuria Urgency Stranguria (difficulty in micturition) Suprapubic pain Hematuria or cloudy urine
Pyelonephritis	Costovertebral angle pain or tenderness Fever Chills Cystitis symptoms (may be absent)
Urosepsis	Fever Chills, rigors Sepsis syndrome

TABLE 284-4 INTERPRETATION OF THE QUANTITATIVE URINE CULTURE

	QUANTITATIVE BACTERIAL COUNT
Asymptomatic bacteriuria	$\geq 10^5$ CFU/mL (two consecutive specimens for women)
Acute uncomplicated cystitis	$\geq 10^2$ CFU/mL of *Escherichia coli* or *Staphylococcus saprophyticus*
Acute uncomplicated pyelonephritis	$\geq 10^4$ CFU/mL (95% have $\geq 10^5$ CFU/mL)
Complicated urinary tract infection	$\geq 10^5$ CFU/mL (lower counts may occur with diuresis)
Intermittent or in and out catheter collection	$\geq 10^2$ CFU/mL
Suprapubic or percutaneous aspiration	Any organisms isolated

DIAGNOSIS

Laboratory Findings

The hallmark of UTI diagnosis is demonstration of bacteriuria in a urine sample that has been incubated in the bladder for at least 2 hours to allow the growth of bacteria. A pretherapy urine culture specimen should be obtained for all patients presenting with pyelonephritis, urosepsis, or complicated UTI or when the diagnosis is uncertain. It is not generally recommended for acute uncomplicated cystitis because the clinical presentation is characteristic, and use of empirical short-course therapy means symptoms are often resolved by the time the culture is available. The urine specimen must be collected in a manner that will limit contamination. The usual collection method is a midstream urine sample. All specimens should be taken promptly to the laboratory to prevent growth during transportation. Urine specimens for culture must be collected before institution of antimicrobial therapy as the urine is rapidly sterilized after initiation of systemic antimicrobials.

Interpretation of the quantitative urine culture varies with the clinical presentation and collection method (Table 284-4). *Significant bacteriuria* is usually 10^5 CFU/mL or more, where one colony-forming unit (CFU) is one or more bacterial cells forming a colony when growing on an agar plate. In women with symptoms of uncomplicated cystitis, 10^2 CFU/mL or more in midstream urine of *E. coli* or *S. saprophyticus* is consistent with infection. Other gram-positive organisms at any quantitative count should be interpreted as contaminants.[8]

Pyuria is present in most patients with symptomatic UTI or asymptomatic bacteriuria. Many other abnormalities are, however, associated with pyuria, and the presence of pyuria does not diagnose infection or differentiate symptomatic from asymptomatic infection. The absence of pyuria has a high negative predictive value to exclude UTI for most patients. However, the absence of pyuria in a urine specimen from a woman with symptoms compatible with cystitis is not an indication to withhold empirical antimicrobial therapy.

For screening of bacteriuria, identification of nitrite in the urine may be useful. Gram-negative bacteria, with the exception of *P. aeruginosa*, will metabolize nitrate to nitrite, which can be demonstrated by a color reaction on a dipstick. Gram-positive bacteria and fungi do not metabolize nitrate. The technique is rapid (<1 minute) and inexpensive. It has a high degree of specificity but is insensitive because it does not detect infections caused by gram-positive organisms.

TABLE 284-5 DECISION PROCESS FOR DIAGNOSIS AND TREATMENT OF UPPER (PYELONEPHRITIS) VERSUS LOWER (CYSTITIS) URINARY TRACT INFECTIONS

	CYSTITIS	PYELONEPHRITIS
SIGNS AND SYMPTOMS		
Fever	No	Yes
Dysuria	Yes	May be present
Frequency	Yes	May be present
Flank pain	No	Yes
DIAGNOSIS		
Pyuria	Yes	Yes
Nitrite test result	Normally positive	Normally positive
Bacteriuria	Yes	Yes
C-reactive protein	Normal	Increased
Blood cultures	Negative	Positive in ≈10-30%
TREATMENT		
First line	Short-term oral therapy (Table 284-6)	Oral: fluoroquinolone for 7 days Parenteral: cephalosporin, fluoroquinolone, or aminoglycoside for 7-14 days (Table 284-7)
Second line	Fluoroquinolone for 3 days or cephalosporin for 7 days	Injectable cephalosporin until afebrile, followed by oral step-down for total of 2 weeks
Pregnant women	Nitrofurantoin or cephalosporin for 5-7 days	Injectable cephalosporin until afebrile, followed by oral cephalosporin for 14 days

Blood culture specimens should be obtained in all patients with suspected urosepsis. Patients with acute pyelonephritis, but not those with acute cystitis, have increased serum levels of C-reactive protein.

Imaging

Early imaging should be performed in any patient with urosepsis to identify abnormalities that require immediate source control. The optimal imaging modality is an infused computed tomography scan. Magnetic resonance imaging may not identify gas in tissues or small stones. Ultrasound may provide a rapid examination to exclude significant obstruction. Investigations would also be indicated for patients with delayed response or failure to respond to appropriate antimicrobial therapy or if there is early relapse of pyelonephritis after completion of therapy. The optimal management of complicated urinary infection requires characterization of underlying abnormalities and correction of these, whenever possible. Selected patients may require studies for diagnosis of vesicoureteral reflux or to characterize differential renal function.

Differential Diagnosis

Clinical manifestations will usually differentiate acute cystitis and acute pyelonephritis (Table 284-5). New-onset frequency, dysuria, and urgency without accompanying vaginal discharge or pain have a positive predictive value of 90% for acute cystitis. The differential diagnosis for women presenting with acute irritative lower tract symptoms includes sexually transmitted infections, vulvovaginal candidiasis, and noninfectious causes such as interstitial nephritis. Some patients who present with only lower tract symptoms may have renal infection, referred to as occult pyelonephritis. Patients with appendicitis and cholecystitis can present with flank pain similar to right-sided pyelonephritis, and pelvic inflammatory disease may be misdiagnosed as urinary infection.

TREATMENT

Rx

Symptomatic UTIs should be treated with antimicrobials to decrease the duration of symptoms and, for pyelonephritis, to limit damage to renal tissue. Antimicrobials selected for treatment should be excreted renally, so

TABLE 284-6 ANTIMICROBIALS USED TO TREAT CYSTITIS

ANTIMICROBIAL	DOSE* AND DURATION
FIRST-LINE THERAPY	
Trimethoprim	100-150 mg q12h for 3 days
Trimethoprim-sulfamethoxazole	80/400 mg q12h for 3 days or 320/1600 mg single dose
Nitrofurantoin	50 mg q8h for 5-7 days
Nitrofurantoin macrocrystals	100 mg bid for 5 days
Fosfomycin trometamol	3 g single dose
Pivmecillinam	400 mg bid for 3-5 days
OTHER	
Amoxicillin-clavulanate	500 mg (amoxicillin dose) q8h for 7 days
Amoxicillin	500 mg tid for 7 days
Cefpodoxime proxetil	100 mg bid for 3 days
Cefuroxime axetil	500 mg bid for 7 days
Cefixime	400 mg/day for 7 days
Ceftibuten	400 mg/day for 5-7 days
Norfloxacin	400 mg q12h for 7 days
Ciprofloxacin	250 mg q12h for 7 days (500 mg qd extended release)
Levofloxacin	250-500 mg/day for 7 days
Doxycycline	100 mg bid for 7 days

*Doses given are for adults with normal renal function. The need to reduce dosages because of renal impairment related to infection in the kidneys, other renal diseases, or advanced age should always be considered.

high antimicrobial concentrations are achieved in the renal parenchyma and urine.

Cystitis

Table 284-6 lists recommended choices for the antimicrobial treatment of cystitis.[9] The shortest effective treatment duration for the antimicrobial should be used. Trimethoprim, trimethoprim-sulfamethoxazole, fosfomycin, pivmecillinam, and nitrofurantoin are recommended first-line treatments because they are effective with relatively short courses, and because there is limited impact on normal flora, resistance emergence is not a concern. Trimethoprim or trimethoprim-sulfamethoxazole should be selected for initial empirical therapy only if the local prevalence of resistance to these agents in community-acquired *E. coli* infections is less than 20%. Fluoroquinolones are not recommended for first-line therapy as widespread use may lead to the emergence of resistance. β-Lactam antimicrobials are about 10% less effective than the first-line agents. Patients with recurrent cystitis can be effectively managed with a strategy of early self-treatment. Early empirical treatment usually leads to prompt improvement of symptoms. Nitrofurantoin and oral cephalosporins are preferred therapy for pregnant women as these are safe for the fetus.

Pyelonephritis

For antimicrobial treatment of pyelonephritis, the initial decision is whether parenteral treatment is needed or whether oral treatment alone will suffice. Table 284-7 lists antimicrobials suitable for the treatment of pyelonephritis. After initial treatment with a parenteral drug, a transition to oral treatment is normally possible at 24 to 48 hours if the patient has clinically improved. The recommended treatment time is 7 to 14 days.

Complicated Urinary Infection

The antimicrobial regimen selected for treatment of complicated UTI is individualized on the basis of the site of infection, severity of the manifestations, new or presumed infecting organism and susceptibility, tolerance of the patient, and nature of the underlying abnormalities.[10] When symptoms are mild, it is preferable to delay initiation of antimicrobial therapy until results of urine culture are available to allow optimal antimicrobial selection. Empirical antimicrobial therapy should be initiated when severe symptoms are present. Oral or parenteral therapy is selected on the basis of the presentation and the likelihood of resistant organisms. Previous urine culture results from the patient and recent history of antimicrobial exposure are helpful to assess the likelihood of resistant organisms. Nitrofurantoin may be used for episodes of bladder infection but is not effective for renal infection and is contraindicated in individuals with renal failure. The empirical therapy selected should be reassessed after 48 to 72 hours, by which time the urine culture result should be available and the response to initial therapy can be assessed. If the organism

TABLE 284-7 ANTIMICROBIALS USED TO TREAT PYELONEPHRITIS

ROUTE OF ADMINISTRATION AND ANTIMICROBIAL	DOSE* AND DURATION
PARENTERAL	
First-Line Therapy	
Gentamicin	4.5 mg/kg/day × 10-14 days
Tobramycin	4.5 mg/kg/day × 10-14 days
Ciprofloxacin	400 mg q12h × 7 days
Levofloxacin	750 mg/day × 5 days
Cefotaxime	1 g q8h × 10-14 days
Ceftriaxone	1-2 g qd × 10-14 days
Other	
Ceftazidime	1 g q12h × 10-14 days
Ertapenem	1g qd × 10-14 days
Meropenem	500 mg q6h × 10-14 days
Piperacillin-tazobactam	3-375 g q6h × 10-14 days
Doripenem	500 mg q8h × 10-14 days
Amikacin	15 mg/kg/day × 10-14 days
Trimethoprim-sulfamethoxazole	160/800 mg q12h × 14 days
ORAL	
First-Line Therapy	
Ciprofloxacin	500 mg q12h × 7 days
Levofloxacin	250-500 mg/day × 5-7 days
Other	
Amoxicillin-clavulanate	500 mg (amoxicillin dose) q8h × 14 days
Cefuroxime axetil	500 mg q12h × 14 days
Cefixime	400 mg/day × 14 days
Ceftibuten	400 mg/day × 14 days
Cefepime	2 g q12h × 14 days

*Doses given are for adults with normal renal function. The need to reduce dosages because of renal impairment should always be considered.

isolated from a pretherapy urine culture specimen is resistant to the empirical antimicrobial therapy initiated, the antimicrobial regimen should be modified to an agent to which the organism is susceptible, irrespective of the clinical response.[11] Antibiotic prophylaxis at the time of catheter removal can reduce the risk of subsequent symptomatic infection.

Asymptomatic Bacteriuria

Asymptomatic bacteriuria should be treated only in pregnant women[12] or when antimicrobials are given as perioperative prophylaxis before a urologic procedure with trauma to the genitourinary mucosa. For all other populations, including elderly women,[13] treatment of asymptomatic bacteriuria has not been associated with improved outcomes but is uniformly followed by reinfection with organisms of increasing antimicrobial resistance. For some populations, evidence suggests that asymptomatic bacteriuria may protect subjects from symptomatic UTI. Bacteriuria in patients with indwelling catheters should not be treated unless the patient has symptoms attributed to urinary infection. Administration of antimicrobials to catheterized patients with asymptomatic bacteriuria inevitably results in reinfection with more resistant organisms.

Urosepsis

The principles of management of urosepsis are similar to those for patients with severe sepsis from any site. Parenteral empirical antimicrobial treatment and supportive care should be initiated promptly. The antimicrobial selected should provide broad-spectrum coverage for potential uropathogens, including resistant bacteria. Antimicrobial therapy is reassessed when urine and blood culture results become available and the specific infecting organism and susceptibilities are identified.

Funguria

Funguria in catheterized patients should be treated only when there is a symptomatic UTI. Symptomatic infection is treated with fluconazole 400 mg

TABLE 284-8 PROPHYLACTIC REGIMENS TO PREVENT RECURRENT URINARY TRACT INFECTION IN WOMEN

PREFERRED	OTHER
Long-term low dose	
Nitrofurantoin 50 mg od or 100 mg qd	Cephalexin 250-500 mg qd*
Trimethoprim-sulfamethoxazole, 40/200 mg qd or every other day	Norfloxacin 200 mg qd
	Ciprofloxacin 125 mg qd
Postcoital (single dose)	
Nitrofurantoin 50 or 100 mg*	Cephalexin 250 mg*
Trimethoprim-sulfamethoxazole 40/200 mg	Ciprofloxacin 125 mg
Trimethoprim 100 mg	Norfloxacin 200 mg

*Suitable for use in pregnancy.

once daily for 1 day, followed by 200 mg once daily for 7 to 14 days. If *Candida* sp resistant to fluconazole is isolated, amphotericin B deoxycholate is the recommended alternative therapy as other antifungals have limited renal excretion.

Follow-up

Patients do not require follow-up urine cultures unless symptomatic infection persists or recurs. When there is early (<30 days) symptomatic recurrence, the infecting organism should be re-evaluated to ensure that it was susceptible to the antimicrobial given.

PREVENTION

Premenopausal women with recurrent acute uncomplicated UTI should avoid spermicide use. For women with frequent recurrent acute uncomplicated UTI (more than two in 6 months or three in 12 months) presenting as either cystitis or pyelonephritis, prophylactic antimicrobial therapy is effective. This may be given as long-term low-dose prophylaxis or as postintercourse prophylaxis. Suggested regimens for prophylactic antimicrobial therapy are provided in Table 284-8. The use of cranberry tablets or juice does not reliably decrease the frequency of recurrent infection,[A6] and probiotics are not effective. For postmenopausal women, use of topical vaginal estrogens may decrease the frequency of infection.[A5] The use of systemic estrogen, however, is associated with an increased frequency of UTI. Prophylactic antimicrobial therapy is more effective than topical vaginal estrogen in these women.

Pregnant women should be screened for asymptomatic bacteriuria early in the pregnancy, usually at 12 or 16 weeks. If bacteriuria is present, these women should be treated and have subsequent follow-up culture specimens obtained monthly. If either asymptomatic or symptomatic recurrent infection occurs, prophylactic antimicrobial therapy with either cephalexin or nitrofurantoin should be continued through the duration of the pregnancy to decrease the risk for development of pyelonephritis in later pregnancy.

Prophylactic antimicrobial therapy has not been shown to be effective for patients with complicated UTI, including those with spinal cord injury or with chronic indwelling catheters. In these patients, the abnormality leading to impaired voiding means that bacteriuria is unavoidable, and antimicrobial therapy simply promotes bacteriuria with increasingly resistant organisms.

Infection control programs of health care facilities should include practices to prevent catheter-acquired UTI. Evidence-based guidelines provide clear recommendations for program components, including ongoing surveillance.[14] The most important intervention is to avoid the use of an indwelling catheter wherever possible and, when there are clear indications for catheter use, to limit the duration to as short a time as possible. The ultimate solution to the problem of catheter-acquired UTI, however, will require development of biofilm-resistant materials.[15]

PROGNOSIS

The prognosis of uncomplicated cystitis and pyelonephritis is good. Women with acute uncomplicated cystitis who do not receive antimicrobial therapy will usually have resolution of symptoms by 1 to 2 weeks, and about half will be culture negative by 6 weeks. Women with even very frequent recurrent acute uncomplicated UTI[16] experience no long-term adverse outcomes, such as renal impairment or hypertension. A small proportion of women with severe presentations of acute nonobstructive pyelonephritis develop renal scars, but these are not associated with impaired renal function. Patients with frequent recurrent complicated UTI may experience substantial morbidity with recurrent infections, but poor long-term medical outcomes are usually determined by the underlying abnormality rather than by infection. Patients with urosepsis have a fatality rate of about 10%. Factors increasing the risk of death are advanced age and significant underlying diseases as well as inadequate initial antimicrobial treatment.

REVIEW QUESTIONS

1. A 32-year-old gravida 2 para 1 woman presents to the obstetric emergency department at 29 weeks' gestation with temperature of 39.2° C and right costovertebral angle pain and tenderness. There is associated vomiting; the blood pressure is stable. She has no history of prior urinary tract infection and has received no antimicrobial therapy during this pregnancy. Intravenous rehydration therapy is initiated, and blood and urine culture specimens are obtained. What is the most appropriate next step?

A. Await results of cultures before initiating antimicrobial therapy.
B. Initiate therapy with ciprofloxacin, 500 mg PO bid.
C. Initiate therapy with ceftriaxone, 1 to 2 g IV q24h.
D. Initiate therapy with levofloxacin, 750 mg IV q24h.
E. Await results of computed tomography scan before initiating antimicrobial therapy.

Answer: C Pregnant women presenting with acute pyelonephritis at this time of gestation are at high risk for premature labor and delivery at a vulnerable stage for the fetus. Empirical antimicrobial therapy should be initiated promptly, and initial therapy should be parenteral. Fluoroquinolone antimicrobials are contraindicated for pregnant women because of concerns with fetal cartilage development. There is no suggestion from her history that she has an increased risk for a resistant organism, and parenteral ceftriaxone would be the treatment of choice. (Vazquez JC, Abalos E. Treatments for symptomatic urinary tract infections during pregnancy. *Cochrane Database Syst Rev.* 2011;1:CD002256.)

2. A 22-year-old woman presents to her family physician with a second episode consistent with acute cystitis in the past 6 months. The previous episode responded promptly to empirical short-term antimicrobial therapy. She is sexually active in a stable monogamous relationship. Empirical antimicrobial therapy is again prescribed for treatment of this episode. What additional advice should she be given with respect to behavioral modification to decrease her risk of subsequent recurrent infection?

A. Ensure bladder voiding immediately after sexual intercourse.
B. Discontinue use of spermicide birth control method.
C. After bowel movements, she should wipe herself from front to back.
D. Increase her intake of cranberry juice.
E. Use showers rather than baths for personal hygiene.

Answer: B The only behavioral risk factor, other than sexual intercourse, that is modifiable is discontinuation of use of spermicide for birth control. Use of spermicide for birth control is associated with at least a two-fold higher risk for recurrent urinary tract infection in sexually active young women. Whereas early studies suggested a modest benefit of cranberry capsules, more recent studies report no significant improvements with the use of cranberry products. The other interventions suggested have consistently been reported not to be associated with recurrent urinary tract infection. (Gupta K, Hooton TM, Naber KG, et al. Executive summary: international clinical practice guidelines for the treatment of acute uncomplicated cystitis and pyelonephritis in women: a 2010 update by the Infectious Diseases Society of America and the European Society for Microbiology and Infectious Diseases. *Clin Infect Dis*. 2011;52:561-564; and Beerepoot MA, Geerlings SE, van Haarst EP, et al. Nonantibiotic prophylaxis for recurrent urinary tract infections: a systematic review and meta-analysis of randomized controlled trials. *J Urol.* 2013;190:1981-1989.)

3. A 42-year-old man with a high-level cervical spinal cord injury was admitted to the rehabilitation unit 2 weeks ago. There is an indwelling catheter in place for bladder management. He has a single temperature elevation to 38.2° C with no localizing findings. Complete blood count and urine and blood culture specimens are obtained. The white blood cell count was normal, and after 48 hours, the blood culture is negative but the urine specimen has returned growing *E. coli* of more than 10^8 CFU/mL and an enterococcus of more than 10^8 CFU/mL. He remains afebrile and otherwise stable. What is the appropriate approach to management at this time?

A. Remove the indwelling catheter and begin intermittent catheterization for management of bladder emptying.
B. Obtain ultrasound and urodynamic studies to exclude urolithiasis.
C. Institute antimicrobial therapy for treatment of the organisms isolated from the urine culture.
D. No changes in management are required.
E. Request urologic consultation.

Answer: D This patient has a chronic indwelling catheter and will be bacteriuric at any time. Thus, the urine culture would be expected to be positive. In the absence of clinical evidence of infection, such as elevated white blood cell count or continuing fever, this is asymptomatic bacteriuria, and antimicrobial therapy is not indicated. It is desirable to remove the indwelling catheter as soon as possible, but in a patient with a high-level cervical spine injury, intermittent catheterization by the patient himself is unlikely to be feasible. All spinal cord–injured patients require urodynamic assessment, but this single fever and positive urine culture would not be an indication for evaluation outside normal management. (Nicolle LE. Urinary tract infections in special populations: diabetes, renal transplant, HIV infection, and spinal cord injury. *Infect Dis Clin North Am.* 2014;28:91-104.)

4. A 63-year-old man presents with temperature of 39.2° C associated with rigors; blood pressure is 70/40. He was diagnosed with a ureteric stone complicated by ureteric obstruction 36 hours previously and 12 hours before fever onset had successful endourologic intervention to extract the stone. The urine culture specimen collected before the procedure is growing *E. coli* of more than 10^8 CFU/mL, but susceptibilities are not yet available. Ciprofloxacin 500 mg PO bid had been initiated before the procedure. What is the appropriate approach at this time?

A. Continue the ciprofloxacin initiated, pending susceptibility information.
B. Change to oral cefixime, 400 mg once daily, to cover potential resistant organisms.
C. Initiate broad-spectrum parenteral antimicrobial therapy effective for ciprofloxacin-resistant *E. coli* immediately.
D. Initiate antimicrobial therapy with gentamicin plus ampicillin to cover additional pathogens.
E. Give a bolus of normal saline and reassess the patient in 4 to 6 hours.

Answer: C This patient has a presumptive diagnosis of postsurgical sepsis. It is essential that effective antimicrobial therapy, together with other supportive therapy, be initiated immediately. When patients progress to septic shock, one variable associated with mortality is delayed institution of effective antimicrobial therapy. In this case, it is possible that the patient has a ciprofloxacin-susceptible organism and the obstruction prevented access of antimicrobial to the infected site. It is also possible that a new organism was introduced at the time of the surgical procedure. However, as the organism may be resistant to ciprofloxacin, broad-spectrum parenteral therapy to cover potentially resistant organisms should be selected. This could be piperacillin-tazobactam or a carbapenem. Gentamicin and ampicillin are usually also reasonable choices. However, given the likelihood of resistant organisms, this regimen may not provide full coverage, and broader spectrum agents seem more appropriate. Blood and urine cultures should be repeated before initiation of the antimicrobial therapy. Obviously, the antimicrobial therapy should be reassessed and appropriate modifications made once the culture results and susceptibilities are available. (Nicolle LE. Urinary tract infection. *Crit Care Clin*. 2013;29:699-716.)

5. An 82-year-old woman with poorly controlled type 2 diabetes is admitted to the intensive care unit with respiratory failure complicating pneumococcal pneumonia. An indwelling urethral catheter was inserted for output monitoring on admission. Because of initial uncertainty about the etiology of her pneumonia, she was treated empirically with broad-spectrum therapy of meropenem and azithromycin. These have been continued, despite *S. pneumoniae* isolated in blood cultures being susceptible to penicillin G. Seven days after admission, the urine is observed to be cloudy, and the nurse sends a urine specimen for culture. It returns with a report of isolation of *Candida albicans* of more than 10^8 CFU/mL. The patient is afebrile and, while still requiring ventilatory support, is showing improvement in oxygenation. What is the appropriate response to the urine culture report?

A. Institute fluconazole 400 mg once daily for *Candida* urinary tract infection.
B. Obtain a blood culture sample for yeast species.
C. No interventions are required.
D. Review the need for the indwelling catheter and remove it if possible.
E. Repeat the urine culture to confirm *Candida* funguria.

Answer: D This patient has diabetes, is receiving broad-spectrum antimicrobial therapy, and has an indwelling catheter in situ. These are the three most important risk factors for acquisition of candiduria. There is no clinical evidence to suggest symptomatic infection from a urinary source. The diagnosis is asymptomatic candiduria, and antifungal treatment is not indicated. For any patient with an indwelling urethral catheter, the need for continuing use of the catheter should be reassessed on a daily basis and the catheter removed as soon as it is no longer necessary to limit development of complications. If the indwelling catheter cannot be removed in this patient, there is no indication for other interventions relevant to the candiduria as long as the patient is clinically improving. (Kauffman CA. Diagnosis and management of fungal urinary tract infection. *Infect Dis Clin North Am*. 2014; 28:61-74.)

285

APPROACH TO THE PATIENT WITH A SEXUALLY TRANSMITTED INFECTION

HEIDI SWYGARD AND MYRON S. COHEN

SEXUALLY TRANSMITTED INFECTIONS

DEFINITION

Sexually transmitted infections (STIs) include a wide variety of organisms that are transmitted through intimate contact involving skin or mucosal surfaces of the oropharynx, vagina, penis, and rectum. STIs can generally be divided into five broad categories (syndromes): urethritis, genital ulcers, epithelial cell disorders, female vaginal discharge, and ectoparasites (Table 285-1).

ETIOLOGY

The interaction between the host and the STI pathogen plays a critical role, and characteristic tissue changes offer exceptionally strong clues about etiology. Several STI pathogens cause local inflammation only (*Neisseria gonorrhoeae*, *Chlamydia trachomatis*, *Trichomonas vaginalis*), with the potential for local tissue invasion (*N. gonorrhoeae*, *C. trachomatis*) or systemic dissemination (*N. gonorrhoeae*). Some STI pathogens cause tissue ulceration (*Treponema pallidum*, *Haemophilus ducreyi*, herpes simplex viruses 1 and 2). Human papillomaviruses (HPVs) cause epithelial cell changes and predispose to neoplasm. Several STI pathogens (human immunodeficiency virus [HIV], hepatitis B and C viruses, cytomegalovirus) routinely use the genital tract for access without causing any local changes.

EPIDEMIOLOGY

STIs are among the most common infections worldwide, and most are never reported. Each year there are almost 10 million new STIs reported among persons aged 15 to 24 years in the United States alone; many infections are subclinical and may escape detection, suggesting that these numbers are an underestimate. Of great concern, STIs are generally transmissible whether they are symptomatic or asymptomatic.

TABLE 285-1 SYNDROMES OF SEXUALLY TRANSMITTED DISEASES

SYNDROME	ORGANISM
URETHRITIS	
Gonococcal	*Neisseria gonorrhoeae*
Nongonococcal	*Chlamydia trachomatis* *Trichomonas vaginalis* *Mycoplasma genitalium* *Ureaplasma urealyticum* Herpes simplex (primary infection)
GENITAL ULCERS	
Syphilis	*Treponema pallidum*
Genital herpes	Herpes simplex
Chancroid	*Haemophilus ducreyi*
EPITHELIAL CELL INFECTIONS	
Genital warts	Human papillomavirus
Molluscum	Molluscum contagiosum
Cervical neoplasia	Human papillomavirus types 16 and 18
FEMALE GENITAL DISCHARGE	
Cervicitis	*Neisseria gonorrhoeae* *Chlamydia trachomatis* *Trichomonas vaginalis* Herpes simplex
Pelvic inflammatory disease	*Neisseria gonorrhoeae* *Chlamydia trachomatis*
Vaginitis	*Trichomonas vaginalis* *Candida albicans*
Bacterial vaginosis	*Gardnerella vaginalis*, anaerobes
ECTOPARASITES	
Pubic lice	*Phthirus pubis*
Scabies	*Sarcoptes scabiei*

Chlamydia, gonorrhea, and syphilis are reportable to the U.S. Centers for Disease Control and Prevention. The incidence of primary and secondary syphilis declined in the 1990s, but since 2000, rates have been increasing among men (8.2 cases per 100,000 in 2011, a 3.8% increase compared with 2010) and men aged 20 to 29 years (23.4 cases per 100,000). Rates declined 9.1% in women (from 1.1 cases per 100,000 to 1.0 case per 100,000). Men who have sex with men accounted for 72% of all cases of primary and secondary syphilis reported in 2011. Following a nadir of 98.1 cases per 100,000 in 2009 (since reporting for gonorrhea began), gonorrhea rates increased slightly (104.2 cases per 100,000 in 2011). Rates are highest among the 15- to 24-year age group for both sexes.

For other STIs, seroprevalence and national surveys provide data that suggest a high burden of viral STIs. From the 2005 to 2008 National Health and Nutrition Examination Survey (NHANES), herpes simplex virus 2 (HSV-2) was shown to affect 16.2% of the survey sample for those aged 14 to 49 years; of 20- to 49-year-old participants seropositive for HSV-2, only 18.9% had been previously diagnosed. Data from NHANES collected between 2001 and 2004 show an overall prevalence of 3.1% for women, with the highest percentage among African American women (13.3%).

The spread of STIs depends on the organism and the host, the length of time an infected person remains contagious, and the number of people exposed. These parameters have been reduced to the following formula:

$$R_o = B \times D \times C$$

where R_o is the basic reproductive rate of an infection, or the mean number of secondary cases a typical single infected person will cause in a population; B is the efficiency of transmission; D is the duration of infectiousness; and C is the number of sexual partners.

PATHOBIOLOGY

The STI pathogens depend entirely on human-human transmission, although *T. vaginalis* may have some inanimate sources. The efficiency of transmission reflects the infectiousness of the index case (which depends on the concentration and phenotype of the organism in the genital tract) and the susceptibility of the sexual partner (which reflects the resistance of the host, whether it is hereditary, acquired, or innate). Because immunity to STIs is rare, reinfections are common, and vaccine development has been difficult; the only STI vaccines available target hepatitis B and HPV.

STIs produce syndromes precisely because each pathogen has a proclivity for one or more tissues and (when symptomatic) can evoke a predictable inflammatory response. For example, gonococci that infect the male urethra generally produce an intense neutrophil response that leads to a purulent discharge and pain with urination, whereas *C. trachomatis* is less likely to produce such a response in the same tissue and is more likely to produce a mild, watery discharge or no symptoms at all.

STIs serve as markers for sexual risk-taking behavior, so coinfections are common. The detection of an STI should lead to a variety of other (seemingly unrelated) tests. STI pathogens move together: gonorrhea and chlamydia cause urethritis; genital ulcers greatly increase the probability of HIV acquisition.

DIAGNOSIS AND TREATMENT

Syndromic Strategies

For a variety of common STI syndromes, treatment of the index case (based on signs and symptoms) is empirical, as is treatment of sexual partners. This approach reflects the facts that the diagnostic accuracy of some tests is imperfect, coinfection demands concomitant therapy that overrides the search for individual pathogens, and patients who are not treated immediately may not return for therapy. Genital ulcer disease and urethral discharge have high sensitivity and specificity compared with laboratory diagnosis, and empirical therapy is so successful that follow-up care ("proof of cure") is usually unnecessary. However, the vaginal discharge syndrome is far less sensitive or specific in terms of true STI diagnosis.[1] In a study of South African women, almost 90% with a laboratory-confirmed STI diagnosis had no clinical symptoms and would therefore not have been treated.[2]

The syndromic approach is particularly critical in resource-constrained countries or in areas of the United States where laboratory tests are not available or their cost is prohibitive. In the United States, concomitant microbiologic diagnosis is preferred because it (1) confirms the choice of empirical therapy or redirects subsequent care; (2) permits the detection and monitoring of resistance to treatment; and (3) enables specific diagnoses to be reported to public health authorities, which is required by state law for many STIs. However, even when laboratory tests are ordered, the most appropriate agents should be provided empirically at the point of care to resolve infection and to reduce onward transmission.

Relationship of STIs to HIV Infection

Diagnosis of an STI demonstrates increased sexual risk-taking behavior and inconsistent condom use and serves as a marker for potential HIV infection. Any patient undergoing evaluation or treatment for an STI should be tested for HIV infection. Early diagnosis of HIV infection has major personal and public health benefits.

Nevertheless, STIs also contribute to HIV acquisition and hamper efforts at optimal prevention of HIV transmission. Genital ulcers increase HIV replication in the infected person. Genital ulcers disrupt the epithelium and allow the entry of HIV; inflammation caused by ulceration recruits macrophages and lymphocytes, increasing the number of target cells for HIV.

SYNDROMES

Urethritis

Urethritis is characterized by some combination of urethral discharge and dysuria, but prostatitis can cause similar complaints. Urethritis is caused by a limited group of pathogens (see Table 285-1) that may be difficult to visualize microscopically or to grow in culture. Accordingly, empirical therapy is provided to treat a spectrum of potentially causative organisms.

Urethritis is diagnosed when one or more of the following are demonstrated: (1) mucopurulent or purulent urethral discharge, (2) Gram stain of urethral secretions demonstrating five or more leukocytes per oil immersion microscopic field, (3) positive leukocyte esterase test result on first-void urine, or (4) microscopic examination of first-void urine demonstrating 10 or more leukocytes per high-power field. If no discharge can be expressed from the urethral meatus, a calcium alginate swab can be inserted 5 mm into the urethra; the material collected is transferred to a slide by rolling the swab along the glass.

A Gram stain of urethral discharge is a simple and rapid diagnostic test to document both urethritis and gonococcal infection (Chapter 299),

TABLE 285-2 SYNDROMIC TREATMENT OF URETHRITIS

GONOCOCCAL*
Recommended
Ceftriaxone 250 mg injected intramuscularly once, *and* Azithromycin 1 g orally (single dose)
NONGONOCOCCAL
Recommended
Azithromycin 1 g orally (single dose), *or* Doxycycline 100 mg orally twice daily for 7 days
Alternative
Erythromycin base 500 mg orally four times daily for 7 days, *or* Erythromycin ethylsuccinate 800 mg orally four times daily for 7 days, *or* Ofloxacin 300 mg orally twice daily for 7 days, *or* Levofloxacin 500 mg orally once a day for 7 days

*Uncomplicated anorectal and genital disease.

characterized by the detection of leukocytes containing intracellular gram-negative diplococci. Confirmation of gonococcal urethritis does not rule out concomitant infection with *Chlamydia* or *Mycoplasma.* As culture and Gram stain have become less popular or less available, nucleic acid amplification tests that are highly sensitive and specific for the detection of organisms have been used routinely. Nucleic acid amplification tests for gonorrhea, *Chlamydia*, and *Trichomonas* can be applied to first-void urine samples (the meatus is intentionally not cleaned so that the urine is contaminated with these organisms) or urethral swab material. Specific diagnosis may enhance the management of sexual partners, and the results from such tests should be reported to the health department. However, in practice, patients and (in most cases) sexual partners must be treated before the results of these tests are available.

Treatment for urethritis should be initiated as soon as possible after the clinical diagnosis and should be directly observed if feasible (Table 285-2). *N. gonorrhoeae* (Chapter 299) has become resistant to many antimicrobials, including quinolones and oral cephalosporins, which are no longer recommended. Thus, the choice of optimal therapies is limited. Dual therapy with azithromycin and ceftriaxone increases the cure rate of uncomplicated urogenital, anorectal, and pharyngeal gonorrhea. Azithromycin can also be expected to cure most cases of nongonococcal urethritis (NGU), including those caused by *Mycoplasma genitalium*, an increasingly recognized cause of NGU. Some studies suggest that doxycycline is more effective than azithromycin for NGU, but a longer course of treatment dependent on the patient's adherence must also be considered. Currently, there is no commercially available diagnostic test for *M. genitalium*, which complicates the treatment question. In some settings in which *M. genitalium* is a consideration, persistent or recurrent NGU should be treated with moxifloxacin for 7 to 10 days.[3] *T. vaginalis*, which is susceptible to metronidazole or tinidazole, also causes urethritis and should be considered in the face of NGU treatment failure.

Women with urethritis present with some combination of dysuria and pyuria, which must be differentiated from bacterial cystitis. Because treatment for urinary tract pathogens may also resolve sexually transmitted urethritis, the clinician treating a presumed bladder infection should consider an STI as well.

Genital Ulcers

In the United States, HSV-1 and HSV-2 (Chapter 374) and *T. pallidum* are responsible for virtually all the ulcers encountered, and HSV-1 and HSV-2 are by far the most common cause.

LYMPHOGRANULOMA VENEREUM

Lymphogranuloma venereum, caused by a serovar of *C. trachomatis* (Chapter 318), is characterized by local lymph node suppuration, ulceration and subsequent fibrosis, fistula formation, and distal edema. Lymphogranuloma venereum has increasingly been emerging as a concern in HIV-infected men who have sex with men, particularly in Europe.

GENITAL HERPES

Genital herpes usually develops after an incubation period of less than 21 days and arises as clustered vesicles on an erythematous base. The vesicles become pustular and then rupture to form shallow, painful ulcers, which may coalesce. The ulcers heal by crusting over, and the process is usually completed 2 to 3 weeks after the initial lesions. Recurrences proceed through the same stages but generally last only about 5 to 7 days. The first (incident) episode of HSV-2 infection may be accompanied by systemic signs and symptoms including fever and headache, the latter reflecting the spread of HSV to the central nervous system. HSV-2 is the putative cause of Mollaret's recurrent meningitis. It may appear after a primary genital infection or as reactivation. It may also occur in the absence of genital lesions or a known diagnosis of HSV-2 infection.

About 20% of infected individuals manifest the classic genital presentation, 60% have mild and atypical signs and symptoms, and at least 20% are completely asymptomatic. Individuals who have acquired HSV-2 shed the virus approximately 3 to 4% of the time (even while asymptomatic), posing an ongoing risk to sexual partners.

SYPHILIS

The ulcerative lesion of syphilis (Chapter 319)—the chancre—is indurated and painless, and in many cases it escapes detection. Dark-field examination of scrapings suspended in saline from a genital ulcer may reveal motile spirochetes, and this finding is diagnostic. Secondary syphilis results when the spirochetes spread systemically, leading to a characteristic rash, alopecia, oral mucous patches, or condyloma latum. These skin manifestations should prompt testing for syphilis. The serologic screening test of choice for syphilis is based on the formation of antibodies to cardiolipin, a constituent of the spirochetal cell wall (e.g., rapid plasma reagin test, Venereal Disease Research Laboratory [VDRL] test, toluidine red unheated serum test [TRUST]). Confirmatory testing requires the search for an antitreponemal antibody (e.g., microhemagglutination assay–*T. pallidum*, fluorescent treponema antibody test). The anticardiolipin test provides a titer that must be used to monitor the response to treatment.

Some larger commercial laboratories have reversed the order of testing, using an antitreponemal test followed by an anticardiolipin test, which allows automation and may be cost-effective in areas of low endemicity. This represents a change in testing and interpretation and must be done with caution[4] because such an approach cannot immediately separate old, treated infections from new infections (Fig. 285-1).

Later stages of syphilis may be identified only serologically or on pathologic specimens. Late latent syphilis and syphilis of unknown duration are managed similarly. Neurosyphilis can occur at any stage of infection and should be suspected in any patient with a positive serologic test result who also has findings suggestive of nervous system involvement, including ocular and vestibular symptoms.

Worldwide, syphilis infection has been detected in a substantial number of people with recognized or unrecognized HIV infection, especially men who have sex with men. Accordingly, the diagnosis of syphilis requires HIV testing.

CHANCROID

Chancroid (Chapter 301), infection with *H. ducreyi*, produces painful, ragged ulcers and tender inguinal lymphadenopathy, which may be fluctuant. Unlike the lesions of HSV infection, these genital ulcers are likely to vary in size.

Epithelial Cell Infections

HUMAN PAPILLOMAVIRUS

Sexually transmitted HPV infection (Chapter 373) is generally transient and asymptomatic, but some patients develop visible genital warts. These warts are painless, soft, moist, pink or flesh-colored swellings that vary in shape and can be raised or flat, single or multiple, small or large, and sometimes cauliflower shaped. Warts occur in the vulva, vagina, and anus; on the cervix; and on the penis, scrotum, groin, or thigh. Genital warts are diagnosed by visual inspection. Treatment is primarily with topical agents but is generally not curative.

Two oncogenic HPV genotypes (16 and 18) are responsible for at least 85% of all cervical neoplasia, and HPV types 6 and 11 are responsible for most cases of genital warts. HPV vaccines are available that target these genotypes. Papanicolaou smears are recommended for sexually active women beginning at the age of 21 years, regardless of risk factor or age at coitarche; HPV testing, however, is not recommended for women younger than 30 years. Frequency of rescreening is influenced by age, previous screening results, and HPV results. An increasing incidence of oral HPV is associated with head and neck squamous cell carcinomas, with more than 70% of U.S. cases demonstrating detectable HPV. Male gender, smoking, and HIV-positive status are significantly associated with prevalent oral HPV.[5]

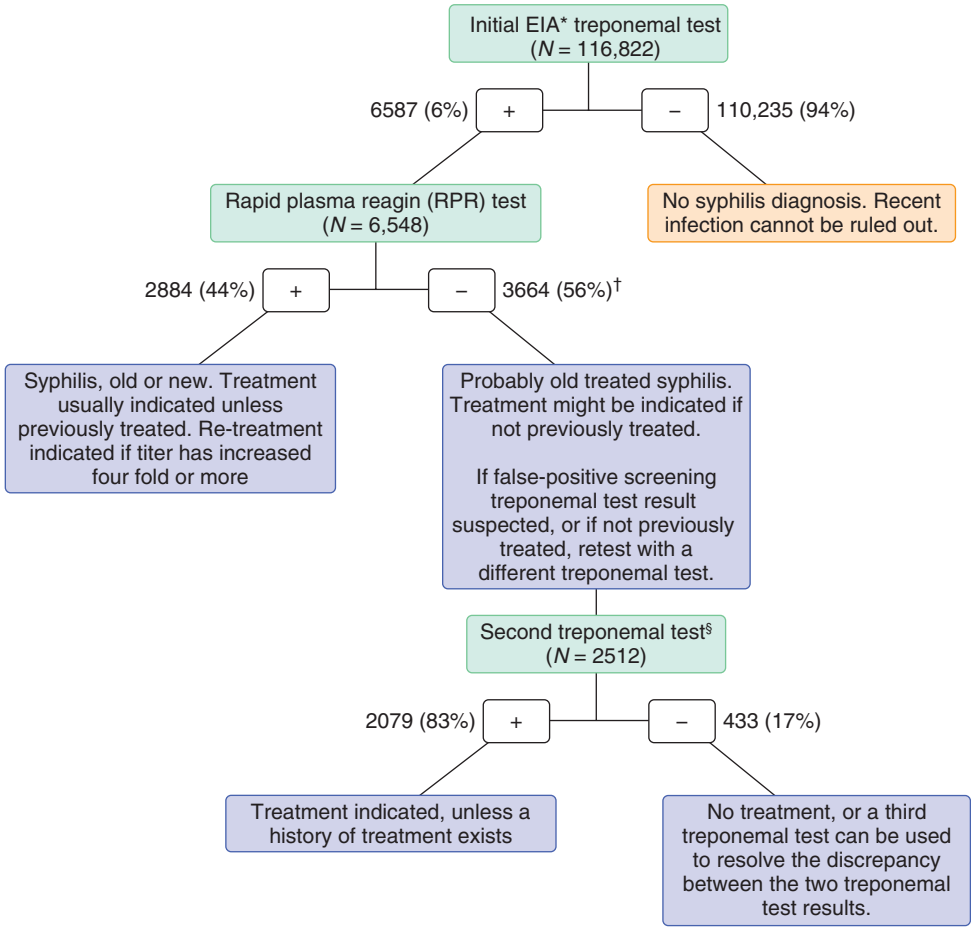

FIGURE 285-1. **Syphilis testing algorithms using treponemal tests for initial screening and recommendations from the Centers for Disease Control and Prevention, 2008. *Enzyme immunoassay. †Reactive with EIA treponemal test but nonreactive with RPR test. §Using *Treponema pallidum* particle agglutination or fluorescent treponemal antibody tests. (Redrawn from the Centers for Disease Control and Prevention. Syphilis testing algorithms using treponemal tests for initial screening—four laboratories, New York City, 2005-2006. *MMWR Morb Mortal Wkly Rep*. 2008;57:872-875.)**

Two HPV vaccines are currently approved by the Food and Drug Administration for use in males and females: a quadrivalent vaccine (protecting against HPV types 6, 11, 16, and 18), and a bivalent vaccine (protecting against HPV types 16 and 18). The quadrivalent vaccine protects against anal precancers and may influence future vaccine recommendations.

Female Genital Discharge

Infections of the female genitourinary tract produce several syndromes with overlapping symptoms (dysuria, vaginal discharge, vulvar irritation), the cause of which can usually be established with a careful history, examination, and laboratory tests. The initial approach depends on the primary anatomic site of infection—urinary tract, endocervix, or vagina. The columnar epithelium of the endocervix is susceptible to infection with *N. gonorrhoeae*, *C. trachomatis*, and *T. vaginalis*, and the vagina is susceptible to infection with *Candida albicans*, *T. vaginalis*, and the syndrome of bacterial vaginosis. The cervix may appear completely normal in women with cervical infection, but mucopurulence at the cervical os or mucosal friability suggests infection. Vaginitis is associated with a visible discharge, and the characteristics of the vaginal fluid offer diagnostic clues.

Female genital discharge is a condition in which syndromic management strategies generally lack sensitivity and specificity. In women with vaginal discharge, microscopic examination of a wet mount preparation may enhance the effectiveness of syndromic treatment, but interpretation of results is difficult and cannot exclude infection with several pathogens concurrently.

BACTERIAL VAGINOSIS

Bacterial vaginosis (BV) is the most common cause of vaginal discharge in the United States. Women with BV are often minimally symptomatic but may note mild vaginal discharge and vaginal odor (which is often increased after coitus). The normal vaginal flora contains hydrogen peroxide–producing lactobacilli such as *Lactobacillus crispatus* and *Lactobacillus jensenii*, which probably help "defend" the vagina against a number of pathogens (an example of innate immunity). *Lactobacillus acidophilus* is rarely found in the normal vagina, which explains the failure of yogurt to serve as a remedy or a preventive. BV begins with the unexplained disappearance of the normal vaginal flora and its replacement with *Gardnerella vaginalis* and many species of anaerobic bacteria. The precise mechanism causing this shift in vaginal flora is poorly understood. Most recently, previously unrecognized anaerobic bacterial species (BV-associated bacteria) have been described as potentially causative. In a study of 220 women with BV, the vaginal milieu demonstrated great species diversity. African American women without BV at the time of sampling had higher numbers of BV-associated bacteria, which could contribute to an increased risk of BV.[6]

The discharge of BV is homogeneous and may contain bubbles. Vaginal pH is elevated above the normal 4.0 to 4.5. Adding 10% potassium hydroxide to the vaginal discharge on the microscope slide or to the discharge present in the extracted speculum elicits an amine-like, fishy odor, yielding a positive "whiff" test result because of the elaboration of amines from the anaerobic flora. Examination of vaginal material as a wet mount reveals the absence of bacilli and their replacement with clumps of coccobacilli. Some vaginal epithelial cells are coated with coccobacilli, which may obscure their edges (clue cells) or the normally clear appearance of the cytoplasm. Relatively few polymorphonuclear leukocytes are observed; large numbers of leukocytes in the wet mount of a woman with BV suggest a coincident infection, possibly trichomoniasis or bacterial cervicitis.

BV is not necessarily a benign change in flora. It is associated with an increased rate of upper tract infection (endometritis, salpingitis) and, on occasion, with complications of pregnancy, including premature rupture of the membranes and preterm delivery. However, treatment of asymptomatic women with BV who are not at high risk for preterm delivery appears to confer no benefit. Women with BV may have increased risk for the acquisition of HIV. Treatment is generally directed against the anaerobic flora and

consists of metronidazole or clindamycin for 7 days. A single oral dose of metronidazole is not recommended for BV because of the high failure rate. The BV relapse rate is about 30%, and treatment of male sexual partners offers no benefit.

CANDIDIASIS

Vulvovaginal candidiasis (Chapter 338) is common and is seen most frequently in women taking antibiotics or using oral contraceptives when endogenous *Candida* species outgrow normal bacterial flora. Women usually complain of vulvar itching and discomfort and may or may not notice an accompanying discharge. The vagina generally maintains normal numbers of lactobacilli, so the vaginal pH is usually normal, which is helpful in discriminating between candidiasis and other vaginal infections. The labia and vaginal walls may be erythematous. Although classically described as "curdy," the discharge of candidiasis is frequently loose and is difficult to distinguish from other discharges. Vaginal material may be treated with 10% potassium hydroxide to destroy other cellular elements and to make the fungi easier to observe. Wet mount, however, has a sensitivity of only about 50%, and a woman with a classic clinical presentation should be treated even if fungal elements are not observed.

A wide range of topical antifungal medications are available (many without a prescription), and all these drugs are approximately equally effective, although the cure rate with some single-dose topical treatments appears to be lower than that with longer regimens. Fluconazole administered as a single oral dose of 150 mg is highly effective. Infection with yeasts other than *C. albicans* may require longer therapy. Recurrent vulvovaginal candidiasis is a problem for many women, and optimal management has not been defined. Recurrent infection should lead the clinician to consider underlying diabetes mellitus or HIV infection. Treatment of sexual partners of women with candidiasis confers no benefit.

TRICHOMONIASIS

Women with *T. vaginalis* infection complain of a purulent discharge and vulvar irritation. The vaginal walls are red, and the vagina may contain excessive yellow or green discharge displaying large bubbles. The ectocervix may also be inflamed or have punctate microhemorrhages, causing the pathognomonic "strawberry cervix" (colpitis macularis). Vaginal pH is elevated, but the whiff test result is generally negative. Wet mount reveals large numbers of polymorphonuclear leukocytes as well as motile protozoa about the same size as the leukocytes, with visible flagella; motile organisms may be recognized in about two thirds of cases. Therapy for trichomoniasis requires metronidazole or tinidazole, but resistant organisms are encountered with increasing frequency.

CERVICITIS

The diagnosis of cervicitis is suggested by tenderness on bimanual examination, visible inspection revealing inflammation, or discharge. The specific diagnosis can be made only by detecting microorganisms from the cervix. *N. gonorrhoeae* and *C. trachomatis* have tropism for cervical tissue, whereas other pathogens (including HIV) can apparently infect the vaginal tissues as well.

PELVIC INFLAMMATORY DISEASE

Each year, more than 800,000 women develop pelvic inflammatory disease (PID) in the United States. The majority of PID cases involve *N. gonorrhoeae*, *C. trachomatis*, and *Mycoplasma* (especially *M. genitalium*); however, one third of PID cases are due to other anaerobic and aerobic bacteria that ascend from the cervix into the uterine cavity, producing endometritis, and then extend to the fallopian tubes, causing salpingitis. Treatment should include therapy directed at anaerobes. Chlamydial salpingitis may be mild, and patients may not seek medical attention. Some intrauterine devices have been associated with an increased risk of salpingitis, and some data suggest that vaginal douching is a predisposing factor.

Adnexal tenderness on bimanual examination leads to the clinical diagnosis of salpingitis. Cervical tenderness, fever, leukocytosis, and an elevated sedimentation rate are sometimes observed. The clinical diagnosis is confirmed laparoscopically in only about 70% of cases, suggesting considerable error in diagnosis. Vaginal ultrasonography or computed tomography is often helpful in defining the cause of pelvic pain syndromes. Pregnant women with evidence of salpingitis should be hospitalized. Other indications for hospitalization include nonresponse to or intolerance of an oral regimen, presence of a tubo-ovarian abscess, and inability to rule out a surgical emergency, such as appendicitis.[7] Infertility complicates approximately 15% of initial attacks of salpingitis and about 75% of women who suffer three or more attacks. Ectopic pregnancy, infertility, and tubo-ovarian abscess are complications of salpingitis.

PREVENTION

STIs are preventable. The Centers for Disease Control and Prevention recommends five strategies as the foundation for an effective prevention program: (1) education and counseling of persons at risk to motivate the adoption of safer sexual behavior; (2) identification of asymptomatic infected persons and symptomatic persons unlikely to seek diagnostic and treatment services; (3) rapid and effective diagnosis and treatment of infected persons; (4) evaluation, treatment, and counseling of exposed sexual partners; and (5) preexposure vaccination of persons at risk for vaccine-preventable STIs.

Behavioral Interventions

Abstaining from sexual intercourse or being in a long-term, mutually monogamous relationship with an uninfected partner is the most reliable way to prevent STIs. Abstinence should be recommended during treatment for an STI and for anyone who wants to avoid STIs and unintended pregnancy. Both partners should be tested for STIs, including HIV infection, before initiating sexual intercourse.

Counseling is essential for people with STIs. Interactive counseling, video presentations, peer groups, and other formats that emphasize correct condom use have reduced the incidence of subsequent infections among STI clinic patients and adolescents. Randomized controlled trials demonstrate that structured risk reduction counseling can reduce the incidence of infections by 25 to 40% among some STI clinic populations. HIV testing is preceded by a counseling session, but there is little evidence of a preventive benefit from this communication.

Barrier Methods

When used consistently and correctly, male latex condoms are effective in preventing the sexual transmission of HIV infection and can reduce the risk of other STIs (gonorrhea, chlamydia, and trichomoniasis). However, because condoms do not cover all exposed areas, they are likely to be more effective in preventing infections transmitted by fluids from mucosal surfaces (e.g., gonorrhea, chlamydia, trichomoniasis, HIV infection) than in preventing those transmitted by skin-to-skin contact (e.g., HSV, HPV, syphilis, chancroid). Male condom failure usually results from inconsistent or incorrect use rather than from condom breakage. Non-latex condoms (those made of polyurethane or other synthetic material) can be used by persons with latex allergy. There is less information available on the effect of female condoms on the incidence of STIs. Although cervical caps and diaphragms cover the cervix, there is little evidence that they can prevent STIs or HIV infection.

Male Circumcision

Male circumcision reduces mucosal tissue susceptible to HIV and STI pathogens. Circumcision of adult men reduces the acquisition of HIV by more than 70% for up to 5 years after circumcision. Circumcision also appears to reduce the acquisition of other viral STI pathogens, including HSV-2 and HPV.

Partner Services

The detection of an STI demands consideration of the infected person's sexual partners, who may have undetected and serious disease. In addition, in the absence of partner treatment, reinfection of the index case can be expected. The probability that a sexual partner is also infected reflects the efficiency of transmission of the STI pathogen, as described earlier. For example, most men with gonococcal urethritis infect their partners, whereas only about half of patients with HIV infection have infected their partners at the time of outreach; partners who differ in terms of STI or HIV infection status are referred to as discordant.

Sexual partners can be notified directly by the infected person or by health care workers, sometimes through proactive contact tracing. In general, dependence on the infected person is a less reliable way to get partners treated. However, in many states it is legal to pursue expedited care by providing the infected patient with the appropriate treatment for his or her partners. Expedited partner care appears to work well for the treatment of gonorrhea and chlamydia infections.

Preexposure Interventions

Preexposure vaccination is the most effective method for preventing the transmission of certain STIs. For example, because hepatitis B virus is

frequently transmitted sexually, hepatitis B vaccination is recommended for all unvaccinated persons being evaluated for an STI. In addition, hepatitis A vaccine is recommended for men who have sex with men and for drug users (both injection and noninjection). Vaccines for HPV are now available for both females and males (Chapter 373). The HPV vaccines now have more than 5 years of follow-up and demonstrate continued high rates of protection in women. HPV vaccination for males may reduce acquisition of genital warts and is protective against anal precancerous lesions, leading to a "permissive" vaccine recommendation for boys aged 9 to 26 years from the Advisory Committee on Immunization Practices.

Several studies have evaluated the effectiveness of antiretroviral agents for HIV preexposure prophylaxis. Results have indicated HIV prevention but only in the setting of high-level (>85%) medication adherence. Furthermore, because the only currently Food and Drug Administration–approved antiretroviral for HIV prevention is also a drug combination used for therapy, regular HIV screening is necessary to prevent the development of resistance should the patient become infected.[8] Topical HIV prevention by vaginal microbicides has been only partially successful, in large part because of poor adherence. Long-acting injectable drugs, vaginal rings, and coformulated options (i.e., contraceptive and antiretroviral agents) are under evaluation.

Postexposure Prophylaxis

After consensual or nonconsensual sexual exposure, a variety of STIs can be prevented with empirical antibiotics. Prevention of HIV infection appears to require several antiretroviral agents that must be used in combination for 28 days.

Contraception

All methods of birth control can influence the acquisition and outcome of an STI. In addition, pregnancy itself (in the absence of effective birth control) affects STI acquisition and the health of the pregnancy and the neonate. Accordingly, STI management demands consideration of the reproductive health of both partners as well as family planning issues. A systematic review suggested that there was no increased risk of HIV infection in oral contraceptive users; however, the data for injectable hormonal contraceptives were more difficult to interpret.[9] Women using injectable hormonal birth control should be cautioned about consistent condom use for STI prevention until these relationships are better clarified.

TOWARD A COMPREHENSIVE MANAGEMENT STRATEGY

Although most STIs are self-limited and readily treated, the comprehensive and proper management of the patient with an STI requires considerable skill.[10] First, the correct syndrome must be recognized, and a decision about specific diagnostic tests must be made. Second, empirical therapy must be provided and must be sufficiently broad to promise cure or reduced duration of illness. Third, the clinician is obligated to search for other STIs of public health or personal significance. Fourth, the clinician must deal with the patient's sexual partners, through either referral or expedited partner therapy. Fifth, the patient needs counseling and adjunctive preventive measures, where appropriate. Such measures might include vaccination for hepatitis B or HPV or antibiotics to prevent another STI, such as incubating syphilis or HIV infection.

REVIEW QUESTIONS

1. The Centers for Disease Control and Prevention has recommended gonorrhea treatment with an injectable third-generation cephalosporin and azithromycin. Which of the following answers is the correct rationale for this recommendation?

A. Azithromycin should be used in conjunction with an injectable third-generation cephalosporin to provide therapy with two different mechanisms of action, thereby delaying emergence of resistance.
B. There is a high rate of concomitant chlamydial infection as well as an increasing recognition of *Mycoplasma genitalium* coinfection that should be treated.
C. Cefixime and azithromycin may be used in some settings without further follow-up.
D. Moxifloxacin may be used to treat *M. genitalium* as well as *Neisseria gonorrhoeae.*

Answer: A A theoretical basis does exist for using two antimicrobials with different mechanisms of action to treat gonorrhea and to prevent emergence of resistance. Although there is a high rate of concomitant chlamydia and mycoplasma coinfection with gonorrhea, it does *not* reflect the rationale for using azithromycin and an injectable third-generation cephalosporin as first-line therapy against gonorrhea. Oral cefixime therapy is a second-line therapy and should be followed with a test of cure. Fluoroquinolones are to be avoided for gonorrhea.

2. Male circumcision is currently recommended by WHO/UNAIDS. Which of the following statements is *incorrect* regarding male circumcision?

A. The long-term effectiveness of male circumcision is well described and has been demonstrated in several studies.
B. Sexually transmitted infection (STI) prevention trials that incorporate interventions like circumcision may lead to a bias/blunting of effect compared with community standards of care.
C. Male circumcision demonstrated greater than 75% reduction in human immunodeficiency virus (HIV) acquisition during a 5-year period in at least two African trials.
D. Circumcision was not accepted by men after completion of the trial.
E. Circumcised men were more likely to engage in risky sexual behaviors compared with uncircumcised men.

Answer: C The uptake of circumcision after the trial approached 80% in the Rakai study. Long-term effectiveness of circumcision has not been *proved* but may be inferred from several studies. In larger randomized controlled trials, circumcision compared with community standard of care did not appear to have a biased effect. Further, in the post-trial surveillance for the Rakai study, there were no statistically significant differences in sexual risk-taking behaviors in men subsequently choosing circumcision compared with those who did not choose circumcision, and there were no statistically significant differences in sexual risk-taking behavior in uncircumcised versus circumcised men.

3. Human papillomavirus (HPV) is a vaccine-preventable STI. Which of the following is true about HPV vaccination?

A. Oral HPV-associated head and neck cancers (associated with smoking, male gender, and HIV infection) can be prevented with vaccination.
B. Two vaccines are currently available. Both protect against HPV types 16 and 18, which are responsible for at least 85% of all cervical neoplasia; one of the vaccines includes types 6 and 11 (responsible for most cases of genital warts and precancerous anal lesions).
C. Papanicolaou smears are recommended for all sexually active women beginning at coitarche, and HPV testing is recommended for women younger than 30 years.
D. The quadrivalent HPV vaccine protects against only genital warts in males.

Answer: B Two vaccines are currently available. Both protect against HPV types 16 and 18, which are responsible for at least 85% of all cervical neoplasia; one of the vaccines includes types 6 and 11 (responsible for most cases of genital warts and precancerous anal lesions). Current HPV vaccines have not been shown to have any effect on head and neck cancers. The quadrivalent vaccine does protect against anal precancers and may influence future vaccine recommendations.

4. Which of the following are true about vaginal discharge and syndromic STI treatment?

A. Vaginal-associated and cervical-associated causes of vaginal discharge are difficult to discriminate on the basis of symptoms alone.
B. Many STIs in females are asymptomatic, leading to underidentification and undertreatment.
C. Subclinical STI may still contribute significantly to genital inflammation and risk of HIV transmission and acquisition.
D. All women possess a similar vaginal milieu that contributes significantly to bacterial vaginosis, a common noninfectious cause of vaginitis.
E. A, B, and C are true.

Answer: E All of the responses are true *except* D. Women possess a heterogeneous vaginal microbiome, some species of which are associated with an increased risk of bacterial vaginosis. Mlisana and coworkers demonstrated elevated cervicovaginal cytokine levels for women with STI, regardless of self-report of vaginal discharge. Vaginal discharge has poor sensitivity, specificity, and positive predictive value as a marker for STIs.

5. Many commercial laboratories have switched to use of treponemal-specific tests for syphilis diagnosis. Which of the following statements is true regarding the "reversed" testing algorithm?

A. Treponemal-specific testing may be used to follow treatment.
B. Some larger commercial laboratories have reversed the order of testing, using an antitreponemal test followed by an anticardiolipin test, which allows automation and may be cost-effective in areas of low endemicity.
C. If a patient has a positive treponemal antibody test result and a negative serologic test result, that patient has a false-positive syphilis test result and does not require treatment.
D. A patient presents with a positive treponemal test result and elevated serologic (1 : 64) titer 9 months ago. He was treated appropriately and lost to follow-up. The patient now presents with a positive treponemal test result and a nonreactive serologic test result. This patient should be retreated.

Answer: B Treponemal-specific tests are not used to follow treatment. Non–treponemal-specific antibody tests (e.g., VDRL, RPR) should still be used to monitor therapy; specifically, a four-fold decrease in titer indicates adequate treatment. A patient with a positive treponemal antibody test result and a negative serologic test result may have old or untreated syphilis. If a false positive is suspected, a second treponemal antibody test should be performed. This patient has evidence of appropriately treated syphilis (as evidenced by a greater than four-fold decrease in titer to a nonreactive serologic test) and does not require further therapy.

286

APPROACH TO THE PATIENT BEFORE AND AFTER TRAVEL

DAVID O. FREEDMAN

Prevention strategies and medical interventions for the traveler need to be individualized according to a risk assessment that considers both the itinerary and factors that are dependent on the prospective traveler. A structured approach to patient interaction (Table 286-1) is the most efficient way to cover the necessary educational and preventive interventions. As many of these measures will be initiated only much later at the traveler's destination, clearly printed instructions in lay language are advisable. The worldwide epidemiology of travel-related diseases is constantly changing. Special needs travelers, such as those who are immunocompromised, are pregnant, or have significant underlying disease, should be referred to a specialized travel medicine clinic.

Globally, approximately 100 million people travel from industrialized to developing countries each year. Several recent analyses have provided much needed new data on the profiles of travel-related illness determined by destination of travel.[1] Depending on destination, 22 to 64% of travelers report some illness; most of these problems are mild, self-limited illnesses, such as diarrhea, respiratory infections, and skin disorders. Infectious diseases account for up to 10% of the morbidity during travel but only 1% of the deaths, with malaria being the most common disease.

IMMUNIZATION

The choice of vaccines for an individual traveler is based on risk of exposure to vaccine-preventable diseases on the chosen itinerary, the severity of disease if it is acquired, and any risks presented by the vaccine itself. Travelers differ in their tolerance of risk. For the vaccine-preventable diseases, the monthly incidence for nonimmune travelers to developing countries is most significant for symptomatic hepatitis A at 0.03% per month overall; the risk of symptomatic hepatitis B is most significant for long-stay travelers at 0.25% per month. Enteric fever (typhoid and paratyphoid) has a risk of 0.03% per month on the Indian subcontinent and is 10 times lower in Africa and parts of Latin America. Risk of yellow fever may be as high as 0.1% per month of travel to an area with current epidemic transmission, but the risk varies greatly between destinations encompassed by the endemic area map. The risk of meningococcal meningitis, rabies, cholera, polio, measles, varicella, and Japanese encephalitis in travelers is not known but is thought to be small (<0.0001%).

Table 286-2 provides data on dosing, administration, need for boosters, and possible accelerated regimens for vaccines administered in the travel medicine setting. Details on vaccine composition, mechanism of action, use for routine adult and childhood primary vaccination, and adverse reactions can be found in Chapter 18. The following discussion focuses on indications for vaccines in the context of travel.

Verification and Update of Routine Immunizations

Because of the increased prevalence of many infections in the developing world, routine adult immunizations need to be current.[2] If no adult doses of tetanus/diphtheria/acellular pertussis (Tdap) have ever been given, a dose of Tdap should be given regardless of the time elapsed since the last tetanus/diphtheria vaccination. Persons born in the United States before 1957 or born anytime in the developing world are considered immune to measles. Other adult travelers should have received at least two doses of live measles–containing vaccine during their life unless a history of measles infection can be documented. Unvaccinated persons who have the accepted routine indications for influenza or pneumococcal vaccines (Chapter 18) should receive these during the pretravel consultation. Two doses of varicella vaccine spaced by at least 4 weeks should be considered for adult travelers without evidence of varicella immunity. Adults born before 1980 in the United States are considered immune.

Vaccines to Consider for All Developing World Travelers

A number of additional vaccines should be administered depending on the travel destinations.[3]

Hepatitis A

Hepatitis A vaccine is indicated for every nonimmune traveler to countries or areas with moderate to high risk of infection, which includes essentially

TABLE 286-1 THE PRETRAVEL CONSULTATION WITH A TRAVELER TO THE DEVELOPING WORLD—A STRUCTURED APPROACH

PERFORM RISK ASSESSMENT
The following must always be ascertained initially to determine appropriate preventive medical recommendations. Preprinted medical record forms may be used to record these.
Exact itinerary, including regions within each country to be visited
Dates of travel to assess risk of seasonal diseases
Age
Past vaccination history
Underlying illnesses
Current medications
Pregnancy status
Allergies
Purpose of trip
Risk exposures—blood, body fluids, adventure or extensive outdoor exposures
Urban versus rural travel
Type of accommodations
Level of aversion to risk
Financial limitations that may necessitate prioritization of interventions
ADMINISTER IMMUNIZATIONS
Administer routine vaccinations that are not up to date.
Administer indicated travel vaccines.
Provide to patient legally mandated Vaccine Information Statements from the Centers for Disease Control and Prevention (http://www.cdc.gov/vaccines/pubs/vis/).
Provide printed checklist to patient listing vaccines administered.
Record in the clinic record vaccines administered, lot number, and date.
Document vaccines offered to but declined by patient as well as nonrecommended vaccines administered at the patient's request.
PROVIDE MALARIA PREVENTION (IF INDICATED)
Determine whether malaria risk exists for the destination country. If yes:
Does the patient's itinerary within that country put him or her at risk? If yes:
Recommend malaria chemoprophylaxis. Several equally effective drugs of choice may be indicated. Ascertain which is best suited to the individual patient and itinerary.
Educate on personal protection against arthropods.
EDUCATE ON TRAVELER'S DIARRHEA
Recommend food and water precautions.
Prescribe and educate on standby therapy with a quinolone antibiotic or azithromycin and advise on use of loperamide and oral hydration if needed.
TEACH ESSENTIAL PREVENTIVE BEHAVIORS
Most travel-related health problems, including vaccine-preventable diseases, can be avoided through simple behaviors initiated by the traveler.
Educate on appropriate strategies in the following categories (some topics are not applicable to all destinations): blood-borne and sexually transmitted diseases, safety and crime avoidance, injury prevention, swimming safety, rabies, skin/wound care, tuberculosis, packing for healthy travel, obtaining health care abroad.
DISCUSS OTHER APPLICABLE HEATH ISSUES
Advise and prescribe for altitude illness, motion sickness, or jet leg.
Discuss prevention of specific travel-related infections that are of some risk to the traveler and have a possible preventive strategy not included in strategies above.
Discuss any minimal-risk conditions (e.g., hemorrhagic fevers) that are a frequent cause of patient anxiety.

everyone traveling outside the United States, Canada, Japan, Australia, New Zealand, Scandinavian countries, and developed countries in Europe. A single dose of hepatitis A vaccine given any time before travel provides adequate protection. Persons with a history of hepatitis or who previously lived in an endemic country for a prolonged period may benefit from prevaccination serum antibody testing.

Hepatitis B

Pretravel hepatitis B vaccination is indicated for all nonvaccinated travelers with standard indications, such as health care workers, and all longer-stay travelers who will be visiting or residing in high- or moderate-risk areas. Transmission by routes such as sexual contact, blood transfusions, contaminated medical equipment, body piercing, tattooing, acupuncture, and sharing of cooking and bathroom facilities is difficult to control or to predict in the context of travel. Vaccination is usually advocated for short-term travelers, especially younger travelers and those anticipating close contact with local populations, even if they have no specific risk factors. Adventure travelers (accident prone), backpackers, and those with underlying medical conditions are more likely to require contact with the medical system. Accelerated and hyperaccelerated schedules (see Table 286-2) are used widely in practice and are approved in many countries. These are helpful in administering all three primary doses necessary for high assurance of protection in the frequent circumstance in which the traveler is leaving in a very short time and is at risk of hepatitis B exposure.

Combination Hepatitis A and Hepatitis B Vaccine

The combined hepatitis A and hepatitis B vaccine provides convenience for travelers with an overlap of indications for use of the individual vaccines. A less well known accelerated 3-week schedule (see Table 286-2) is approved by the Food and Drug Administration.

Typhoid

Typhoid vaccine is indicated for all travelers to the Indian subcontinent and considered for those traveling to other endemic areas under all but the most deluxe and protected of conditions. Risk increases with trip duration, lodging and eating with local residents, and extent of travel off the usual tourist itineraries. Current typhoid vaccines do not protect against *Salmonella paratyphi*, which is emerging in many areas.[4] Adherence to the oral vaccine regimen may be as low as 70%.

Influenza

Influenza is transmitted year-round in the tropics. Increasing data show that influenza may be the most common vaccine-preventable illness in travelers. An increased risk of influenza has been reported among cruise ship passengers. All travelers to destinations with current influenza virus circulation, not just those with the usual risk factors, should strongly consider influenza vaccination.[5]

Vaccines for Certain Destinations

Yellow Fever

The primary indication for yellow fever vaccination is to prevent infection in individuals at risk. A map of risk areas can be found at www.cdc.gov/travel. However, yellow fever is currently the only vaccine that falls under the International Health Regulations that may necessitate vaccination purely for regulatory reasons. A number of African countries and one in South America (French Guiana) require proof of yellow fever vaccination from all arriving travelers. Other countries, both within and outside the risk zone, have submitted more complex requirements to the World Health Organization. Current country-by-country yellow fever entry requirements are at www.who.int/ith/chapters/en/index.html. A Centers for Disease Control and Prevention–designated yellow fever vaccination center should be consulted for detailed requirements. Neither yellow fever vaccine nor any other vaccine is currently required for readmission to the United States. In general, all healthy adult travelers to areas with a risk of yellow fever transmission should be vaccinated. The true duration of immunity from yellow fever vaccination is probably much longer than the stated 10 years and may exceed 30 years.[6]

Meningococcus

Meningococcal vaccine is recommended for travelers to Africa's sub-Saharan "meningitis belt" during the dry season from December through June, especially if prolonged contact with the local populace is likely. Out-of-season epidemics have occurred in Ethiopia, Somalia, and Tanzania, indicating possible changes in epidemiologic trends perhaps due to climate changes. Muslims undertaking Hajj and Umrah pilgrimages in Saudi Arabia are at a higher risk of meningococcal disease, and proof of vaccination with quadrivalent vaccine within the past 3 years is required to obtain pilgrimage visas.

Rabies

A preexposure rabies series is indicated for long-stay travel to endemic areas of Latin America, Asia, or Africa where the rabies threat is constant and where access to adequate postexposure rabies immune globulin and vaccine is likely to be limited. For short-term travel, risk groups for whom immunization should be considered include adventure travelers, bikers, hikers, cave explorers, and business travelers who travel for short but frequent trips and plan to go running outdoors on these trips.

Japanese Encephalitis

Japanese encephalitis is endemic to many rural farming areas of Southeast Asia and the Indian subcontinent. Sporadic cases with severe sequelae

TABLE 286-2 TRAVEL-RELATED VACCINES OF ADULTS

DISEASE	VACCINE	PRIMARY COURSE	ROUTE	FURTHER BOOSTERS
VACCINES TO CONSIDER FOR ALL DEVELOPING WORLD TRAVELERS				
Hepatitis A	Killed virus	0, 6-18 months	IM	None
Hepatitis B	Recombinant viral antigen	0, 1, 6 months A: 0, 1, 2 weeks and 12 months A: 0, 1, 3 weeks and 12 months*	IM IM IM	None None None
Hepatitis A/B	Combination of monovalent preparations	0, 1, 6 months A: 0, 1, 3 weeks and 12 months	IM IM	None None
Typhoid	Capsular Vi polysaccharide Live attenuated Ty21a bacteria	Single dose 0, 2, 4, 6 days	IM Oral	2-3 years 5 years
Influenza	Inactivated viral Live attenuated virus	Single dose Single dose (<50 years of age only)	IM Nasal	Annual Annual
Varicella	Live attenuated virus	0, 4-8 weeks	SC	None
VACCINES FOR CERTAIN DESTINATIONS				
Yellow fever	Live attenuated 17D virus	Single dose	SC	10 years
Meningococcus	Quadrivalent conjugated polysaccharide (A, C, Y, W135)	Single dose	IM	5 years
Rabies	Inactivated viral cell culture	0, 7, 21-28 days	IM†	None routinely but two doses after each exposure
Japanese encephalitis (Vero cell)	Inactivated viral	0, 28 days	IM	1 year if at continued risk; no data on subsequent doses
Polio‡	Inactivated viral	Single dose if adequate childhood series	SC; IM acceptable	None
Cholera§	Killed bacteria + recombinant B toxin subunit‖	0, 1 week	Oral	2 years for cholera; 3 months for ETEC

*Regimen not approved by the U.S. Food and Drug Administration for monovalent hepatitis B vaccine but approved for combination hepatitis A/B vaccine containing the same quantity of hepatitis B antigen.
†Intradermal rabies preexposure vaccine is no longer produced, and the intramuscular 1.0-mL vials are not licensed for intradermal use in a 0.1-mL dose.
‡Oral polio vaccine is no longer produced in the United States.
§Not available in the United States but available in Canada and most European countries. No cholera vaccine of any kind is currently available in the United States.
‖Also licensed in some countries for traveler's diarrhea due to enterotoxigenic *Escherichia coli*.
A = accelerated regimen to be used for imminent departures; ETEC = enterotoxigenic *E. coli*; IM = intramuscular; SC = subcutaneous.

continue to occur in travelers.[7] In temperate regions, the transmission season is from April through November. In tropical or subtropical regions of Oceania and Southeast Asia, transmission may occur year-round. Vaccination is recommended for (1) long-stay travel to an endemic rural area; (2) expatriation to anywhere in an endemic country; (3) short-term travel to endemic rural areas with extensive unprotected outdoor exposure, such as with adventure travel; and (4) short-term travel in the face of a current local epidemic.

Polio

Because of eradication efforts, poliomyelitis remains in only a few countries, but complete control remains elusive. Adults traveling to countries that are currently polio endemic (updated information at www.polioeradication.org) and who have previously completed a primary vaccine series should receive a one-time single dose of inactivated polio vaccine as a booster if the last dose or booster dose was administered at least 10 years previously.

Cholera

Cholera vaccination is no longer required by any country, and the risk to typical travelers is insignificant.[8] However, medical and aid workers staying for short periods in disaster areas or refugee camps may consider cholera vaccine. A highly effective oral killed whole cell–B subunit vaccine is available widely outside the United States.

Sequence of Travel-Related Vaccines

All currently indicated immunizations can and should be given at the same time and in any combination (Chapter 18). If two live viral antigens are not administered on the same day, they must be spaced by a month. However, yellow fever vaccine can be given at any interval with respect to single-antigen measles vaccine. Minimum intervals between vaccine doses must be respected, although 4 days or fewer before the next interval are acceptable. Regimens that involve 1-week intervals (rabies, Japanese encephalitis, accelerated hepatitis) are exceptions. There is not a maximum interval between doses of a primary vaccine series; interrupted series (except oral typhoid and rabies) need not be restarted but can be resumed beginning with the dose that is overdue.

MALARIA CHEMOPROPHYLAXIS

An average of 1500 imported cases of malaria are reported annually in the United States. Estimates of risk in travelers not taking chemoprophylaxis vary widely by destination but range from 3.4% per month in West Africa to one tenth that on the Indian subcontinent and a further 10-fold reduction in South America. The majority of cases of imported malaria in the United States and Europe occur in noncitizen immigrants visiting friends and relatives abroad.

Resources describing current country-specific malaria microepidemiology should be accessible immediately to those prescribing malaria prophylaxis. Dosing and pharmaceutical properties of antimalarial drugs are described in Chapter 345. In the limited number of countries where it is still effective, chloroquine, 500 mg salt (300 mg base) per week beginning the week before the first exposure to malaria and continuing for 4 weeks after the last exposure, is still the drug of choice. However, atovaquone/proguanil may still be used by short-stay travelers who prefer the shorter duration of that regimen.

For all other areas of the world, three drugs are equally effective, and the choice depends on both traveler and itinerary factors. Atovaquone/proguanil (250/100 mg) is a well-tolerated, once-a-day drug that should be started 1 day before arrival in the malarious area (may not coincide with first overseas destination) and continued for 7 days after the last exposure. The short period of postexposure use makes it convenient for the many travelers on typical 1- to 3-week itineraries. High cost and daily dosing make it difficult to use for extended periods. Weekly mefloquine (250 mg) is given 2 and preferably 3 weeks before the first exposure to malaria and continued for 4 weeks thereafter. Weekly dosing and a long track record of efficacy make this drug the most effective for long-stay travelers. If contraindications to mefloquine exist for long-stay travelers, daily doxycycline (100 mg) beginning 1 day before exposure can be used; unlike atovaquone/proguanil, it must be continued for 4 weeks after exposure. Approximately 5% of individuals who take either mefloquine or doxycycline discontinue therapy because of side effects. Chemoprophylaxis may be started well before departure (3 to 4 weeks for mefloquine) in those concerned about possible intolerance to any drug.

Travelers should be reminded in writing to continue antimalarial drugs for the appropriate period after the last possible exposure, that malaria can still

occur despite chemoprophylaxis, and that a malaria smear or malaria rapid diagnostic test is mandatory for any febrile illness occurring within 3 months after travel. Prevention of malaria in travelers residing in malarious areas for 6 months or more presents complex problems that have been reviewed elsewhere.

DENGUE

An estimated 100 million cases of dengue fever and 250,000 cases of dengue hemorrhagic fever occur annually (Chapter 381). The past 20 years have seen a dramatic geographic expansion of epidemic dengue fever and dengue hemorrhagic fever. Dengue accounts for up to 2% of all illness in returned travelers, and dengue is the most common systemic febrile illness in returned travelers from every region except sub-Saharan Africa, where malaria still predominates. Several dengue vaccine candidates are in advanced clinical trials. Dengue fever is transmitted by day-biting *Aedes* mosquitoes, reinforcing the need to instruct travelers to the tropics in the need for both day and night use of repellents.

TRAVELER'S DIARRHEA

The most frequent cause of traveler's diarrhea is enterotoxigenic *Escherichia coli* and in some locations enteroaggregative *E. coli*. *Salmonella*, *Shigella*, and *Campylobacter* each account for about 5 to 15%, and in Asia noncholera vibrios are significant.[9] Protozoa account for less than 5%. In adults, norovirus and rotavirus are increasingly detected. The mean duration of traveler's diarrhea, even if it is untreated, is 4 days.

All travelers to the developing world should be thoroughly educated in self-therapy for diarrheal disease and carry the appropriate agents while traveling.[10] Eighty percent of patients respond to a regimen of loperamide and an antibiotic within 24 hours. A single dose of a self-administered quinolone is usually sufficient, but patients should be instructed to complete 3 days of therapy with 500 mg of levofloxacin daily or 500 mg of ciprofloxacin twice daily should the traveler's diarrhea not resolve within 24 hours. Because of a significant increase in quinolone-resistant *Campylobacter* in Southeast Asia, India, and Nepal, travelers to those destinations should self-treat with azithromycin, 500 mg/day for 3 days or a single dose of 1000 mg.

Most guidelines do not recommend prophylaxis for the typical traveler because of potential adverse drug effects while away from medical care and because effective rapid-onset therapy is available for diarrhea should it occur. Exceptions include travelers with advanced human immunodeficiency virus (HIV) infection, those who have an underlying chronic medical problem that makes them more prone to adverse consequences from diarrhea, and travelers on a vital mission for a short period (less than 1 week) who cannot tolerate even a day of disability. Antibiotic prophylaxis should be carried out with a quinolone once per day or with rifaximin twice per day; prophylaxis should be used only for trips of 2 weeks or less.

PREVENTIVE BEHAVIORS

Most travel-related health problems, including many infectious diseases, can be significantly reduced through appropriate behavior by the traveler.

Mosquito Protection

Antimalarial chemoprophylactic drugs are less than 100% effective. Protection against arthropods will help prevent dengue, leishmaniasis, filariasis, and a number of important arboviral diseases. Travelers should be instructed to clothe themselves to reduce as much exposed skin as practicable and to apply a repellent containing DEET (concentration of 30% to 35%) to all exposed, nonsensitive areas of the body every 4 to 6 hours.[11] More frequent application is required for agents containing lower concentrations of DEET. Travelers should sleep under a permethrin-impregnated bed net in malarious areas unless they are in a sealed air-conditioned environment. Although anopheline mosquitoes are night biters, *Aedes* spp and culicine mosquitoes are usually day biters, so vigilance at all times of day is necessary.

Food and Water Precautions

Travelers to developing countries should be diligent in washing their hands frequently; avoiding food from dubious eating places, markets, and roadside vendors; avoiding buffets where there are no food covers or fly controls; avoiding high-risk food such as shellfish, reef fish (ciguatera risk), undercooked meats and poultry, dairy products, unpeeled fruits, cold sauces, and salads; avoiding both tap water and drinks or ice made from tap water; and using sealed bottled water or chemically treated, filtered, or boiled water for drinking and brushing their teeth.

Sex

Education on the incidence of HIV infection and sexually transmitted diseases among professional sex workers abroad, on the use of condoms, and on the failure rate of condoms (3 to 5% breakage/slippage) should be given regardless of the apparent circumstances of the traveler. Unprotected sex even with fellow travelers is considered high risk.[12] Travel is a disinhibiting experience in itself, and alcohol consumption tends to increase during travel.

Blood-borne Pathogens

Blood, blood products, syringes, and contaminated medical or dental instruments are a risk following accidents or trauma. Travelers should consider carrying an infusion set, needles, and a suture kit for high-risk areas. If possible, they should defer medical treatment and travel to a facility where safety can be ensured. Tattooing, acupuncture, and body piercing carry similar risks. Health care workers and others at risk in areas of high HIV prevalence without sophisticated medical infrastructure may consider carrying a 1- to 2-week supply of Truvada (200 mg of emtricitabine plus 300 mg of tenofovir), 1 tablet per day, plus raltegravir 400 mg, 1 tablet twice a day to begin immediate twice-daily postexposure prophylaxis, with the understanding that this is only an initial measure to allow time for travel to an adequate medical facility able to provide sophisticated testing and counseling.

Protection Against Skin Diseases

Infected mosquito bites are common. Practicing good hand hygiene in dirty environments and covering open wounds are preventive measures that all travelers should take. Scabies and lice infestations can be prevented by carrying out good personal hygiene. In Africa, all clothes dried outdoors should be ironed to avoid cutaneous myiasis due to the tumbu fly. Hats and sunscreen are mandatory in the tropics. Sunscreen should always be applied to skin before, and not after, an application of DEET.

Swimming and Water Exposure

Travelers should be instructed to avoid recreational (swimming, rafting, wading) or other exposure to fresh water in areas that are endemic for schistosomiasis. Hikers, bikers, and adventure travelers should consider prophylaxis with 200 mg of doxycycline once per week because of the significant risk of leptospirosis that exists in fresh water throughout the developing world. Walking barefoot in tropical areas predisposes to hookworm, *Strongyloides* infection, cutaneous larva migrans, and tungiasis.

Prevention of Tuberculosis

A predeparture baseline tuberculin skin test with annual retesting is indicated for long-stay travelers to developing countries. Aggressive treatment of skin test converters will prevent cases of active tuberculosis later. Travelers should avoid crowded public transportation or crowded public places and distance themselves immediately from anyone with a chronic or heavy cough. Expatriates should screen domestic help for tuberculosis.

NONINFECTIOUS TRAVEL PROBLEMS

Traveler's Thrombosis and Jet Lag

A causal relationship between travel-related immobility and deep venous thrombosis or pulmonary embolism in otherwise healthy travelers has become established. Risk of pulmonary embolus is essentially absent on flights lasting less than 6 hours. Those with clear, known risk factors are at highest risk. All travelers should avoid dehydration, avoid alcohol, and exercise the legs regularly in flight. Of many recommendations for prevention, only the use of graded 15 to 30 mm Hg compression stockings for those at higher risk is supported in trials, although prophylactic subcutaneous low-molecular-weight heparin just before departure and again 24 hours later for those with thrombophilia or previous thrombotic events is often used in practice. Aspirin therapy is of no proven benefit in this setting.

Jet lag (Chapter 405) occurs after crossing three or more time zones, and zolpidem (5 mg) taken for a few nights at bedtime at the destination is generally effective.

Altitude Illness

Whether ascending by car or airplane, acute mountain sickness occurs in at least 25% of people who ascend rapidly to 2500 m or more and in most people who go quickly to 3000 m or more. Gradual ascent during days is rarely practiced by modern travelers. For prevention of altitude illness, acetazolamide, 125 mg twice a day beginning the morning of the day before ascent and continuing through the day after ascent, is effective. If

symptoms of mountain sickness, such as nausea, vomiting, anorexia, lightheadedness, fatigue, or insomnia, persist beyond the day after ascent, travelers may continue to take one tablet each evening.[13] Other medications such as dexamethasone also can be used (Chapter 94). Severe complications, such as pulmonary or cerebral edema, occur uncommonly under 3500 m and are best treated by oxygen and immediate descent. Those traveling above 3500 m for longer than a brief transit of a few hours should consult an expert.

POST-TRAVEL CARE

The approach to the patient requires knowledge of world geography, the epidemiology of disease patterns in 230 or so countries, and the clinical presentation of a wide spectrum of disorders. Most illnesses are mild, most are self-limited, and many are noninfectious. Based on 43,000 ill-returned travelers seen by the GeoSentinel Surveillance Network, specific travel destinations are associated with the probability of the diagnosis of certain diseases (E-Table 286-1). Diagnostic approaches and empirical therapies can be guided by these destination-specific differences. Important region-specific disease occurrence data indicate that (1) febrile illness is most important from Africa and Southeast Asia; (2) malaria is one of the top three diagnoses from every region, yet during the past decade, dengue has become the most common febrile illness from every region outside of sub-Saharan Africa;[14] (3) in sub-Saharan Africa, rickettsial disease is second only to malaria as a cause of fever; (4) respiratory disease is most important in Southeast Asia and sub-Saharan Africa; and (5) acute diarrhea is disproportionately from South Central Asia.

Fever in a traveler who has recently returned from the tropics is a potential emergency and must be evaluated immediately so that antimalarial or other definitive treatment can be initiated rapidly if it is indicated. Persistent gastrointestinal symptoms in a returning traveler require prompt evaluation and treatment (E-Table 286-2).[15] Certain long-term travelers should be evaluated by a travel or tropical medicine specialist when they return to be screened for conditions that may be asymptomatic, such as schistosomiasis or strongyloidiasis.

Travelers who become ill during or any time up to several months after a foreign trip will frequently associate that illness with a possible travel-specific etiology. This may be the case, but often it is not. Routine things are common, and common things are common whether they are actually acquired during travel or at some time after the trip.

E-TABLE 286-1 SOME KEY DISEASES REPORTED IN FIVE OR MORE TRAVELERS AMONG >43,000 REPORTED ILLNESSES

DIAGNOSES	# OF CASES	TRAVEL HISTORY
GASTROINTESTINAL		
Giardia	1426	India, Thailand, Nepal, and Ghana
Campylobacter	753	India, Thailand, Indonesia, and Tanzania
Strongyloides	483	India, Vietnam, Ghana, and Dominican Republic
Salmonella enteritis	367	Thailand, India, Indonesia, and Egypt
Shigella	271	India, Egypt, Ghana, and Indonesia
Entamoeba histolytica	340	India, Indonesia, Mexico, and Thailand
Vibrio	9	5 cases in Latin America (2 cases acquired in Mexico), 3 in Asia, 1 in sub-Saharan Africa
FEBRILE		
Plasmodium falciparum	1990	Ghana, Comoros, Nigeria, and Côte d'Ivoire
Plasmodium vivax	480	India, French Guyana, Myanmar, and Papua New Guinea
Dengue	1473	Thailand, Indonesia, India, and Brazil
Enteric fever	467	India, Nepal, Pakistan, and Bangladesh
Spotted fever rickettsia	267	South Africa (68.9%), Zimbabwe, Tanzania, and Swaziland
Chikungunya	164	India, Malaysia, Indonesia, and Thailand
Hepatitis A	120	India, Morocco, Egypt, and Mexico
Acute HIV	84	Thailand, Brazil, Guinea, and Germany
Leptospirosis	83	Thailand, Laos, and Costa Rica
Hepatitis E	45	India (40%), Pakistan, and Bangladesh
Brucellosis, acute	33	India, Sudan, and Iraq
Measles	33	India, Thailand, and France
Histoplasmosis	23	Guatemala and Costa Rica
Rickettsia typhi (flea-borne)	17	Cambodia, Malaysia, Vietnam, Indonesia, and Nepal
Visceral leishmaniasis	16	India, Greece, Portugal, and Spain
Orientia tsutsugamushi (scrub typhus)	14	Thailand and Vietnam
Rubella	11	Vietnam and Thailand
Melioidosis	9	Thailand, Singapore, and Malaysia
Mumps	8	Different country for each case (2 in Western Europe, 4 in sub-Saharan Africa, 1 in Latin America, and 1 in Asia)
African trypanosomiasis	6	Zambia (3 cases), Tanzania, Zimbabwe, and Burkina Faso
Relapsing fever	6	Senegal, South Africa, and Morocco
Ross River virus	5	Australia
DERMATOLOGIC		
Rabies prophylaxis after bite or scratch	1249	Thailand, Indonesia, China, and India
Cutaneous larva migrans	806	Thailand, Brazil, Mexico, and Malaysia
Leishmaniasis (cutaneous or mucocutaneous)	264	Bolivia, Afghanistan, and Costa Rica
Myiasis	174	Senegal, Brazil, Costa Rica, and Belize
Tungiasis	87	Brazil, Madagascar, Uganda, and Ethiopia
Gnathostomiasis	12	Cambodia and Indonesia (92% from Asia)
Leprosy	11	Pakistan and Vietnam
Cutaneous atypical mycobacteria	6	All different (Caribbean, sub-Saharan Africa, and South-Central Asia)
RESPIRATORY OR PHARYNGEAL		
Influenza	367	
H1N1	176	United States, Australia, United Kingdom, and Philippines
Influenza A or B	191	Indonesia, Thailand, India, and China
Tuberculosis	170	
MDR or XDR pulmonary tuberculosis	3	1 case each for Nigeria and India (1 case unknown)
Legionellosis	35	China, Italy, and Spain
Pulmonary atypical mycobacteria	35	China, Thailand, Kenya, South Africa, and North America
Pertussis	30	India and China
NEUROLOGIC		
Ciguatera intoxication	51	Bahamas and Dominican Republic
Neurocysticercosis	21	India
Tuberculosis meningitis or tuberculoma	13	India and Pakistan
Scombroid, neurotoxic or paralytic shellfish poisoning	7	Mauritius (2 cases) and other (2 cases in Western Europe and 2 cases in Southeast Asia)
West Nile virus	5	1 case each in Afghanistan, Costa Rica, Greece, and Israel (1 unknown)

E-TABLE 286-1 SOME KEY DISEASES REPORTED IN FIVE OR MORE TRAVELERS AMONG >43,000 REPORTED ILLNESSES—cont'd

DIAGNOSES	# OF CASES	TRAVEL HISTORY
OTHER		
Schistosomiasis	792	Malawi, Uganda, Tanzania, and Ghana
Filariasis	113	Cameroon, Gabon, Democratic Republic of Congo, and Central African Republic
Lyme disease	77	United States, Germany, and Italy
Visceral larva migrans	16	6 cases in Southeast Asia (2 cases acquired in Thailand), 5 in Latin America and the Caribbean, 3 in sub-Saharan Africa, and 2 cases unknown
Fasciola	14	Australia, Germany, France, and the Netherlands
Clonorchis	12	Thailand, Laos, and China
Trichinellosis	12	Poland and Serbia

HIV = human immunodeficiency virus; MDR = multidrug-resistant; XDR = extensively drug-resistant.

E-TABLE 286-2 COMMON INFECTIOUS AGENTS CAUSING CHRONIC GASTROINTESTINAL DISEASE IN THE RETURNING TRAVELER

	INCUBATION PERIOD (DAYS)	CLINICAL MANIFESTATIONS	DIAGNOSIS	TREATMENT
Giardia	7-10	Abdominal pain, nausea, persistent watery diarrhea	Stool microscopy and stool antigen	Metronidazole, 250 mg, 3 times/day for 7-10 days or 500 mg twice a day for 5-7 days
Entamoeba histolytica	11-21	Abdominal pain, fever, persistent watery diarrhea	Stool antigen assay	Metronidazole, 500-750 mg, 3 times/day for 7-10 days; plus paromomycin, 500 mg, 3 times/day for 7 days
Strongyloides	11-21	Larva currens, abdominal pain, persistent diarrhea	Stool microscopy	Ivermectin, 200 μg/kg of body weight/day for 2 days
Schistosoma	14-84	Katayama syndrome, abdominal pain, persistent diarrhea, hematuria	Stool and urine microscopy	Praziquantel, 40 mg/kg twice a day for 1 day for *S. hematobium* and *S. mansoni*, and 60 mg/kg 3 times/day for 1 day for *S. japonicum*
Campylobacter	1-4	Acute watery diarrhea, fever	Stool culture	Azithromycin, 500 mg once a day for 3 days
Shigella	1-8	Severe diarrhea, dysentery, fever	Stool culture	Ciprofloxacin, 500 mg twice a day for 3 days
Salmonella				
Serovar Typhi	5-14	Fever, headache, malaise, abdominal pain, diarrhea	Blood and stool culture	Ciprofloxacin, 20 mg/kg/day for 7 days; or azithromycin, 20 mg/kg/day for 7 days
Nontyphoidal	8-24 hours	Fever, headache, malaise, abdominal pain, diarrhea	Blood and stool culture	Ciprofloxacin, 20 mg/kg/day for 7 days; or azithromycin, 20 mg/kg/day for 7 days

REVIEW QUESTIONS

1. A tourist visiting Burkina Faso (West Africa) for 1 week during the dry season (December to June) should receive which of the following vaccines?

A. Plague
B. Cholera
C. Hepatitis C
D. Meningococcal
E. Japanese encephalitis

Answer: D Burkina Faso is in the meningitis belt of Africa. There is no plague vaccine currently and no risk to routine tourists in Africa. Cholera vaccine is indicated only for aid and refugee workers. Japanese encephalitis occurs only in Asia.

2. A traveler to Lake Titicaca (3800 m) in Bolivia should consider pre-ascent prophylaxis with

A. Ibuprofen
B. Acetazolamide
C. Prednisone
D. Furosemide
E. Isosorbide dinitrate

Answer: B Acetazolamide hastens acclimatization by causing a bicarbonate diuresis and metabolic acidosis. Ibuprofen can prevent altitude headache but has no effect against more serious altitude manifestations. Dexamethasone but not prednisone can be used to treat but not to prevent cerebral edema. Furosemide has no effect against high-altitude pulmonary edema and does not prevent it. Nitrates are ineffective against the increased pulmonary artery pressures induced by altitude.

3. The most common vaccine-preventable disease of travelers is

A. Hepatitis A
B. Typhoid
C. Yellow fever
D. Influenza
E. Measles

Answer: D Studies indicate that up to 2% of all travelers acquire influenza during their trip. This is orders of magnitude more common than the risk of the other diseases listed.

4. Acute diarrhea occurs disproportionately in travelers returning from which region?

A. Africa
B. South America
C. South Central Asia
D. China
E. Caribbean

Answer: C Epidemiologic evidence from the GeoSentinel network is described in the text and can be found in reference 1.

5. Travelers should be instructed to avoid what exposure in areas that are endemic for schistosomiasis?

A. Recreational (swimming, rafting, wading) or other exposure to fresh water
B. Eating of unpasteurized dairy products
C. Caves
D. Undercooked shellfish
E. Ticks

Answer: A Schistosomiasis is acquired when larvae that are harbored by freshwater snails are excreted into lakes, rivers, streams, or ponds and penetrate the skin of the traveler.

287

ANTIBACTERIAL CHEMOTHERAPY

GEORGE L. DRUSANO

Antibiotics have been classified as "miracle drugs" since their introduction and have transformed our expectations regarding the outcome of infection. More recently, they have been the backbone of modern interventional medicine. Barriers not meant to be breached have been. Catheters have been inserted into veins and arteries, the bladder, and the tracheal tree. These interventions support the seriously ill patient, but they also give bacteria access to normally sterile areas. Therapies for cancer and immune-mediated disease often leave patients severely immunosuppressed. Bacterial infections in such patients are serious and, when untreated or treated late, frequently result in death. Antibacterial agents allow critical life-saving support for such patients.

What is clear is that the overuse and poor use of antibiotics have allowed many pathogens to develop resistance to drugs. Multiresistant *Staphylococcus aureus* has become a plague both in the hospital and, of late, in the community. Extended-spectrum β-lactamases and *Klebsiella pneumoniae* carbapenemase enzymes have mediated resistance to many of our most potent and broad-spectrum β-lactam agents, including the carbapenems. Consequently, it is important to understand the principles of antibacterial chemotherapy to obtain the best clinical outcomes for our patients but also, in a broader sense, to lower the probability of the emergence of resistance and to maintain the potency of the drugs we currently have in our therapeutic armamentarium.[1,2]

CHOICE OF ANTIBIOTIC, ANTIBIOTIC DOSE, AND SCHEDULE TO OPTIMIZE CLINICAL OUTCOME

As in all of clinical medicine, a well-done history and physical examination are central to proper decision making and to the achievement of optimal therapeutic outcomes in patients with infections. Key to choosing the correct drug, dose, and schedule is recognition that an infection exists. The next step is to document where the infection exists and then to identify the dominant organisms present at each site of infection. The next step is to determine whether there are any risk factors that might predict the presence of drug-resistant pathogens.

As an example, we know that community-acquired pneumonia is caused by certain traditional pathogens. *Streptococcus pneumoniae*, *Haemophilus influenzae*, and perhaps *Moraxella catarrhalis* are the "classic" bacterial pathogens associated with this entity. "Atypical" pathogens such as *Legionella* species, *Mycoplasma pneumoniae*, and *Chlamydophila pneumoniae* may also be seen. In contrast, intra-abdominal infections are dominated by *Escherichia coli* and other Enterobacteriaceae and anaerobic organisms such as *Bacteroides* species. Consequently, it is important to understand the dominant pathogens present at different infection sites so that the best drug or combination of drugs can be chosen to treat the infection.

Knowing the source of infection is also critical because drugs penetrate differently into different spaces.[3] Classically, penetration is poorer into spaces where there are tight junctions, such as the central nervous system, the eye, and the prostate. In general, the penetration of many classes of antibacterial agents is good into complicated skin and skin structure infection sites. What is often not appreciated is the divergent penetrations of different agents and even agents within the same class into the lung to treat bacterial pneumonia. For instance, the penetration by macrolide antibiotics into skin infection sites is modest, but their penetration into the lung is good, with penetration ratios (area under the concentration-time curve [AUC] in epithelial lining fluid/AUC in plasma) ranging from 4 to 20. The penetration of β-lactam drugs can range from 15 to 100%, but there is no set of variables (at least to date) that explains such a range of penetrations. Table 287-1 presents a partial list of

TABLE 287-1 PRIMARY INFECTION SITES AND THE DOMINANT BACTERIAL SPECIES PRESENT

SITE	BACTERIA
Complicated skin or skin structure infection	*Staphylococcus aureus* and *Streptococcus* spp
Diabetic foot ulcer	Organisms above plus Enterobacteriaceae
Intra-abdominal infections	*Escherichia coli* and other Enterobacteriaceae plus anaerobes
Community-acquired bacterial pneumonia	*Streptococcus pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis*, "atypical" pathogens
Hospital-acquired pneumonia	*S. aureus*, *Klebsiella pneumoniae*, *Enterobacter* spp, *Pseudomonas aeruginosa*, *Acinetobacter* spp
Meningitis	*S. pneumoniae*, *H. influenzae* (nontypable), meningococci; in hospital settings, *S. aureus* and gram-negatives may be seen
Urinary tract infections	Enterobacteriaceae, particularly in sexually active women; multiresistant gram-negatives in patients with complicated urinary tract infections or those instrumented; enterococci, particularly in elderly men
Prostatitis	Enterobacteriaceae, enterococci, atypical pathogens

infection sites and their dominant pathogens. The point is not to have an encyclopedic knowledge of infection sites or of pathogens but to appreciate that different infection sites require different drugs to provide adequate coverage for the most likely pathogens present.

It is also important to understand other factors that increase the probability that a resistant organism is present at the primary infection site. An example is a patient who has recently taken antibiotics before acquiring the present infection. Other examples are the acquisition of an infection in the hospital or in an extended care facility and in a patient who is immunosuppressed. In such patients, the choice of antimicrobial agents must be carefully considered to cover more resistant pathogens.

CULTURE AND GRAM STAIN

Once the site of infection has been definitively identified or the most likely source of infection has been determined, it is critical to obtain culture specimens from that site as well as to obtain blood culture samples. Coordination with the microbiology laboratory is key to make sure that culture specimens are handled appropriately. Also of great importance is the performance and interpretation of a Gram stain on the specimen. This can be straightforward if the specimen is from a normally sterile space, or it may require considerable skill in interpretation if the specimen is from an area where mixed flora is normally present, such as sputum.

Although it is not possible to make a definitive diagnosis on the basis of the cellular morphology of the organism, it is possible to combine information on the morphology, the organism's gram positivity or negativity, the infection site, and the most likely pathogens to make an initial antimicrobial choice with the highest probability of producing effective chemotherapy. The initial antibiotic chosen to cover organisms present at the primary infection site has a significant influence on the outcome of therapy. Initial choices should err on the side of caution. When definitive cultures are available, the chemotherapy can be "streamlined" to provide the most effective and least toxic antimicrobial for the patient. As the seriousness of the infection increases, providing the correct initial coverage becomes more important with regard to the ultimate outcome.

SUSCEPTIBILITY

Because infections occur at a specific place, it is important to have an understanding of the antimicrobial susceptibility patterns in one's particular hospital. Most frequently, the microbiology susceptibility patterns are different in the culture specimens taken from patients on the general wards as opposed to those in intensive care units (ICUs) because the former are generally (but not always) infected with pathogens derived from the community setting. In severely infected patients, particularly those whose infections were acquired in the ICU, it is critical to know the susceptibility patterns for these pathogens, which are likely to be multiply resistant to different classes of agents.

After the definitive culture, the identified pathogen must be examined in an antimicrobial susceptibility test. This can be automated, in which case the information returned is the minimal inhibitory concentration (MIC), or it can be reported from a disc diffusion test, where the results are typically reported as S (susceptible), I (intermediate), or R (resistant). The MIC is often misunderstood as the concentration of drug that prevents the pathogen from growing, but it is actually the concentration of drug that allows a tube (or well) containing the pathogen to remain clear by visual examination after 18 to 24 hours. If one starts with an organism concentration of 1 to 5×10^5 colony-forming units (CFUs)/mL, this criterion can actually allow almost a 1 $\log_{10}$ (CFU/mL) increase in bacterial count over this time frame and still be read as the MIC. With all its limitations, the MIC provides critical information about drug choice. For several infections, such as meningitis, endocarditis, and perhaps bacteremia, knowing the minimal bactericidal concentration (defined as the concentration required for kill of 99.9% of organisms during 18 to 24 hours) is valuable. In these cases, it is important to obtain multi-log killing of the organism to ensure a high probability of a good clinical outcome. For meningitis and endocarditis, there is also the confounding problem of penetration of the drug to the primary infection site. In other circumstances (e.g., ventilator-associated pneumonia) in which bacterial burdens are high, optimizing the probability of cure requires highly bactericidal therapy.

DETERMINING THE "CORRECT" DRUG DOSE

The correct drug dose is the one that produces a high likelihood of achieving a good clinical response with a low probability of causing a concentration-driven adverse event. Another consideration is that the optimal dose should have a high probability of suppressing the emergence of resistant mutants. To be confident that a drug dose has a high likelihood of producing a good clinical outcome requires an understanding of the relationship between the measure of drug exposure and infection outcome, that is, pharmacodynamics (Chapter 29).

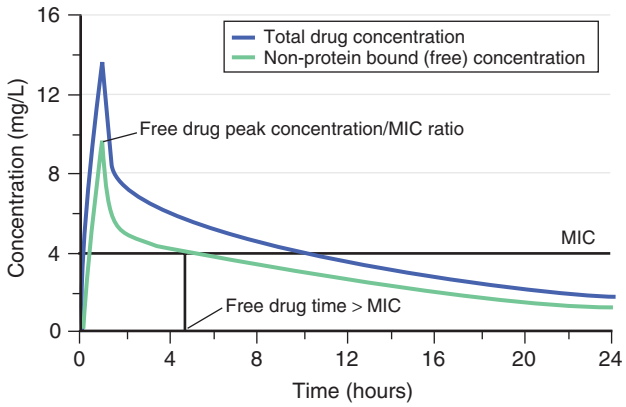

FIGURE 287-1. Three measures of drug exposure are important to the measure of potency, or the minimal inhibitory concentration (MIC). These measures are free drug peak concentration/MIC ratio, free drug time greater than MIC, and free drug area under the curve (AUC)/MIC ratio.

When we administer a drug either intravenously or orally, the drug concentration starts low, increases to a maximal value, then declines over time until another dose of the drug is given (in a multidose regimen). This drug concentration–time profile should be seen relative to a measure of drug potency against the pathogen in question: the MIC (or minimal bactericidal concentration). It is also critical to note that protein binding is important because in almost all cases, it is the free or non–protein bound drug that kills the causative pathogen. So understanding the pharmacodynamics of a drug or class of agents first requires knowledge of the concentration-time profile, protein binding, and MIC (Fig. 287-1). For drugs that kill organisms much faster as their concentrations rise (e.g., fluoroquinolones, aminoglycosides), the free drug AUC/MIC ratio is most closely linked to drug effect. For other drugs (e.g., penicillins, carbapenems, cephalosporins, monobactams), the rate of organism kill rises with concentration and plateaus quickly, in which case the free drug time greater than MIC is most closely linked to drug effect. On occasion, the free drug peak concentration/MIC ratio is linked to drug effect. This is seen when there is a rapid and frequent emergence of resistance and the peak concentration helps suppress the amplification of resistant mutant subpopulations.

These measures of drug exposure need to be linked to drug effect. There are a number of ways to do this, but two are most common. In the first and most valuable way, patients are studied during the course of a clinical trial. Multiple plasma samples are taken for documentation of the drug's pharmacokinetics and corrected for protein binding. The MIC of the infecting pathogen is determined for the drug being administered, and the three measures of drug exposure cited earlier are calculated. The outcome of the patient is then determined (usually success or failure, but in some instances, time to success or failure serves as the outcome measure). If the outcome is success or failure, the appropriate measure of drug exposure is linked to the outcome through logistic regression analysis. By creating such a relationship, we can directly estimate the probability of a patient's having a successful outcome if a certain measure of drug exposure is achieved. For example, if a patient receiving a drug that is a concentration-dependent killing agent achieves a free drug AUC/MIC ratio of 88, the logistic regression relationship allows the calculation that the probability of a good outcome is a specific number (perhaps 91%). During the past 10 years, we have been able to generate such relationships for a great number of drugs and across drug classes. The most common relationships are for the fluoroquinolone antimicrobials, but examples can be found for the aminoglycosides, oxazolidinones, β-lactams, and glycylcyclines, among others.

The second way to link exposure to antibacterial effect is through preclinical animal models of infection. Here, the end point is most often microbiologic, although survivorship models have been employed. We observe the drug concentration–time profile in the animals and at the end of the experiment determine the number of organisms left after therapy at the infection site (the baseline number of organisms having been previously determined).

We can then link the measure of drug exposure (as earlier) to the number of bacterial cells killed by a specific regimen. It is most often the case that drugs are administered to the animals in a "dose fractionation" fashion. For example, 400 mg/kg/day regimen of a β-lactam may be administered as the whole dose daily, half the dose every 12 hours, or one quarter of the dose every 6 hours. In this way, we can determine whether free drug peak concentration/MIC ratio, free drug AUC/MIC ratio, or free drug time greater than MIC is the best measure of drug exposure for the class of drug being studied.

How does knowing the relationship between drug exposure and microbiologic effect in an animal infection model help in treating patients? On the basis of experience with different drugs and drug classes, it has become possible to link a drug's microbiologic effect in an animal model to clinical outcome.[4] For instance, in the therapy of complicated skin and skin structure infections, a drug exposure in the animal model that stops organisms from growing for 24 hours or reduces their number by approximately 1 $\log_{10}$ (CFU/g) is adequate to generate a high probability of a good clinical outcome. This has been documented for oxazolidinones and glycylcyclines. For severe community-acquired pneumonia or for hospital-acquired pneumonia, a greater cell kill—generally 2 $\log_{10}$ (CFU/g) or greater—is required for a high likelihood of a good clinical outcome.

When we have clinical data with a logistic regression function, it is possible to identify an exposure target that is associated with a specific probability of a good outcome (e.g., a free drug AUC/MIC ratio of 88 generates a 91% probability of a good outcome). In the case of the animal model, it is possible to identify a target drug exposure that will achieve a certain microbiologic effect associated with a good clinical outcome (the logic is one step removed). In both cases, we have a target drug exposure, and this is used to identify the "correct" dose.

When the same dose of a drug is administered to a number of patients, no two concentration-time curves will be identical. Indeed, it is not unusual to have a 10-fold range in measures of drug exposure (e.g., peak concentration, trough concentration, AUC). When these are transformed by incorporating MIC values, ranges of 100- to 1000-fold are commonly encountered. As part of the drug development process, the pharmacokinetics of new agents are now identified in a large number of patients with the infection of interest. As part of this process, the interpatient variability in important pharmacokinetic parameters (e.g., drug clearance = 10 ± 4 L/hour) is determined. This information is then used with a tool called Monte Carlo simulation to ask and answer a key question: If I give this specific drug dose to a large number of patients and I recognize that the MIC values I am likely to encounter will range (for example) between 0.06 and 8 mg/L, how many patients will achieve the desired measure of drug exposure to give them a high likelihood of a good clinical outcome? This can be calculated directly from the data indicated earlier plus the MIC distribution for the drug and the type of infection one wishes to treat. Indeed, many of the dosage recommendations for new drugs are calculated in this manner and validated in large phase III clinical trials. It provides the clinician with a degree of confidence that the recommended doses are likely to work if the infecting pathogen is still susceptible to the drug.

EMERGENCE OF RESISTANCE

If the drug is properly chosen, the organism should have a high probability of being susceptible to it. However, during the course of therapy, the organism has many mechanisms available to make it less susceptible (the MIC increases) to the drug being used. This leads to less effect than was originally envisioned, which results in a lower probability of cure.

When are organisms likely to become resistant? There are many determinants, but five factors account for the majority of cases of resistance emerging during therapy. The first is the mutational frequency of the organism being treated. Because mistakes are made by the organism during replication, mutations occur in the genome at a specific rate, which is organism dependent. For antibiotic resistance, the mutational frequency rate is generally around $1/10^8$ to $1/10^6$. There are organisms, however—referred to as hypermutators—that have mutations in other places in the genome (often mutS) that alter their DNA replication error-checking mechanisms. These organisms' mutational frequencies are generally 10- to 100-fold higher than those of organisms without these other mutations.

The second factor is related to the bacterial burden. The higher the bacterial burden, the more likely it is that a preexistent mutant is already extant in the bacterial population. Antibiotic pressure then provides this mutant with a selective advantage, and it amplifies in the population while its more susceptible cousins are killed by the antibiotic. As the bacterial burden increases and ultimately surpasses the inverse of the mutational frequency to resistance, it becomes more and more likely that a resistant mutant exists in the population. For instance, if the mutational frequency to resistance is $1/10^7$ (1 resistant organism per a population of 10^7) and the patient has a bacterial infection in which the total bacterial burden is 10^9 organisms, it is highly likely that a resistant organism is present in the population a priori. A calculation of the actual probability can be performed by a Poisson distribution, the bacterial burden, and the mutational frequency to resistance. Consequently, infections in which the bacterial burden is high are more likely to generate resistance during therapy. For example, in clinical trials of ventilator-associated pneumonia, single-agent β-lactam drugs or fluoroquinolones allowed the emergence of resistance during therapy 33 to 50% of the time.

The third issue is drug penetration. There are circumstances (e.g., empyema) in which the bacterial burden is high but the drug's penetration to the infection site is reduced. In this case, the emergence of resistance is more likely. In contrast, poor penetration with relatively low bacterial burdens (e.g., meningitis) generally does not result in a high probability of the emergence of resistance.

The fourth issue has to do with error-prone replication in bacterial pathogens. When resistance occurs relatively late in therapy and the bacterial burden is modest, error-prone replication is often to blame. Antibiotics differ greatly with respect to their ability to induce the bacterial isolate to perform error-prone replication. Perhaps the best example is the fluoroquinolone antimicrobials because these drugs strike at the heart of DNA replication. The organism senses the attack of the antibiotic, and a whole cascade of events takes place, the most important of which is the induction of error-prone polymerases (e.g., pol V). These polymerases markedly increase the error rate in DNA replication. Most of these errors are lethal to the organism and therefore unhelpful to it. However, because this is a totally random process, by chance, a mutation can occur in a spot that provides protection from the onslaught of the antibiotic (e.g., a mutation in the DNA gyrase when the patient is receiving a fluoroquinolone). We perceive this as the organism's having a selective replication advantage (emergence of resistance), and we see an increase in the MIC of the mutant organism relative to the baseline organism.

The fifth factor has to do with mechanisms other than antibacterial target site mutations that allow the organisms to survive in the face of appropriate antibiotic chemotherapy. One extremely common mechanism seen in the majority of both gram-positive and gram-negative organisms is the upregulation of efflux pumps. These pumps are indiscriminate in their ability to pump molecules; they can eject multiple classes of antibacterials from the organism as well as natural substances that can harm it, such as metal ions. These pumps keep drug concentrations at their target sites much lower than they would be in the absence of the pumps. The pumps can be induced and then downregulated once the threat has passed, or occasionally, the organism can pick up a mutation in the part of the genome where expression of the pump is regulated, so the pump is always expressed (constitutive expression).

A similar process is seen with the production of β-lactamases. Often, these enzymes are situated on plasmids and are produced all the time. Sometimes, as with the efflux pumps, they sense the attack by the β-lactam, and their production is markedly increased (the phenomenon of induction, seen with ampC-type enzymes, which generally reside on the chromosome). Sometimes, also like the pumps, the organisms pick up a mutation in the part of the genome that regulates production of the β-lactamase. This is referred to as stable de-repression, and the enzyme is made all the time. The enzyme hydrolyzes its substrate (the β-lactam drug), thus preventing the binding to the target sites, the β-lactam–binding proteins.

Finally, in gram-negative organisms, the drug must cross the diffusional barrier of the outer membrane before binding to β-lactam–binding proteins (if the drug is a β-lactam) in the periplasm of the organism, or it must cross the inner membrane if its target site is actually inside the organism. For many agents, particularly those that are water soluble, a large percentage of their influx is due to passage through porin proteins. These proteins are water-filled channels that pass through the entirety of the outer membrane of gram-negative bacteria. Part of their function is to provide access to nutrients for the organism and allow the easy diffusion of waste products. These channels are also used to obtain passage by water-soluble antibacterial agents. The organism has the ability to downregulate these channels, either temporarily or permanently (by mutation). An example is *Pseudomonas aeruginosa*, in which downregulation of the porin channel oprD markedly diminishes the penetration of carbapenem antibiotics (β-lactam agents), with a resultant

two- to eight-fold rise in MIC. With all these mechanisms that can be brought to bear, it is no surprise that poor dosing and prolonged courses of therapy often lead to the emergence of resistance.

These mechanisms also interact. In the case of fluoroquinolone antimicrobials, where error-prone replication almost always occurs under pressure, the upregulation of efflux pumps relieves some of the antibiotic pressure, allowing the organisms to undergo more rounds of replication per unit of time, giving the error-prone replication mechanism more time to find a mutation that is not lethal and provides protection against the drug at the primary target site.

SUPPRESSING THE EMERGENCE OF RESISTANCE

Suppressing the emergence of resistance is an end point that is different from achieving a good clinical or microbiologic outcome. The antimicrobial exposure (free drug peak concentration/MIC ratio, free drug AUC/MIC ratio, or free drug time greater than MIC) necessary to suppress resistance is always at least as high as that required to attain maximal killing of bacterial cells, and in many instances, it is substantially higher.

Recently, it has been shown experimentally that it is possible to identify doses and schedules of drugs that suppress the emergence of resistance as well as provide optimal killing of bacterial cells. Unfortunately, many of the exposures necessary to achieve such an outcome are high enough to result in increased drug toxicity. Nevertheless, as new agents are developed, it will become important to identify resistance-suppressive exposures and to ascertain whether they are too toxic to be used clinically, as a way of retaining the potency of the antibacterial therapeutic armamentarium.

The other way to help suppress the emergence of resistance is to employ combination chemotherapy. Combination therapy has major advantages, but there are significant disadvantages as well. Among the advantages are that combination therapy can improve the spectrum of coverage in the setting of empirical treatment as well as help suppress the emergence of resistance. This is best seen in the treatment of *Mycobacterium tuberculosis*, although there is growing evidence that this may also be true for difficult-to-treat pathogens such as *P. aeruginosa* and *Acinetobacter* species. Combination therapy can be effective against some pathogens in serious infections for which a single agent would not be adequate. Enterococcal endocarditis is the classic example; ampicillin or vancomycin is generally static and not up to the task of curing this disease, and the second agent (an aminoglycoside, streptomycin, or gentamicin) is somewhat resistant when it is used alone (MIC values <500 mg/L). Yet the combination produces excellent bacterial kill in the endocarditic vegetation, with a high probability of cure if the patient can tolerate the combination for the requisite time. Some authors have discussed reducing drug doses in combination as a way of ameliorating toxicity, but this theoretical advantage is difficult to demonstrate convincingly in the clinical setting.

The disadvantages of combination therapy are also well known. At full doses of each, there may be added toxicity, and there are certainly greater costs associated with combinations. Finally, combinations of agents may interact antagonistically instead of either additively or synergistically. For example, the combination of tetracycline and penicillin is somewhat antagonistic and caused a number of failures in the treatment of pneumococcal meningitis in the 1950s. However, there are circumstances in which weak antagonism is tolerable. It has been shown that isoniazid plus rifampin, part of the standard therapy for *M. tuberculosis*, is somewhat antagonistic with respect to cell killing, but the combination provides superb protection against the emergence of resistance. Consequently, in discussing drug interactions (synergy, additivity, antagonism), it is important to be specific about the end point to which one is referring.

MECHANISM OF ACTION

The search for new antimicrobials begins with the principle that the target that affects pathogens must not be in the human genome or must be sufficiently different that the agent in question does not cause appreciable human toxicity. β-Lactam antibiotics are a good example; the inhibition of peptidoglycan synthesis has no effect on humans because this target is simply not present. An example of differing susceptibility to inhibition because of poor sequence homology between bacteria and humans can be seen in the inhibitors of the bacterial ribosome. The bacterial ribosome is much smaller than that in humans and has differing affinities for such drugs as aminoglycosides, tetracyclines, macrolides, and clindamycin. Consequently, such agents are an important part of the therapeutic armamentarium and cause only minor adverse effects related to their primary mode of action. In some cases, so-called off-target toxicity may take place. Again, an example is the β-lactams; a major toxicity is accelerated allergic reaction, even though the target for the agents is not present in humans. Table 287-2 lists the sites of action and the effects of many antimicrobial agents.

Often, antimicrobials are thought of as either *bacteriostatic* or *bactericidal*, for which there are standard definitions. An agent that causes a 1000-fold decline (3 $\log_{10}$ [CFU/mL] decrease) in an in vitro test system during 18 to 24 hours is defined as being bactericidal. Any agent that causes a smaller decline is defined as bacteriostatic. It is clear that these definitions are arbitrary; however, there is a clinical connection. In some circumstances, such as meningitis and endocarditis, it is critical to kill every last organism with the combination of drugs employed and the immune system. Obviously, the more organisms the antimicrobial kills, the easier this is to accomplish. In other circumstances, such as multilobar pneumonia, it is critical to kill as many of the organisms as possible so as not to overwhelm the body's immunologic defenses. For these reasons, clinicians generally prefer bactericidal to bacteriostatic agents.

MECHANISMS OF RESISTANCE

Earlier, how to suppress the emergence of resistance was examined. Here, the mechanisms by which organisms can become less susceptible to antimicrobial agents are examined. As stated earlier, in most cases, resistance is caused by an alteration in the target site; by an enzyme that alters the drug, resulting in a lack of activity; by the drug's being pumped out of the organism; or, in the case of gram-negative pathogens, by the loss or downregulation of a transmembrane porin protein. These mechanisms, along with error-prone replication, can interact to cause large increases in the MIC. For example, a gram-negative pathogen that acquired a mutation in its gyrase enzyme would generally have only a four-fold increase in its MIC value for a fluoroquinolone antimicrobial; however, if this isolate also had an efflux pump upregulated, the MIC could change 8- to 16-fold. Table 287-3 shows the mechanisms of resistance for multiple drug classes as well as the most common organisms in which these mechanisms are seen.

EFFECTS OF PHARMACOKINETIC CHANGES

Whereas antimicrobial pharmacodynamics is the study of the effect of a drug on an infecting organism, pharmacokinetics is the study of the effect of the body's processes on the drug concentration–time profile and the drug's ability to penetrate to the infection site (or the toxicity site). As such, it is a prime determinant of whether a drug will be able to kill or to inhibit the offending pathogen and, because many toxicities are concentration related, whether a serious drug-related toxicity will occur.

Earlier, the algorithm for identifying appropriate drug doses and schedules was outlined. Table 287-4 shows recommended doses and schedules of important antimicrobial agents as well as their protein-binding ability and whether alterations in renal or hepatic function generate major changes in the concentration-time profile. As in all chemotherapy, the aim is to generate a concentration-time profile in the plasma to generate a concentration-time profile at the infection site that allows the drug to inhibit or to kill the pathogen without causing toxicity.

Although there is almost always a guide to the concentration-time profile that results in an appropriate antimicrobial effect, it is more difficult to identify a linkage between drug exposure and the occurrence of toxicity. Data in this regard are available for the aminoglycosides, including a considerable amount of information on the association between drug concentrations and the likelihood of nephrotoxicity, and for daptomycin, for which a link between exposure and the likelihood of creatine kinase elevation has been elucidated.

For aminoglycosides, the relationships between drug exposure and the likelihood of a good clinical outcome and between drug exposure and the likelihood of nephrotoxicity have been determined. These are in the form of logistic regression functions, so the actual probability of both outcomes can be calculated. The one difference is that for the relationship with good outcome, the MIC value is part of the evaluation, whereas it does not figure in the toxicity relationship. Nevertheless, it is possible to derive appropriate information by making the outcome relationship MIC specific. Figure 287-2 illustrates the effect and toxicity relationships for aminoglycosides at three different MIC values. As shown, it is relatively easy to achieve a high probability of good clinical outcomes with aminoglycosides when the MIC is 0.25 mg/L, but it is virtually impossible to do so when the MIC rises to a value of 1.0 mg/L. The evaluation in the figure is based on twice-daily dosing; daily aminoglycoside dosing markedly improves this circumstance. Also,

TABLE 287-2 MECHANISMS OF ACTION OF ANTIMICROBIAL AGENTS

AGENT	SITE OF ACTION	EFFECT	BACTERICIDAL	BACTERIOSTATIC
β-Lactams (penicillins, cephalosporins, carbapenems, aztreonam)	Cell wall: penicillin-binding proteins	Inhibit cross-linking of peptidoglycan (transpeptidation), impair cell wall synthesis	+	Occasionally (enterococci)
Vancomycin, teicoplanin, dalbavancin, telavancin	Cell wall: terminal D-alanyl-D-alanine of pentapeptide peptidoglycan precursor	Inhibit polymerization of disaccharide precursors to peptidoglycan (transglycosylation), impair cell wall synthesis	+	Occasionally (enterococci)
Daptomycin	Cell membrane	Rapid depolarization of membrane potential	+	Occasionally (enterococci)
Aminoglycosides	Protein synthesis: 30S ribosome subunit	Inhibit peptide elongation, cause misreading of genetic code, inhibit protein synthesis	+	
Tetracyclines, glycylcyclines	Protein synthesis: 30S ribosome subunit	Inhibit binding of transfer RNA, inhibit protein synthesis	Occasionally	+
Chloramphenicol	Protein synthesis: 30S ribosome subunit	Blocks attachment of aminoacyl transfer RNA, inhibits protein synthesis	Occasionally	+
Macrolides, azalides, ketolides	Protein synthesis: 50S ribosome subunit	Block transfer of amino acids to peptide chain, inhibit protein synthesis	Occasionally	+
Clindamycin	Protein synthesis: 50S ribosome subunit	Blocks transfer of amino acids to peptide chain, inhibits protein synthesis	Occasionally	+
Quinupristin-dalfopristin	Protein synthesis: 50S ribosome subunit	Block extrusion of peptide chains, inhibit protein synthesis	+	+ (with quinupristin resistance)
Linezolid	Protein synthesis: 50S ribosome subunit	Blocks formation of 70S initiation complex, inhibits protein synthesis	Occasionally	+
Rifampin	Nucleic acid synthesis: β-subunit of DNA-dependent RNA polymerase	Inhibits RNA synthesis	+	
Metronidazole	Nucleic acid synthesis	Damages nucleic acids, inhibits DNA synthesis	+	
Quinolones	Nucleic acid synthesis: DNA gyrase, topoisomerase IV	Impair supercoiling of DNA, prevent decatenation of DNA molecules after replication, inhibit DNA synthesis	+	
Sulfonamides	Folic acid synthesis: dihydropteroate synthetase	Competitive inhibition of synthesis of dihydrofolate from *p*-aminobenzoic acid, pteroate, and glutamic acid	Occasionally (when used with trimethoprim)	+
Trimethoprim	Folic acid synthesis: dihydrofolate reductase	Inhibits reduction of dihydrofolate to tetrahydrofolic acid	Occasionally (when used with sulfonamide)	+

these relationships permit one to calculate the probabilities of effect and toxicity when, for example, aminoglycoside AUC is increased owing to renal dysfunction because these agents are largely eliminated renally.

When no toxicity relationship is available, there is still a target for good clinical effect. Achievement of this target should be paramount, and alterations for renal or hepatic impairment should strive to maintain the high likelihood of effect seen in patients with a relatively normal clearance function. One can change the dose or schedule of a drug to decrease its accumulation in the presence of renal or hepatic impairment (depending on the drug) and then recalculate the impact on the likelihood of attaining a good clinical outcome. One can also calculate the amount of accumulation with the proposed dose reduction or extension of the dosing interval. For the increase in exposure (relative to that in normally clearing patients), there is no clear guidance, but one can accept a certain maximal amount of accumulation as long as the proposed dose adjustment maintains a high likelihood of a good outcome. The acceptability of the increased drug exposure after dosage adjustment is usually based on a combination of preclinical toxicology and the largest exposures seen in phase I and phase II clinical trials. However, the overarching issue is that the proposed dose or schedule alteration maintains a high probability of a good clinical outcome.

DRUG CLASSES AND THEIR PROPERTIES

During the past 70 years, a large number of different classes of antimicrobial agents have been developed. These classes differ in their mechanisms of action, mechanisms of emergence of resistance, and whether they kill substantial numbers of organisms or only shut off bacterial growth. The following sections examine some of the properties of the major classes of antimicrobial agents in use today.

β-Lactam Agents

This class of drugs is arguably the most important group of antimicrobials. With chemical modification, they have an exceptionally broad spectrum of activity and, in general, an excellent safety profile. The major toxicity is related to allergic reactions to a degradation product of the drug. There are a number of different types of β-lactams, including the penicillins, the cephalosporins, the monobactams, and the carbapenems.

These agents bind to their targets, the β-lactam–binding proteins (sometimes referred to as penicillin-binding proteins). These binding proteins have an active site serine, and the drug forms a covalent bond with this site through the carbonyl of the β-lactam ring. Sometimes, the binding has direct effects on the organism's shape. For example, in gram-negative organisms, binding to penicillin-binding protein (PBP)–2 causes the organism to assume a spherical shape, whereas binding to PBP-3 causes the formation of long chains of organisms. In general, high-affinity binding to PBP-1 leads to the rapid death of the organism, sometimes accompanied by lysis. The classic response of *S. pneumoniae* to penicillin G is rapid lysis of the organism. Binding to PBP-1 (1a or 1b) leads to activation of *N*-acetylmuramic acid amidase, which destroys the bacterial cell wall, resulting in lysis.

The most common way for pathogens to protect themselves from β-lactams is by elaborating β-lactamases.[5] The genes for these enzymes may be on plasmids or other bits of transmissible DNA, or they may reside on the bacterial chromosome. Some drugs, such as the carbapenems, are resistant to hydrolysis by many enzymes (but certainly not all of them, especially the metallo-β-lactamases and *K. pneumoniae* carbapenemase-type β-lactamases). One of the ways developed to protect these drugs is to add a second agent, the β-lactamase inhibitor. Examples include potassium clavulanate,

TABLE 287-3 MECHANISMS OF ANTIMICROBIAL RESISTANCE

ANTIBACTERIAL AGENT	MECHANISM	REPRESENTATIVE ORGANISM
β-Lactams (penicillins, cephalosporins, carbapenems, aztreonam)	Altered target (penicillin-binding proteins)	Methicillin-resistant *Staphylococcus aureus* (MRSA), penicillin-resistant *Streptococcus pneumoniae, Enterococcus faecium*
	Reduced permeability	*Enterobacter* spp, *Pseudomonas aeruginosa, Acinetobacter spp*
	Enhanced efflux	*P. aeruginosa, Acinetobacter* spp
	β-Lactamases	*S. aureus*, Enterobacteriaceae (includes ESBLs), *Haemophilus influenzae, Moraxella catarrhalis, Neisseria gonorrhoeae, Enterococcus faecalis, P. aeruginosa, Acinetobacter spp*
Aminoglycosides	Inactivating enzymes (acetylation, adenylation, phosphorylation)	*S. aureus,* enterococci, *P. aeruginosa,* Enterobacteriaceae
	Reduced permeability	Enterobacteriaceae, *P. aeruginosa,* enterococci
	Enhanced efflux	*P. aeruginosa*
	Decreased ribosomal binding	*S. aureus, E. faecalis,* mycobacteria (streptomycin), gram-negative pathogens (aminoglycoside ribosomal methylase)
Chloramphenicol	Enhanced efflux	*H. influenzae*
	Reduced permeability	Enterobacteriaceae
	Inactivating enzyme (acetylation)	*S. aureus, S. pneumoniae,* enterococci
Daptomycin	Altered target	*S. aureus*
Glycylcyclines	Enhanced efflux	Enterobacteriaceae, especially *Proteus*
Macrolides, clindamycin, ketolide, quinupristin	Altered target (methylation of ribosomal RNA)	*S. aureus, S. pneumoniae* (not ketolide), streptococci, *Bacteroides fragilis*
	Enhanced efflux (not clindamycin or ketolide)	*S. pneumoniae*, streptococci
	Reduced permeability	Enterobacteriaceae
	Inactivating enzymes	*Escherichia coli, Klebsiella pneumoniae, S. aureus*
Linezolid	Altered target	Enterococci, *S. aureus*
Quinolones	Altered target (DNA gyrase, topoisomerase IV)	Enterobacteriaceae, *P. aeruginosa*
	Reduced permeability	Enterobacteriaceae, *P. aeruginosa*
	Enhanced efflux	*E. coli, P. aeruginosa*
Tetracyclines	Altered target (ribosome)	*N. gonorrhoeae*, streptococci
	Enhanced efflux	*E. coli, S. pneumoniae*
	Reduced permeability	Enterobacteriaceae
	Drug inactivation	*B. fragilis*
Rifampin	Altered target (β-subunit of polymerase)	*E. coli, S. aureus, Mycobacterium tuberculosis*
Sulfonamides, trimethoprim	Altered target (dihydropteroate synthetase or dihydrofolate reductase)	Enterobacteriaceae, *M. catarrhalis*
	Enhanced *p*-aminobenzoic acid production	*S. aureus, N. gonorrhoeae*
	Reduced permeability	*P. aeruginosa,* Enterobacteriaceae
Vancomycin	Altered target (peptidoglycan precursor binding site)	*E. faecium, E. faecalis, S. aureus*

ESBLs = extended-spectrum β-lactamases.

sulbactam, tazobactam, and, most recently, NXL-104 (an experimental drug now referred to as avibactam). These agents inhibit different types of β-lactamases, with NXL-104 being the only one able to inhibit the ampC-type enzymes carried by *P. aeruginosa*, *Enterobacter* species, *Citrobacter* species, *Serratia marcescens*, and indole-positive *Protea* (SPICE organisms).

All β-lactams are relatively non–concentration dependent in their kill rate, and free drug time greater than MIC is the important factor for increased organism killing. The classes differ somewhat, with carbapenems requiring approximately 40% free drug time greater than MIC for near-maximal cell killing. For penicillins, this percentage is approximately 50%, and for cephalosporins and monobactams, it is 60 to 70%. When these agents need to penetrate to a site of infection, such as epithelial lining fluid or central nervous system, the targets may change somewhat.

Aminoglycosides

These important agents were discovered in the late 1940s for the treatment of *M. tuberculosis* (streptomycin). Screening of natural products identified a number of different aminoglycosides, such as kanamycin, neomycin, gentamicin (actually a combination of three congeners), and tobramycin. Other semisynthetic agents, such as amikacin, netilmicin, and arbekacin (among others), have been discovered and used for therapy in the United States and elsewhere.

Nephrotoxicity and middle ear toxicity (hearing loss or loss of balance) are the defining dose-limiting toxicities of aminoglycosides and resulted in their going out of favor in the 1990s and early in the first decade of the 21st century. It has now been recognized that most (but not all) of the nephrotoxic potential can be ameliorated by intermittent dosing of these drugs (usually once daily). Even with daily therapy, however, prolonged use can still result in nephrotoxicity or ototoxicity.

The recent rise in resistance, particularly among gram-negative isolates, and new resistance mechanisms mediating resistance to even our best β-lactam agents have resulted in renewed interest in existing aminoglycosides and a search for new ones that are more resistant to inactivation by the aminoglycoside-modifying enzymes.[6]

These drugs are concentration dependent in terms of their kill rate and are rapid killers. Hence, the AUC/MIC ratio (or, as sometimes reported, peak concentration/MIC ratio) is the factor most closely associated with bacterial cell killing. Therefore, large doses administered daily to patients with normal renal function would be expected to optimize bacterial cell killing while minimizing the probability of inducing an aminoglycoside-related toxic event.

The older aminoglycosides (streptomycin and gentamicin) have the best profile for synergizing with drugs active against gram-positive streptococci (particularly enterococci). Tobramycin generally has the most potent activity against *P. aeruginosa* (depending on the aminoglycoside-modifying enzymes present in a specific locale), and less resistance is generally seen with amikacin (again, depending on the locale). Streptomycin and amikacin, because of the number of amino groups carried, are usually about four-fold less potent

TABLE 287-4 DOSAGE REGIMENS OF ANTIBACTERIALS, PHARMACOKINETICS, AND DOSE ADJUSTMENT IN PATIENTS WITH RENAL OR HEPATIC FAILURE

than gentamicin or tobramycin. Consequently, their dosages are approximately three- to four-fold higher.

These agents should be thought of as components of combination regimens for seriously ill patients, particularly those thought to be infected by gram-negative organisms, in the empirical therapy setting.

Quinolones

These agents are completely synthetic and do not exist in nature. They are inhibitors (depending on the drug and the organism) of topoisomerases II and IV. This means that they strike at the heart of DNA replication, making them rapidly bactericidal. The use of a fluorine substitution markedly enhanced the microbiologic activity of these drugs, so they became useful for both community-acquired infections (especially urinary tract infections and pneumonia) and hospital-acquired gram-negative infections.

These drugs penetrate well into most spaces, with substantial concentrations inside cells. This makes them active against obligate intracellular pathogens such as *Chlamydophila*, *Legionella*, and *Mycoplasma*. They also penetrate well into spaces with tight junctions (prostate, eye, central nervous system) and into epithelial lining fluid.

Typically, the toxicities associated with these drugs are "off target." A number of these drugs were either withdrawn from the marketplace or given black box warnings by health authorities because of the infrequent occurrence of torsades de pointes (Chapter 65) or other serious and life-threatening toxicities, such as eosinophilic hepatitis.

These agents are concentration-dependent bacterial killers, indicating that the free drug AUC/MIC ratio is best associated with a regimen's ability to kill bacterial cells. Of interest, particularly for a drug that is completely synthetic, there are a number of resistance mechanisms that allow bacterial escape from drug pressure. The combination of efflux pump overexpression and error-prone replication, resulting in target site mutants as well as serious underdosing for some of the earlier drugs in the class, has resulted in the emergence of considerable resistance, particularly among gram-negative isolates and in the ICU setting.[7]

Macrolides, Tetracyclines, Ketolides, Clindamycin, and Linezolid

These agents bind to different places in the bacterial ribosome, making them inhibitors of protein synthesis and, for the most part, drugs with limited bactericidal activity. An exception may be their activity against *S. pneumoniae*.

Macrolides (particularly clarithromycin and azithromycin) are most useful for community-acquired respiratory tract infections, for two reasons. First, their spectrum is well suited to the classic and atypical pathogens encountered in these patients. Second, they concentrate well in the epithelial lining fluid, with an accumulation that ranges from 6-fold to almost 20-fold that in plasma. This accumulation also partially explains why these agents have fared much better in the respiratory tract setting than in the skin and skin structure setting. Telithromycin, a ketolide, retains activity against many (but not all) macrolide-resistant isolates.

The macrolides and telithromycin are free drug AUC/MIC ratio–driven drugs with respect to bacterial activity, but for different reasons. Telithromycin is somewhat concentration dependent with regard to its microbiologic activity, whereas classic macrolides are not. Telithromycin is more like aminoglycosides or quinolones in terms of the association between exposure indices and bacterial effect. Classic macrolides, especially azithromycin, induce a long persistent or post-antibiotic effect and are *not* concentration dependent in their bacterial effect. This post-antibiotic effect suppresses bacterial regrowth after the drug concentration declines below the MIC until the next dose of drug is administered. In this way, we perceive the linkage to be driven by the free drug AUC/MIC ratio, but with a mechanism different from that of agents whose bacterial kill rate is concentration dependent.

Most of the toxicities seen here are off target and gastrointestinal. However, there is also some elongation of the QT interval (Chapter 54).

Tetracyclines have an exceptionally broad spectrum of activity, including both gram-positive and gram-negative pathogens, and are active against atypical pathogens. The latest incarnation of a tetracycline-type agent (tigecycline, a glycylcycline) has good activity against methicillin-resistant *S. aureus* (MRSA) as well. Tigecycline differs from previous tetracyclines (e.g., doxycycline, minocycline) in that its structure prevents many efflux pumps from removing the drug from the bacteria and also provides a degree of ribosomal protection.

The lincosamide antibiotic clindamycin has a spectrum that covers most clinically significant anaerobes, including many in the *Bacteroides* group (although some resistance is being seen). It is thus a useful agent for infections in which anaerobes play a prominent role, such as lung abscesses and intra-abdominal infections. In many areas of the country, it retains activity against MRSA, but this should be verified with a D-test (inducible macrolide-lincosamide-streptogramin resistance) in the microbiology laboratory. It also has good activity against many streptococci. Because it is a protein synthesis inhibitor, it may provide improved results when the staphylococcal or streptococcal isolate elaborates a great deal of toxin.

Again, most toxicity is off target, with gastrointestinal symptoms being most frequent. Antibiotic-associated diarrhea and the more serious *Clostridium difficile* colitis can occur.

Linezolid is a member of the oxazolidinone class of antibiotics and is a protein synthesis inhibitor. It is distinguished by having excellent gram-positive activity and robust activity against MRSA. It has been used in skin and skin structure infections and has been evaluated in MRSA nosocomial pneumonia. Linezolid penetrates well into skin as well as into the epithelial lining fluid, which is the reason for its evaluation in hospital-acquired MRSA against vancomycin. It is also distinguished by having an oral formulation that is highly bioavailable.

The free drug AUC/MIC ratio is the pharmacodynamic index most associated with cell killing for linezolid. Its toxicity is reflected by dropping counts of bone marrow–derived cells, particularly platelets, seen most frequently

TABLE 287-5 DIVERSE EFFECTS OF ANTIMICROBIAL AGENTS

AGENT	GENERAL	SKIN	GI TRACT	BLOOD CELLS	KIDNEY	NERVOUS SYSTEM	OTHER
Penicillins	Hypersensitivity, anaphylaxis, serum sickness	Rash, urticaria, erythema multiforme	Diarrhea (ampicillin, amoxicillin-clavulanate), hepatitis (oxacillin)	Coombs-positive hemolytic anemia, impaired platelet function (ticarcillin), leukopenia, thrombocytopenia	Nephritis (methicillin), hypokalemia (carboxy- and ureido-penicillins)	Seizures, twitching (high doses, renal failure)	Inactivates aminoglycosides when admixed; possible with concurrent therapy in renal failure
Cephalosporins	Serum sickness (cefaclor), hypersensitivity, anaphylaxis (rare)	Rash, urticaria	Diarrhea, hepatic dysfunction, precipitates in bile (ceftriaxone), mild increase in LFTs	Neutropenia, increased prothrombin time, bleeding (due to MTT side chain), positive Coombs test	Enhances aminoglycoside toxicity, acute renal failure (rare), interstitial nephritis		Disulfiram-like reaction with alcohol use (MTT side chain)
Carbapenems	Hypersensitivity	Rash, urticaria, erythema multiforme	Vomiting with rapid infusion (imipenem), abnormal LFTs	Bone marrow suppression, positive Coombs test	Renal dysfunction	Seizures, myoclonus	
Aminoglycosides	Fever	Rash			Reversible renal failure	Irreversible vestibular toxicity and/or auditory damage, muscle blockade (with anesthetics and myasthenia gravis)	
Vancomycin	Allergy, fever	Rash		Leukopenia, thrombocytopenia	Nephrotoxic	Decreased hearing, neuropathy	Histamine release with flushing and hypotension (infusion <1 hr, antihistamines can prevent)
Quinolones	Headache, allergy, anaphylaxis (rare)	Rash (gemifloxacin), urticaria, photosensitivity (lomefloxacin)	GI distress, abnormal LFTs			Dizziness, insomnia, nervousness, tremors, visual changes, seizures	Tendon rupture arthropathy in young animals
Sulfonamides	Hypersensitivity, anaphylaxis, serum sickness, fever	Rash, Stevens-Johnson syndrome, photosensitivity	Hepatitis	Hemolysis (G6PD deficiency), agranulocytosis, marrow suppression	Crystalluria	Neuropathy	Vasculitis
Trimethoprim ± sulfamethoxazole	Fever	Rash, erythema multiforme, Stevens-Johnson syndrome, TEN	Hepatitis, pancreatitis	Marrow suppression	Hyperkalemia, acute renal failure		
Chloramphenicol	Fever			Marrow suppression (dose related), aplastic anemia		Optic neuritis, neuropathy	Circulatory collapse (gray baby syndrome in neonates)
Tetracyclines	Hypersensitivity	Photosensitization (doxycycline)	GI discomfort, hepatotoxicity in azotemia or pregnancy		Antianabolic aggravation of azotemia (except doxycycline)	Vertigo (minocycline)	Deposition in bone (dysplasia) and teeth (staining)
Macrolides	Fever	Rash	GI discomfort			Reversible decreased hearing	Phlebitis (IV erythromycin), metallic taste (clarithromycin)
Clindamycin	Fever	Rash	Diarrhea, pseudomembranous colitis				
Metronidazole	Headache, hypersensitivity		Nausea, metallic taste, pancreatitis	Leukopenia		Peripheral neuropathy, ataxia	Mutagenic, carcinogenic in rodents, disulfiram-like reaction with alcohol

GI = gastrointestinal; G6PD = glucose-6-phosphate dehydrogenase; LFT = liver function test; MTT = methylthiotetrazole; TEN = toxic epidermal necrolysis.

with prolonged use. Resistance occurs rarely and is seen with enterococci more frequently than with *S. aureus*. There are five or six gene copies of the target site. As more and more copies become mutated through homologous recombination, the MIC increases almost linearly. Because these mutated targets have some biofitness cost, there is a slow reversion to wild-type targets when therapy is discontinued. If all copies become mutated, however, they cannot revert to wild type. The early detection of MIC changes should lead to the consideration of changing or stopping therapy.

Vancomycin, Quinupristin-Dalfopristin, and Daptomycin

Although structured differently, these agents (along with linezolid) are distinguished by having reliable activity against MRSA.

Vancomycin acts at the cell wall and is bactericidal. The free drug AUC/MIC ratio is the driver of antimicrobial effect. Vancomycin has activity against many gram-positive pathogens and has lately become distinguished for its activity against *C. difficile* when it is administered orally. As with most drugs, wide use has caused the emergence of vancomycin resistance in both enterococci and *S. aureus* (although the latter is rare).

Although vancomycin has a reputation for being a somewhat slow killer, no new agent has significantly outperformed it, at least in trials of skin and skin structure infections. MIC creep has been documented. Although many *S. aureus* isolates were once susceptible with MIC values of 0.25 and 0.5 mg/L, these are now in the distinct minority; 1.0 mg/L represents the modal value, with a few isolates having values of 2.0 mg/L. The higher MICs make these isolates more difficult to treat reliably with standard dosing (1 g IV every 12 hours). Also, it has recently become clear that higher vancomycin doses are associated with a significantly higher risk of nephrotoxicity, even when the agent is administered alone. In addition to nephrotoxicity, vancomycin causes histamine release ("red man syndrome") when it is administered too quickly intravenously. Infusion times of approximately 1 hour are recommended for standard doses.

Quinupristin-dalfopristin is a combination of streptogramin A and streptogramin B antibiotics. Although each is bacteriostatic, the combination can produce some cell killing because the two drugs are synergistic. The synergy is lost, however, with the emergence of resistance to either drug. Further, the amount of bacterial cell killing is modest because of the drugs' rapid half-lives and the imposition of a 12-hour dosing interval. This combination product has activity against resistant enterococci as well as MRSA. Its toxicity includes relatively severe muscle pain in some patients. It is also phlebitogenic and has to be administered with a central venous catheter, limiting its utility.

Daptomycin is a lipopeptide antibiotic discovered in the 1980s and resurrected in the 1990s with a greater understanding of the relationship between exposure and effect versus exposure and toxicity. It was discovered that the antibacterial effect against MRSA was driven by the free drug AUC/MIC ratio. Muscle effects were seen early in its development that limited therapy. Trough concentrations of daptomycin drive this toxicity and can be ameliorated by once-daily dosing (thus minimizing trough concentrations).

This agent has been licensed for skin and skin structure infections and, of note, for complicated *S. aureus* bacteremia and right-sided endocarditis. It also has activity against enterococci. The drug is bound up in epithelial lining fluid by surfactant, excluding its use in the therapy for pneumonia.

Daptomycin may cause muscle toxicity, which is rare, but this may be preceded by the harbinger of an elevated creatine kinase level. The muscle damage is driven by daptomycin trough concentrations, generally above a concentration of about 25 mg/L. Monitoring of creatine kinase concentration is useful in the management of patients receiving daptomycin therapy.

TOXICITIES

All antimicrobials have toxicities. The most common observed toxicities for many antimicrobial agents are presented in Table 287-5.

DURATION OF THERAPY

Relatively little is known about the optimal duration of therapy. Some work has been done to define certain circumstances in which short courses of chemotherapy are effective. For instance, gonorrhea is highly likely to be cured by a single dose of drug (ceftriaxone, cefixime, fluoroquinolones), as long as the organism is susceptible to the drug given.

For trimethoprim-sulfamethoxazole and fluoroquinolones, controlled trials have shown that 3 days of therapy is adequate for uncomplicated urinary tract infections. For β-lactam antimicrobials, a somewhat longer duration is required.

In community-acquired pneumonia, controlled trials with fluoroquinolones have demonstrated optimal results with 5 days of therapy, most likely because of concentration-dependent killing. For bacterial sinusitis, direct sampling from the infected sinus has demonstrated that bacterial pathogens were eradicated by day 3 of therapy or earlier, particularly for *S. pneumoniae* infections.

In ventilator-associated pneumonia, a double-blind comparison of 8 versus 15 days of therapy demonstrated that, with a single exception, clinical outcomes were just as good, there was less emergence of resistance, fewer antibiotics were administered, and there was less toxicity in the group receiving 8 days of therapy. The single exception was when a nonfermenting gram-negative rod was recovered (*P. aeruginosa* or *Acinetobacter* species). In this circumstance, there were significantly more relapses with 8-day versus 15-day treatment, but clinical outcomes were no different.

In some infections, the organisms are slow growing and require more time for control. Both endocarditis and osteomyelitis are examples. Therapy durations of 4 to 6 weeks and occasionally longer may be required for cure in this circumstance.

Finally, one of the longest durations of therapy is seen in the treatment of tuberculosis. In this case, some organisms are in the "non-replicative persister" (NRP) state, indicating that they are not growing or metabolically active. When recovered, they are still fully susceptible to the antimicrobials being used, but while in the NRP state, they cannot be readily killed with current chemotherapy (phenotypic, not genotypic resistance). Therapy durations of 6 months for wild-type organisms and 18 to 24 months for multidrug-resistant tuberculosis are required because of the need to use suboptimal regimens. Indeed, it is a major research goal to find drugs that will readily kill organisms in the NRP state and thus substantially shorten the therapeutic course for *M. tuberculosis*.

FAILURE OF ANTIMICROBIAL THERAPY

Antimicrobial therapy occasionally fails, with failure defined as the persistence of signs and symptoms of infection or the persistence of fever. When one is confronted with failure after what was thought to be adequate antimicrobial therapy, it should set off a sequence of investigations: Did resistance emerge, or did superinfection occur? Is there an obstructed hollow viscus (e.g., urinary or gastrointestinal tract)? Is there an undrained abscess or infected collection (e.g., empyema)? Is there an infected foreign body (e.g., intravenous catheter or prosthesis), or is there devitalized tissue (e.g., sequestrum in osteomyelitis)? Is the fever (if present) attributable to a drug being administered? Thoughtful re-examination should sort out the cause in many instances.

REVIEW QUESTIONS

1. For β-lactam antibiotics, the index that is most closely linked to the ability of the drug dose and schedule to kill the target pathogen is

A. Free drug Cmax/MIC ratio
B. Free drug AUC/MIC ratio
C. Time (fraction of a dosing interval) that free drug concentrations exceed the MIC
D. Total drug AUC/MIC ratio

Answer: C β-Lactam drugs are not particularly concentration dependent in their rate of kill and reach a maximal kill rate at low multiples of the MIC (usually around four-fold). Except in unusual circumstances, there is little in the way of persistent microbiologic effect after drug concentrations at the infection site decline below the MIC. Consequently, the ability to kill target pathogens is increased as time of free drug exceeding the MIC increases. Again, in the majority of instances, only free (non–protein bound drug) is microbiologically active.

2. In choosing an optimal drug dose and schedule for a patient's serious infection, which of the following is the most important consideration?

A. MIC of the pathogen
B. Drug dose chosen
C. Protein binding of the antibiotic chosen
D. Site of infection
E. Toxicity profile of the drug chosen
F. All of the above

Answer: F There are a small number of factors that clinicians can control that have an impact on the ability of a chosen drug dose and schedule to help a patient recover from an infection. Knowledge of the MIC of the infecting pathogen is critical as irrespective of the drug chosen, a lower MIC value will give a higher probability of attaining the target for a good therapeutic outcome. Likewise, the drug chosen has properties that may help or hinder in a specific case. For example, an agent that is not bactericidal is not likely to be an optimal choice in a patient with meningitis. As part of this, only free drug is (in the main) microbiologically active, so this is a serious consideration. The dose size and frequency will have a direct impact on the likelihood of achieving an exposure target that will optimize the likelihood of a good outcome. Understanding the probable infection site is important as penetration will be different into skin, cerebrospinal fluid, epithelial lining fluid, and prostate. Finally, the toxicity profile is important. Choosing a nephrotoxic agent for an intensive care unit patient would be improvident, unless there was little alternative. Consequently, all of the factors need to be considered by the clinician.

3. Which of the following is most important for resistance emergence?

A. Mobile genetic element
B. Efflux pump upregulation
C. Drug-inactivating enzymes (like β-lactamases)
D. None of the above
E. All of the above

Answer: E Each of these represents a way for the infecting pathogen to increase survivorship in the face of antimicrobial therapy. In A and C, there is most often a destruction of the drug. In B, the drug that does penetrate into the organism is actively pumped out, lowering the drug concentration below the critical level necessary for organism kill. These mechanisms also may interact with each other.

4. Of the drugs listed, which are nephrotoxic?

A. Linezolid
B. Vancomycin
C. Meropenem
D. Gentamicin
E. B and D
F. All of the above

Answer: E The nephrotoxic potential of aminoglycosides (e.g., gentamicin, tobramycin, amikacin) has been known for decades. Only more recently have we come to understand that higher doses of vancomycin (>2 g/day) are associated with a substantial risk of nephrotoxicity. (Lodise TP, Lomaestro B, Graves J, Drusano GL. Larger vancomycin doses are associated with an increased incidence of nephrotoxicity. *Antimicrob Agents Chemother*. 2008;52:1330-1336; and Lodise TP, Patel N, Lomaestro B, et al. Relationship between initial vancomycin concentration-time profile and nephrotoxicity among hospitalized patients. *Clin Infect Dis*. 2009;49:507-514.

5. Which of the following patients is likely to have the highest antimicrobial drug clearance (and hence lowest levels of the antibiotic)?

A. A 70-year-old woman with hospital-acquired pneumonia caused by an organism carrying a carbapenem-resistant Enterobacteriaceae
B. A 20-year-old patient who has crashed his Kawasaki Ninja into a tree, causing head injury, and who has developed a ventilator-associated pneumonia caused by *Pseudomonas aeruginosa* and is septic
C. A 50-year-old diabetic man with an infected foot ulcer
D. A 30-year-old sexually active woman with an uncomplicated urinary tract infection
E. A 40-year-old man with a pneumococcal superinfection after having developed an influenza virus infection (he did not get the vaccine)

Answer: B Most people think that seriously ill intensive care unit patients will, of necessity, have lower drug clearances because of illness. However, in this case, the young age of the patient, coupled with the sepsis, which will give him a hyperdynamic state, puts him at highest likelihood for having a very high drug clearance. Whereas many ascribe this to change in glomerular filtration rate (e.g., such a patient may have an estimated glomerular filtration rate in excess of 150 mL/minute), the hyperdynamic state also increases blood flow to other clearing organs, such as the liver, so even agents like a glycylcycline (e.g., tigecycline), which are not heavily renally cleared, can have very high clearances. Such patients have been shown to have a high rate of failure in clinical trials. (Ambrose PG, Bhavnani SM, Ellis-Grosse EJ, Drusano GL. Pharmacokinetic-pharmacodynamic considerations in the design of hospital-acquired or ventilator-associated bacterial pneumonia studies: look before you leap! *Clin Infect Dis*. 2010;51[Suppl]:S103-S110.)

STAPHYLOCOCCAL INFECTIONS

HENRY F. CHAMBERS

DEFINITION

Staphylococci are well adapted as both commensals and pathogens. Coagulase-negative species constitute a significant proportion of the normal human cutaneous microbiome. *Staphylococcus aureus,* a coagulase-positive species, is present in nasopharyngeal flora in a third of individuals, most of whom will not become infected. As a pathogen, *S. aureus* is one of the most common causes of bacterial infections, which range in severity from relatively trivial skin infections to lethal invasive disease. Coagulase-negative species are intrinsically less virulent and less invasive than *S. aureus* but are responsible for one in four health care–associated infections, frequently involving an indwelling medical device. Prevalence of antibiotic-resistant strains of staphylococci has a profound impact on therapy.

The genus *Staphylococcus* consists of more than 30 distinct species. These organisms have coevolved as normal flora of mammals and birds. They are gram-positive spherical cells (i.e., cocci) 0.5 to 1.5 µm in diameter that divide in multiple planes to form clusters resembling grapes (*staphylo-* is derived from the Greek word for "bunch of grapes") when viewed under the microscope. Staphylococci are nonmotile, nonsporulating, hardy organisms that are resistant to desiccation, extremes of pH, and high salt concentrations and are capable of growth under aerobic or anaerobic conditions. Staphylococci produce catalase, an enzyme that degrades hydrogen peroxide into water and oxygen, which definitively distinguishes them biochemically from streptococci and enterococci. The coagulase test is the basis for differentiating *S. aureus* from the numerous other nonpathogenic, coagulase-negative species. Coagulase is a secreted cell surface protein that, in the presence of a prothrombin-like plasma protein, converts fibrinogen to fibrin, forming a clot. *S. aureus* produces a variety of other species-specific surface proteins (e.g., protein A) that differentiate it from other species.

The staphylococcal chromosome is circular. Approximately 75% of the genes constitute a core genome common to all staphylococcal species. The remaining 25% contains species-defining elements and mobile genetic elements acquired by horizontal gene transfer. The *S. aureus* genome is abundant in genes encoding toxins, superantigens, and adhesins, whereas coagulase-negative species contain few adhesin and no toxin or superantigen genes. Genetically, *S. aureus* is sufficiently uniform to classify it as a single species; greater diversity among coagulase-negative species merits their classification as distinct species.

STAPHYLOCOCCUS AUREUS

EPIDEMIOLOGY

S. aureus is maintained in the human population primarily through asymptomatic colonization of the anterior nares, mucous membranes, and other moist areas of the body as well as of the groin, perineum, and perianal area in healthy children and adults. Infants become colonized by strains from their mothers within weeks of birth. Carriage rates are higher in children than in adults. Higher than average *S. aureus* carriage rates are associated with atopic dermatitis, eczema, chronic skin ulcers, and other acute and chronic skin conditions; insulin-dependent diabetes; dialysis; human immunodeficiency virus infection; and recreational injection drug use. Carriers have a several-fold higher risk for development of a subsequent *S. aureus* infection compared with noncarriers. The principal mode of transmission of *S. aureus* is direct contact with an infected individual or an asymptomatic carrier, probably through transient hand carriage. *S. aureus* may also contaminate environmental surfaces, where it can persist for days. The role of environmental contamination in transmission is not well defined, but it may be important if heavily contaminated surfaces or materials are contacted. Droplet and aerosol transmission of *S. aureus* plays little if any role.

S. aureus is responsible for millions of infections in the United States each year, most of which are community-acquired skin infections. Approximately 5 to 10% of *S. aureus* infections are invasive and are often associated with bacteremia. *S. aureus* also causes hundreds of thousands of health care–associated infections each year, 50 to 60% of which are caused by methicillin-resistant *S. aureus* (MRSA). Before the mid-1990s, MRSA strains were almost exclusively hospital or health care associated, but they have now become prevalent in the community. Community-associated MRSA strains are distinct from classic health care–associated MRSA strains in several ways (E-Table 288-1).

PATHOBIOLOGY

Virulence Factors

S. aureus is highly adapted to humans through millions of years of coevolution with hominids. Well above 50 virulence factors, including adhesins, toxins, enzymes, surface-bound proteins, and capsule polysaccharides, may be produced (E-Table 288-2). Genes encoding virulence factors may be located on the chromosome either as part of the core genome or within mobile genetic elements (or their remnants), including bacteriophages, pathogenicity islands, and cassettes, or on plasmids. Alpha-toxin, Panton-Valentine leukocidin, and phenol-soluble modulins, all of which provoke potentially deleterious host inflammatory response and cause host cell lysis, appear to be important virulence factors mediating disease severity, especially in community MRSA strains.[1] Protein A, a B-cell superantigen that promiscuously triggers B-cell proliferation and supraclonal expansion and apoptosis, interferes with host antibody-mediated adaptive immunity.[2]

Virulence factors serve to promote binding to host tissues; to evade, circumvent, or disrupt host immune responses; and to facilitate cell injury and tissue invasion. Variability in both the presence of virulence determinants and their expression among strains allows extreme diversity among clinical isolates and the remarkable adaptability and versatility of *S. aureus* as a pathogen. An extensive network of two component response systems, DNA-binding proteins and regulatory RNAs, controls the expression of virulence (and other) factors in response to environmental conditions. Principal among these is the accessory gene regulator *agr*, a two-component quorum sensing and global gene regulator that controls the expression of numerous surface and secreted proteins. Mutations in *agr* have been associated with reduced susceptibility to vancomycin and loss of virulence.

Biofilm formation occurs in the presence of foreign material, such as vascular catheters or implanted devices. Biofilm is a complex network of extracellular polysaccharides, DNA, and protein in which bacterial cells become embedded, rendering them inaccessible to clearance by host defense mechanisms. Organisms within biofilms tend to be metabolically inactive and tolerant to killing by antimicrobial agents.

Mechanisms of Disease

Pathogenesis of *S. aureus* disease occurs by two mechanisms: tissue invasion, which may be local or systemic; and toxin mediated. The characteristic lesion of tissue invasion is the abscess, a focal collection of pus (liquefied and necrotic host tissue, blood, inflammatory cells, DNA, and cellular debris) and bacterial cells surrounded by an ill-defined layer of edematous and inflamed tissue infiltrated by acute and chronic inflammatory cells.
